It follows that all extensions of **G** have the fixed point property.

THEOREM 110 (Maksimova). *All extensions of* **G** *have the global Beth-property.*

Call a formula φ $\vec{q}$**-boxed** if every occurrence of a variable from $\vec{q}$ is in the scope of some modal operator.

LEMMA 111. *Let L be a logic containing* **G**. *Let q_i, $i < n$, be distinct variables and p a variable not contained in $\vec{q}$. For a set $S \subseteq n$ define χ_S by $\chi_S := \bigwedge_{i \in S} q_i \wedge \bigwedge_{i \in n-S} \neg q_i$. Suppose that $\varphi(p, \vec{q})$ is $\vec{q}$-boxed and that for some S,*

$$\vdash_L \chi_S \to \varphi(p, \vec{q}). \tag{107}$$

Then already $\vdash_L \varphi(p, \vec{q})$.

LEMMA 112. *Let $\varphi(p, \vec{q})$ be a formula. Then there exist $\vec{q}$-boxed formulae $\psi_1(p, \vec{q})$, $\psi_2(p, \vec{q})$, $\chi_1(p, \vec{q})$ and $\chi_2(p, \vec{q})$ such that*

$$\vdash_{\mathbf{G}} \varphi(p, \vec{q}) \leftrightarrow ((p \vee \psi_1(p, \vec{q})) \wedge (\neg p \vee \psi_2(p, \vec{q}))) \tag{108}$$

$$\vdash_{\mathbf{G}} \varphi(p, \vec{q}) \leftrightarrow ((p \wedge \chi_1(p, \vec{q})) \vee (\neg p \wedge \chi_2(p, \vec{q}))) \tag{109}$$

Now suppose that $\varphi(p, \vec{q})$ is a global implicit definition of p in L, and $L \supseteq \mathbf{G}$. Then $\varphi(p, \vec{q}); \varphi(r, \vec{q}) \Vdash_L p \leftrightarrow r$. Using Lemma 112 we get $\vec{q}$-boxed formulae $\chi_1(p, \vec{q})$ and $\chi_2(p, \vec{q})$ such that

$$\vdash_L \varphi(p, \vec{q}) \leftrightarrow ((p \wedge \chi_1(p, \vec{q})) \vee (\neg p \wedge \chi_2(p, \vec{q}))) \tag{110}$$

Write

$$\boxdot\varphi := \varphi \wedge \Box\varphi \tag{111}$$

Since we also have (by transitivity of L) that

$$\vdash_L \boxdot\varphi(p, \vec{q}) \wedge \boxdot\varphi(r, \vec{q}) \to (p \leftrightarrow r) \tag{112}$$

we now get

$$\vdash_L (\Box\varphi(p, \vec{q}) \wedge \Box\varphi(r, \vec{q}) \wedge p \wedge \chi_1(p, \vec{q}) \wedge \neg r \wedge \chi_2(r, \vec{q})) \to (p \to r) \tag{113}$$

This formula has the form $(\mu \wedge p \wedge \neg r) \to (p \to r)$, where μ is $\vec{q}$-boxed. This is equivalent to $\neg\mu \vee \neg p \vee r$, or $(p \wedge \neg r) \to \neg\mu$. By use of Lemma 111 we deduce that $\vdash_L \neg\mu$, that is,

$$\vdash_L \Box\varphi(p, \vec{q}) \wedge \Box\varphi(r, \vec{q}) \to (\chi_1(p, \vec{q}) \to \neg\chi_2(r, \vec{q})) \tag{114}$$

We substitute p for r and obtain

$$\vdash_L \Box\varphi(p, \vec{q}) \to (\chi_1(p, \vec{q}) \to \neg\chi_2(p, \vec{q})) \tag{115}$$

Now from this and (110) it follows after some boolean manipulations

$$\vdash_L \boxdot\varphi(p, \vec{q}) \to \boxdot(p \leftrightarrow \chi_1(p, \vec{q})) \tag{116}$$

By the fixed point theorem for **G** there is a $\psi(\vec{q})$ such that

$$\vdash_{\mathbf{G}} \boxdot(p \leftrightarrow \chi_1(p, \vec{q})) \to (p \leftrightarrow \psi(\vec{q})) \tag{117}$$

So we obtain

$$\vdash_L \boxdot\varphi(p, \vec{q}) \to (p \leftrightarrow \psi(\vec{q})) \tag{118}$$

which is nothing but

(119) $\varphi(p, \vec{q}) \Vdash_L p \leftrightarrow \psi(\vec{q})$

So $\psi(\vec{q})$ is an explicit definition. [1] take a slightly different approach. They show

THEOREM 113 (Areces & Hoogland & de Jongh). *Let L be a transitive logic in which the rule*

(120) $\boxdot p \rightarrow (\Box q \rightarrow q)/ \boxdot p \rightarrow q$

is admissible. Then L has the local Beth property iff it satisfies the fixed point theorem.

Notice that the admissibility of (120) implies that the Löb-rule (121) is admissible.

(121) $\Box p \rightarrow p/p$

For if $\Box\varphi \rightarrow \varphi$ is a theorem, so is $\boxdot\top \rightarrow (\Box\varphi \rightarrow \varphi)$. By (120), $\boxdot\top \rightarrow \varphi$ is a theorem, whence $\varphi \in L$. The following is folklore.

THEOREM 114. *A transitive logic contains* **G** *iff it satisfies the Löb rule.*

Proof. Suppose $L \supseteq \mathbf{G}$ and $\Box\varphi \rightarrow \varphi \in L$. Then $\Box(\Box\varphi \rightarrow \varphi) \in L$, from which $\Box\varphi \in L$. Hence, using (MP$_\rightarrow$) we get $\varphi \in L$. Conversely, assume that the Löb rule is admissible. Put $\chi := \Box(\Box p \rightarrow p)$, $\psi := \Box p$. We need to show that $\chi \rightarrow \psi$ is a theorem of L.

(122)
$$\begin{aligned}
&\vdash_{\mathbf{K4}} \Box(\chi \rightarrow \psi) \rightarrow (\Box\chi \rightarrow \Box\psi)\\
&\vdash_{\mathbf{K4}} \chi \rightarrow (\Box\psi \rightarrow \psi)\\
&\vdash_{\mathbf{K4}} \chi \rightarrow \Box\chi\\
&\vdash_{\mathbf{K4}} \Box(\chi \rightarrow \psi) \rightarrow (\chi \rightarrow \psi)
\end{aligned}$$

Since the Löb rule is admissible in $L \supseteq \mathbf{K4}$, $\chi \rightarrow \psi \in L$. ❑

On the other hand, the same method can be used to show that if $L \supseteq \mathbf{G}$ then (120) is admissible. Suppose namely that $\boxdot\varphi \rightarrow (\Box\chi \rightarrow \chi)$ is a theorem. Then so is

(123) $\Box \boxdot \varphi \rightarrow \Box(\Box\chi \rightarrow \chi)$

From this we get $\Box \boxdot \varphi \rightarrow \Box\chi$ with the **G**-axiom. But $\boxdot\varphi \rightarrow \Box \boxdot \varphi \in \mathbf{G}$, and so $\boxdot\varphi \rightarrow \Box\chi$, which together with the premiss yields $\boxdot\varphi \rightarrow \chi$. Therefore, the coverage of Theorem 113 is not larger than that of Theorems 109 and 110.

5.5 Uniform Interpolation

L has **uniform interpolation** if

① given φ and variables $\vec{q}$ there exists a formula χ such that $\mathrm{var}(\chi) \subseteq \vec{q}$ and for all formulae ψ such that $\varphi \vdash_L \psi$ and $\mathrm{var}(\varphi) \cap \mathrm{var}(\psi) = \vec{q}$ we have $\varphi \vdash_L \chi \vdash_L \psi$ (**uniform preinterpolation**) and

② given ψ and variables $\vec{q}$ there exists a formula χ such that $\mathrm{var}(\chi) \subseteq \vec{q}$ and for all formulae φ such that $\varphi \vdash_L \psi$ and $\mathrm{var}(\varphi) \cap \mathrm{var}(\psi) = \vec{q}$ we have $\varphi \vdash_L \chi \vdash_L \psi$ (**uniform postinterpolation**).

By classical logic, L has uniform preinterpolation iff it has uniform postinterpolation. Notice that uniform interpolation of L can be used to define second order quantification inside the modal language. Let L^q be the extension of L by propositional quantifiers. Now, $(\forall p)\varphi \vdash_L \varphi$ is always valid. Moreover, if $\mathrm{var}(\psi) = \mathrm{var}(\varphi) - \{p\}$ and $\psi \vdash_L \varphi$ then also $\psi \vdash_{L^q} (\forall p)\varphi$. So, $(\forall p)\varphi$ is up to equivalence *the* uniform preinterpolant. If L has uniform interpolation, there is a preinterpolant χ in the variables $\mathrm{var}(\varphi) - \{p\}$. Hence, $(\forall p)\varphi$ is equivalent to χ, and L^q reduces to L in expressivity. This idea has been one of the reasons to study uniform interpolation (see [47]). The logics **K**, **Grz** and **G** have uniform interpolation, **S4** fails to have uniform interpolation (see [57] and [27]). Furthermore, the following is known about fusions, see [62].

THEOREM 115 (Wolter). *If L and L' have uniform interpolation, so does $L \otimes L'$.*

Notice that if $\varphi_1 \vdash_L \psi$ and $\varphi_2 \vdash_L \psi$, and if χ_i are interpolants for φ_i and ψ, then $\chi_1 \vee \chi_2$ is an interpolant for both:

$$(124) \qquad \varphi_1 \vdash_L \chi_1 \vdash_L \chi_1 \vee \chi_2 \vdash_L \psi$$

So if a logic has interpolation and there are up to equivalence only finitely many formulae in n variables then L has uniform interpolation as well ([62]).

THEOREM 116 (Wolter). *Let L have interpolation. If $\mathcal{V}(L)$ is locally finite then L also has uniform interpolation.*

We shall sketch a proof that **K** has uniform interpolation. For example, we show that it has uniform preinterpolation. The proof uses tableau calculi again. By induction on the length of Σ we prove the following: *Let $\vec{q}$ be a set of variables. There is a χ in the variables $\vec{q}$ such that for any Δ such that* $\mathrm{var}(\Delta) \cap \mathrm{var}(\Sigma) = \vec{q}$, *given a closing tableau for $\Delta^a; \Sigma^c$ both $\Delta^a; (\neg\chi)^c$ and $\chi^a; \Sigma^c$ have a closing tableau.* In other words, the interpolant is determined by the ^{c}-set alone (in addition to the set of shared variables). The proof of this fact is actually not hard. We look again at the proof sketched above. Suppose that the tableau closes. It closes in six possible situations. (1) $p^a; (\neg p)^a$, (2) $p^a; (\neg p)^c$, (3) $(\neg p)^a; p^c$, (4) $p^c; (\neg p)^c$, (5) $\bot^a$ and (6) $\bot^c$. In Case (5) $\chi := \bot$ and in Case (6) $\chi := \neg\bot$ satisfy the requirements. Consider the other cases. (A) $p \in \vec{q}$. Then only (2) and (3) can arise. The interpolant is completely determined by knowing Σ. (B) $p \notin \vec{q}$. Then (1) or (4) arise. Again, the interpolant is determined solely by knowing Σ.

We consider briefly the other cases. If (w) has applied, the interpolant χ for the lower sequent is an interpolant for the upper sequent. Clearly, it only depends on the upper ^{c}-set if that was true for the lower ^{c}-set. The same happens with $(\neg E)$ and $(\wedge E)$. Next we look at $(\vee E)$.

$$(125) \qquad \frac{\Delta^a; (\neg(\varphi \wedge \psi))^a; \Sigma^c}{\Delta^a; (\neg\varphi)^a; \Sigma^c \mid \Delta^a; (\neg\psi)^a; \Sigma^c}$$

By inductive hypothesis there is an interpolant χ depending only on Σ^c, not on the ^{a}-set. Therefore we can use the same formula as follows:

$$(126) \qquad \frac{\Delta^a; (\neg(\varphi \wedge \psi))^a; \chi^c}{\Delta^a; (\neg\varphi)^a; \chi^c \mid \Delta^a; (\neg\psi)^a; \chi^c}$$

This tableau closes. Now suppose that the rule application is

$$(127) \qquad \frac{\Delta^a; (\neg(\varphi \wedge \psi))^c; \Sigma^c}{\Delta^a; (\neg\varphi)^c; \Sigma^c \mid \Delta^a; (\neg\psi)^c; \Sigma^c}$$

By inductive hypothesis there are interpolants χ_1 and χ_2 independent of Δ for the left and right hand side. Now we get

(128)
$$\frac{\Delta^a; (\neg(\chi_1 \wedge \chi_2))^c}{\Delta^a; (\neg\chi_1)^c \mid \Delta^a; (\neg\chi_2)^c} \qquad \begin{array}{c|c} \multicolumn{2}{c}{(\chi_1 \wedge \chi_2)^a; (\neg(\varphi \wedge \psi))^c; \Sigma^c} \\ \hline (\chi_1 \wedge \chi_2)^a; (\neg\varphi)^c; \Sigma^c & (\chi_1 \wedge \chi_2)^a; (\neg\psi)^c; \Sigma^c \\ \hline \chi_1^a; \chi_2^a; (\neg\varphi)^c; \Sigma^c & \chi_1^a; \chi_2^a; (\neg\psi)^c; \Sigma^c \\ \hline \chi_1^a; (\neg\varphi)^c; \Sigma^c & \chi_2^a; (\neg\psi)^c; \Sigma^c \end{array}$$

Both tableaux close by assumption. The desired interpolant is $\chi_1 \wedge \chi_2$. So far the interpolant did not depend on what Δ is.

The rule $(\Box E)$ is the last and most complex to consider. Here we face two options: either it was applied to an ^{a}-formula, and then $\neg\Box\neg\chi$ is the new interpolant, or it was applied to a ^{c}-formula, and then the interpolant is $\Box\chi$. Case (1). There is no Δ such that $(\Box E)$ can be applied to an ^{a}-formula. Then the preinterpolant is $\neg\Box\neg\chi$. Case (2). There is no Δ such that $(\Box E)$ can be applied to a ^{c}-formula. Then $\Box\chi$ is the interpolant. Case (3). There is Δ_1 such that $(\Box E)$ can be applied to an ^{a}-formula, and Δ_2 such that $(\Box E)$ can be applied to a ^{c}-formula. Then $\neg\Box\neg\chi \vee \Box\chi$ is the desired interpolant. For by assumption, $(\neg\Box\neg\chi)^a; \Sigma^c$ and $(\Box\chi)^a; \Sigma^c$ both close, and so does therefore $(\neg\Box\neg\chi \vee \Box\chi)^a; \Sigma^c$. And given Δ, either $\Delta^a; (\neg\Box\neg\chi)^c$ closes or $\Delta^a; (\Box\chi)^c$. However, this means that $\Delta^a; (\neg(\neg\Box\neg\chi \vee \Box\chi))^c$ closes.

6 ADMISSIBLE RULES

The study of admissible rules in modal logic has been the topic of the monograph by Vladimir Rybakov, [53], from which most of the results of this section are taken. Studying admissibility can be taken to mean the study of the consequence relations $\vdash_L^m$, where $\vdash_L^m$ is the largest consequence relation whose set of tautologies is L. For in this consequence relation every admissible rule is derived. Thus, we may either speak of characterizing the consequence $\vdash_L^m$ or about the admissible rules of $\vdash_L$, or, for that matter, L itself. We shall prefer the latter. Historically, the first breakthrough was the solution by Rybakov to Problem 40 of the list of 102 problems by Harvey Friedman, [22]. It asked whether admissibility of a rule in **Int** is decidable, which by way of the Gödel translation can be turned into a problem of **Grz**, see Theorem 121. Based on this, Rybakov has extended the results to cover large classes of extensions of **K4**, giving criteria of when admissibility of rules is decidable, and when $\vdash_L^m$ is finitely axiomatisable.

6.1 General Theory

We start with some general considerations. Let $\Delta = \{\delta_i : i < m\}$. A modal algebra satisfies the rule $\langle\Delta, \varphi\rangle$ iff it satisfies the Horn-formula

(129)
$$\bigwedge_{i<m} \delta_i = \top \rightarrow \varphi = \top$$

Admissibility can be characterized as follows. Let L be a logic. $\langle\Delta, \varphi\rangle$ is admissible in L iff for all m

(130)
$$\mathfrak{Fr}_L(n) \vDash \bigwedge_{i<m} \delta_i = \top \rightarrow \varphi = \top$$

where $\mathfrak{Fr}_L(n)$ denotes the freely n-generated L-algebra. For notice that for every valuation h into $\mathfrak{Fr}_L(n)$ there are formulae σ_i, $i \in \omega$, such that $h(p_i) = \sigma_i$. Hence with κ the map induced by the identity and $\sigma : p_i \mapsto \sigma_i$, $h(\varphi) = \kappa(\varphi^\sigma)$. So, if $h(\varphi) = 1$ in $\mathfrak{Fr}_L(n)$ there is a substitution σ for which $\kappa(\varphi^\sigma) = 1$, which means that $\varphi^\sigma \in L$. Equivalently we have

PROPOSITION 117. *Let* $\Delta = \{\delta_i : i < n\}$. $\langle \Delta, \varphi \rangle$ *is admissible in* L *iff* $\mathfrak{Fr}_L(\omega) \vDash \bigwedge_{i<n} \delta_i = \top \to \varphi = \top$.

We shall restrict our attention to extensions of **K4**. The problem whether admissibility of a rule is decidable in intuitionistic logic can be turned into a question of modal logics. Let us note that each rule can be brought into the form $\langle \{\chi_1\}, \chi_2 \rangle$, also written χ_1/χ_2. Now, call a substitution s a **unifier** for χ in L if $\vdash_L s(\chi)$. Then the rule χ_1/χ_2 is admissible in L if every unifier for χ_1 in L is also a unifier for χ_2. Thus admissibility can be checked by inspecting the unifiers of a given formula. In a logic L, say that s is **more general than** s', in symbols $s \leq s'$ if there is a substitution t such that $t(s(p)) \leftrightarrow s'(p) \in L$. Classical logic enjoys the property that if a formula has a unifier, it also has a unique most general unifier and it can effectively be found ([45]). Given that, admissibility can be checked in boolean logic as follows. Determine the most general unifier, say s, for χ_1. Now decide whether $s(\chi_2)$ is a theorem. This fails in intuitionistic logic for the reason that there is no single most general unifier. The strategy can however be generalized. Suppose for any given formula χ we can compute a finite set Π_χ of minimal unifiers, then we can decide admissibility if the logic is decidable. (If L is undecidable, admissibility is a fortiori undecidable.)

[25] gives a proof along these lines that admissibility is decidable in intuitionistic logic. The methods are similar for modal logic. A formula χ is called **projective** if there is a unifier s such that for all $p \in \mathrm{var}(\chi)$:

$$\chi \vdash p \leftrightarrow s(p) \tag{131}$$

It is possible to construct such a unifier. Let S be a subset of $\mathrm{var}(\chi)$. Define θ^S_χ by

$$\theta^S_\chi(p) := \begin{cases} \chi \to p & \text{if } p \in S \\ \chi \wedge p & \text{otherwise} \end{cases} \tag{132}$$

This substitution satisfies (131) but is not necessarily a unifier. Define an enumeration S_i, $i < k$, $k := 2^{|\mathrm{var}(\chi)|}$ of the subsets of $\mathrm{var}(\chi)$ so that if $S_i \subseteq S_j$, then $i \leq j$. Next put

$$\theta_\chi := \theta^{Sk-1}_\chi \circ \theta^{S_{k-2}}_\chi \circ \cdots \circ \theta^{S_0}_\chi \tag{133}$$

THEOREM 118 (Ghilardi). θ_χ *is a unifier for* χ *iff* χ *is projective.*

This serves as a test for projectivity. Define $c(\chi)$ to be the maximum nesting of $\to$ (alternatively, $c(\chi)$ is the $\to$-depth of χ). There are only finitely many formulae χ over a given finite set of variables such that $c(\chi) \leq n$, for any given n. (The other connectives are $\wedge$, $\vee$ and $\neg$. Obviously, this requires showing that from a given set of formulae, there is a bounded number of formulae that can be built using $\neg$, $\vee$ and $\wedge$.) Say that a set U of substitutions is **complete** for χ in L if for every unifier t for χ there is an $s \in U$ such that $s \geq t$. To check the admissibility of a rule χ/φ in L it is enough to be able

to determine whether a formula has a unifier and if so to be able to construct a finite complete set for it. For then it is enough to check the complete set for φ against that for χ.

THEOREM 119 (Ghilardi). *Every unifiable formula has a finite complete set of unifiers in* **Int**.

This set is found as follows. Let

$$S_\chi := \{\psi : \mathrm{var}(\psi) \subseteq \mathrm{var}(\chi), \psi \text{ projective and } c(\psi) \leq c(\chi)\} \tag{134}$$

This set is shown to be finite. Then $\{\theta_\psi : \psi \in S_\chi\}$ is complete. What we really need, though, is a set of substitutions that is a basis, where S is a **basis** iff it is complete and for every $s, t \in S$, if $s \neq t$ then $t \not\leq s$. To get a basis, let Π_χ be any subset of S_χ for which (i) if $\psi_1, \psi_2 \in \Pi_\chi$ and $\psi_1 \vdash \psi_2$ then $\psi_1 = \psi_2$ and (ii) for every $\psi \in S_\chi$ there is a $\psi' \in \Pi_\chi$ such that $\psi \vdash \psi'$. Such a set obviously exists and is easy to construct on the basis of S_χ. The set $\{\theta_\psi : \psi \in \Pi_\chi\}$ is a basis for χ. Now the rule χ/χ' is admissible iff for every $\psi \in \Pi_\chi$: $\psi \vdash \chi'$.

Let us briefly mention some relations with modal logic. Consider the dual of $\mathfrak{Fr}_L(n)$, the weak canonical frame $\mathfrak{Can}_L(n)$. Let $\mathfrak{Ch}_L(n)$ be the subframe of all points of finite depth. This is also called the n-**characterizing frame**, while $\langle \mathfrak{Ch}_L(n), \kappa\rangle$, $\kappa : p_i \mapsto p_i$, is called the n-**characterizing model**.

LEMMA 120. *Assume that $L \supseteq$* **K4** *has the finite model property. Then the rule $\delta_0, \ldots, \delta_{m-1}/\varphi$ is admissible in L iff for all n,*

$$\mathfrak{Ch}_L(n) \vDash \bigwedge_{i<m} \delta_i = \top \to \varphi = \top \tag{135}$$

Recall the Gödel-translation T from intuitionistic logic to modal logic. Let L be a superintuitionistic logic. Put $\sigma(L) :=$ **Grz** $\oplus T(L)$.

THEOREM 121. *The rule $\delta_0, \ldots, \delta_{n-1}/\varphi$ is admissible in L iff the translation*

$$T(\delta_0), \ldots, T(\delta_{n-1})/T(\varphi) \tag{136}$$

is admissible in $\sigma(L)$.

6.2 Frame Characterisation of Admissibility

A logic has **branching below** m if whenever in some frame for L there is a cluster with d immediate successor clusters, then whenever we find d incomparable clusters in $\mathfrak{Ch}_L(n)$, there is a cluster C having these clusters as its immediate successor clusters. The effective m-drop point property is still more cumbersome to define. To understand it, recall the selection procedure of Fine and Zakharyaschev (see [20] and [63]). This procedure extracts a finite model out of a given model $\mathfrak{M}$ on the basis of a set Σ of formulae closed under subformulae. Denote this frame by $X(\mathfrak{M}, \Sigma)$, and by $X_m(\mathfrak{M}, \Sigma)$ the model containing both $X(\mathfrak{M}, \Sigma)$ and the points of depth at most m. (We are assuming that the model is based on finitely many generators.) Crucially, this procedure does not preserve the truth of all formulae, since we are taking not necessarily generated subframes, but it does preserve the truth of all formulae from Σ. For cofinal subframe logics this

shows that they have the finite model property. The m-**drop point property** says the following. Suppose that we have a finite n-generated L-model $\mathfrak{M}$ and that it is large. Then it contains a submodel $\mathfrak{W} \supseteq X_m(\mathfrak{M}, \Sigma)$ which is contractible onto an L-frame of no more than $g(x, y)$ elements, where g is a recursive function and $x = |\Sigma|$, and y the number of points of depth at most m in $\mathfrak{M}$.

THEOREM 122 (Rybakov). *Suppose that L is a logic containing* **K4**. *Suppose further that*

1. *L has fmp,*
2. *L has branching below m for some $m \in \omega$, and*
3. *L has the effective m-drop point property for some $m \in \omega$.*

Let ρ be a rule with k variables. Then ρ is admissible in L iff it is valid in the algebra of all subsets of the Kripke-frame underlying the k-characterizing frame. Furthermore, suppose that there is an algorithm which decides for a finite frame whether it is an L-frame. Then there exists an algorithm deciding whether a given inference rule is admissible for L.

The proof of this theorem uses the selection procedure. It shows that if ρ is refutable in the n-characterizing model then we can construct a model whose size we can estimate a priori and in which ρ is refuted as well. This model also has the so-called **view-realizing** property. Conversely, if such a model exists, ρ is refutable in the n-characterizing model. The proof of the latter statement is the most involved, but it seems that it can be simplified using the technique of homogenisation proposed in [39].

Let I_n be an axiom saying that the frames are of width at most n (that is, have no antichain of length $n + 1$).

COROLLARY 123. *Admissibility of rules is decidable in the modal systems* **K4**, **S4**, **GL**, **Grz**, **S5**, *and in the logics $L \oplus I_n$, where L is any of the aforementioned logics.*

Ghilardi and Sacchetti apply in [26] the method of [25] and develop criteria for extensions L of **K4**. Let us be given a formula χ. There are infinitely many substitutions s such that χ^s is a theorem of L. Say that unification in L is **filtering** if for any two unifiers s_0 and s_1 for a formula χ there is a unifier t such that $t \leq s_0, s_1$. Evidently, if unification is filtering in L then a complete set is either infinite or contains just one member. (If the latter is always the case, L is called **unitary**.)

THEOREM 124 (Ghilardi & Sacchetti). *Let $L \supseteq$* **K4**. *Then unification is filtering iff $L \supseteq \mathbf{K4} \oplus \mathbf{2}^+ := \mathbf{K4} \oplus \neg \boxdot \neg \boxdot p \to \boxdot \neg \boxdot \neg p$.*

The additional axiom is similar $\mathbf{2} = \Diamond\Box p \to \Box\Diamond p$, only that we use $\boxdot$ in place of $\Box$. So, above **S4** this axiom reduces to **2**. The condition also has algebraic analogs. Say that an algebra $\mathfrak{A}$ is **projective** in a variety $\mathcal{V}$ if there is a free algebra $\mathfrak{Fr}_{\mathcal{V}}(X)$ and maps $p : \mathfrak{Fr}_{\mathcal{V}}(X) \to \mathfrak{A}$ and $m : \mathfrak{A} \to \mathfrak{Fr}_{\mathcal{V}}(X)$ such that $p \circ m = 1_{\mathfrak{A}}$. Say that an algebra is **finitely presented** in $\mathcal{V}$ if there is a finite set X and a finite set E of equations such that $\mathfrak{A} \cong \mathfrak{Fr}_{\mathcal{V}}(X)/\Theta(E)$, where $\Theta(E)$ is the smallest congruence containing E.

THEOREM 125 (Ghilardi & Sacchetti). *Unification in L is filtering iff finitely presented projective L-algebras are closed under binary products.*

Let $\mathfrak{F}_i = \langle F_i, \lhd \rangle$ be a family of L-frames. $(\bigoplus_{i \in I} \mathfrak{F}_i)^\circ$ and $(\bigotimes_{i \in I} \mathfrak{F}_i)^\bullet$ are defined like the disjoint union, except that a root world is added, which is irreflexive in the first, and

reflexive in the second case. Finally, $\mathrm{irr}((\bigoplus_{i\in I}\mathfrak{F}_i)^\circ)$ and $\mathrm{irr}((\bigoplus_{i\in I}\mathfrak{F}_i)^\bullet)$ are obtained by identifying all final clusters (assuming that they are isomorphic). Now L has the **2-glueing property** if whenever L has a Kripke-frame containing an irreflexive point (a reflexive point) and $\mathfrak{F}_i$, $i \in I$, are L-frames whose final clusters are isomorphic, then $\mathrm{irr}((\bigoplus_{i\in I}\mathfrak{F}_i)^\circ)$ and $(\mathrm{irr}((\bigoplus_{i\in I}\mathfrak{F}_i)^\circ))$ is an L-frame.

THEOREM 126 (Ghilardi & Sacchetti). *Unification is unitary in $L \supseteq$ **K4** if L contains **K4** $\oplus$ $\mathbf{2}^+$, has the finite model property and has the 2-glueing property.*

In particular, for every L satisfying these conditions the admissibility of inference rules is decidable, which implies that the logics are decidable. For clearly, if admissibility of a rule in L is decidable L must be decidable. But the converse need not hold.

THEOREM 127 (Chagrov). *There is a logic which is decidable, but admissibility of rules is undecidable.*

6.3 Axiomatizing the Admissible rules

There also is a question whether the admissible rules can actually be axiomatized. In the present terms this means axiomatizing $\vdash^m_L$. One speaks of a **basis** for the set of admissible rules. In [53], a series $\mathfrak{E}_n$, $n \in \omega$, of frames is defined.

1. $E^1_n := \{x^0_0\}$, $x^0_0 \lhd_0 x^0_0$.
2. $E^2_n := E^1_1 \cup \{x^1_i : i < 2^n + 2\}$. $x^i_j \lhd_2 x^{i'}_{j'}$ iff $i' = 0$ or $i = i'$ and $j = j'$.
3. Let H be the set of all antichains of $E^i_n - E^{i-1}_n$. $E^{i+1}_n := E^i_n \cup \{x^i_h : h \in H\}$. $\lhd_{i+1}$ satisfies (a) $\lhd_{i+1} \restriction E^i_n = \lhd^i$, (b) $x^i_h \lhd_{i+1} x^j_k$ iff $j = i-1$ and $k \in h$ or there is a x^{i-1}_p such that $p \in h$ and $x^{i-1}_p \lhd_i x^j_k$.

$$\mathfrak{E}_n := \langle \bigcup_i E^i_n, \bigcup_i \lhd_i \rangle \tag{137}$$

Furthermore, the following is established.

THEOREM 128 (Rybakov). *Let $L \supseteq$ **S4** be a logic with the following properties.*

① *For all n: $\mathfrak{F}_n \vDash L$.*

② *L has the finite model property and branching below 1.*

③ *L has the effective m-drop point property.*

Then $\vdash^m_L$ cannot be axiomatized by finitely many rules.

Similar criteria are established for superintuitionistic logics and logics containing **K4**. What is important is the following consequence.

THEOREM 129 (Rybakov). *The logics **S4**, **S4.1** and **S4.2** have no finite basis for the admissible rules.*

[53] also shows that the logics **K4**, **K4.1**, **K4.2**, and **G** have no finite basis for admissible rules.

6.4 Decidability of the Admissibility of a Rule

Lemma 120 can be strengthened. A rule is admissible in L with finite model property iff it is valid in $\mathfrak{Ch}_L(n)$, where n is the number of variables occurring in the rule. We obtain the following.

THEOREM 130 (Rybakov). *Let $L \supseteq$ **K4** be finitely axiomatisable. Suppose that $\mathcal{V}(L)$ is locally finite. Then the admissibility of a given rule in L is decidable.*

6.5 Structural Completeness

For a class $\mathcal{K}$ of algebras, $\mathcal{K}^Q$ denotes the least quasi-variety containing $\mathcal{K}$. The following is a useful criterion.

THEOREM 131 (Rybakov). *A modal logic $L \subseteq$ **K4** is structurally complete iff every subdirectly irreducible $\mathfrak{A} \in \mathcal{V}(L)$ is contained in $(\mathfrak{Fr}_L(\omega))^Q$. This is the case iff $\mathcal{V}(L) = (\mathfrak{Fr}_L(\omega))^Q$.*

If L is a logic that has the finite model property then the free algebra $\mathfrak{Fr}_L(\omega)$ is a subalgebra of the product of the finite subdirectly irreducible L-algebras. Under this condition, a logic L is structurally complete iff every finite subdirectly irreducible L-algebra is embeddable into the algebra $\mathfrak{Fr}_L(\omega)$ (or some $\mathfrak{Fr}_L(n)$, $n \in \omega$). Suppose $\mathfrak{A}$ is a finite, subdirectly irreducible **K4**-algebra. Then $\mathfrak{A}$ has an opremum ω. Now, for each element a of $\mathfrak{A}$ let p_a be a variable and let $r(\mathfrak{A})$ be the following rule:

$$r(\mathfrak{A}) := \frac{\{p_{a*b} \leftrightarrow p_a * p_b : a, b \in A\} \cup \{p_{\circ a} \leftrightarrow \circ p_a : a \in A\} \cup \{p_1\}}{p_\omega} \tag{138}$$

where $*$ runs through all the basic binary connectives and $\circ$ through all the basic unary connectives. This is the **quasi-characteristic** inference rule of $\mathfrak{A}$. Now the following holds:

THEOREM 132 (Citkin). *Let $\mathfrak{A}$ be a finite, subdirectly irreducible* **K4***-algebra. Then for any* **K4***-algebra $\mathfrak{B}$, $r(\mathfrak{A})$ is invalid in $\mathfrak{B}$ iff $\mathfrak{A}$ is isomorphically embeddable into $\mathfrak{B}$.*

This technique is reminiscent of the technique of splittings (see [10] and [11]).

It is not hard to show that no **K4**-algebra with at least two elements is embeddable into $\mathfrak{Fr}_{\mathbf{K4}}(\omega)$. Armed with this result one can show that there are infinitely many admissible rules which are independent from each other. One has to show only that there are infinitely many simple, finite **K4**-algebras. On the other hand, the set of admissible quasi-characteristic rules of **S4** and **Grz** have a finite basis. In the latter case the generalized Mints' rule alone forms a basis:

$$\frac{[(p \to q) \to (q \vee r)] \vee u}{[((p \to q) \to q) \vee ((p \to q) \to r)] \vee u} \tag{139}$$

For **S4** we need in addition to the modal translation of this rule two more, one of which is the quasi-characteristic rule of the two element cluster, which is equivalent to the rule $\Diamond p; \Diamond\neg p/q$.

This can be brought to bear on extensions of **S4.3** in the following way.

LEMMA 133. *Let L be a modal logic containing* **S4.3** *and $\mathfrak{A}$ a finite, subdirectly irreducible L-algebra. Then $\mathfrak{A} \times \mathbf{2}$ is a subalgebra of $\mathfrak{Fr}_L(\omega)$, where $\mathbf{2}$ is the two-element* **S4***-algebra.*

LEMMA 134. *The rule $\Diamond p; \Diamond\neg p/q$ is valid in $\mathfrak{A}$ iff the algebra of the two element cluster is not embeddable into $\mathfrak{A}$.*

Now, any extension L of **S4.3** is finitely axiomatisable and has the finite model property, by results of [7] and [18]. L has the property of branching below 1 and the effective m-drop point property for some m. It follows that the admissibility of inference rules is decidable for L. Second, if we add the rule $\Diamond p; \Diamond\neg p/q$ then the resulting consequence relation axiomatizes the quasi-variety containing all finite L-algebras of the form $\mathfrak{A} \times \mathbf{2}$. Since L is determined by such algebras, we see that this quasi-variety contains $\mathfrak{Fr}_L(\omega)$. Moreover, since the smallest quasi-variety containing $\mathfrak{Fr}_L(\omega)$ must contain these algebras, the two are equal.

THEOREM 135 (Rybakov). *Let $L \supseteq$ **S4.3**. Then $\vdash^m_L$ is axiomatized over $\vdash_L$ by (MN) and $\Diamond p; \Diamond\neg p/q$.*

We derive that **Grz.3** is structurally complete, since the rule $\Diamond p; \Diamond\neg p/q$ is actually derivable in $\Vdash_{\mathbf{Grz.3}}$. It follows that **LC** is also structurally complete, since $\mathbf{Grz.3} = \sigma(\mathbf{LC})$.

Call a logic L **hereditarily structurally complete** if all its extensions are structurally complete. L is **structurally precomplete** if it is not structurally complete, but all its proper extensions are.

THEOREM 136 (Rybakov). *There are exactly 20 structurally precomplete logics containing* **K4***, and they are all tabular of the form* $\mathrm{Th}(\mathfrak{H}_i)$, $i < 20$.

The Kripke-frames $\mathfrak{H}_0 - \mathfrak{H}_{19}$ mentioned in the theorem are known. (They are for example of width and depth at most 3.) We derive the following.

COROLLARY 137. *$L \supseteq$ **K4** is hereditarily structurally complete iff*

(140) $\qquad L \supseteq \mathbf{K4}/\{\mathfrak{H}_i : i < 20\}$

From this, results on **S4** and **Int** can be immediately derived (since the frames are explicitly known). All these logics must be of width 2.

7 FURTHER TOPICS

There are notions of consequence that are not included in this study that we shall mention here only briefly. First, a **multiple conclusion rule** is a pair $\langle\Delta, \Theta\rangle$ of sets of formulae. A multiple conclusion rule is **derived** in $\vdash$ if whenever Δ is made true by a substitution, that substitution makes at least one member of Θ true. It is **admissible** in L if for every substitution such that $\Delta^\sigma \subseteq L$ we have $\theta^\sigma \in L$ for at least one $\theta \in \Theta$. A case in point is the pair $\langle\{p \vee q\}, \{p, q\}\rangle$. This rule is admissible in intuitionistic logic but not in classical logic. Its reflex in modal logic is the rule $\langle\{\Box p \vee \Box q\}, \{\Box p, \Box q\}\rangle$. A modal logic has the **disjunction property** if this rule is admissible. Since the disjunction property does not specify which of the alternatives holds, it is not characterisable in terms of single-conclusion rules. In [33] a modal logic is said to **provide the rule of disjunction** if all of the rules $\langle\{\Box \bigvee_{i<n} p_i\}, \{\Box p_i : i < n\}\rangle$ are admissible, and it is shown that if a logic provides the rule of disjunction then the canonical frame is generated by a single point, which is the set $\{\neg\Box\varphi : \varphi \notin L\}$. More on the disjunction property can be found in [9].

The multiple conclusion rules are more general than ordinary rules, which we may call also **single conclusion rules**.

There is also a **strong rule of disjunction**:

$$(141) \qquad \langle\{\bigvee_{i<n} \Box p_i\}, \{p_i : i < n\}\rangle$$

(see [58]) and the **rule of margins**

$$(142) \qquad \langle\{p \to \Box p\}, \{p, \neg p\}\rangle$$

(see [59]).

Another kind of rule is presented by the **irreflexivity rule**.

$$(143) \qquad \frac{\neg(p \to \Diamond p) \to \varphi}{\varphi} \qquad \text{provided } p \text{ does not occur in } \varphi$$

This rule has been proposed in [23]. It is called irreflexivity rule since in tense logic adding that rule to a logic L gives the logic of the irreflexive frames of L. In ordinary modal logic this does not go through ([56]), unless one adds infinitely many of them (see [24]). See also the chapter on hybrid logics. The difference between this rule and the standard or multiple conclusion rules is the reference to variables, which we know from predicate logic but is quite uncommon elsewhere in propositional logic. The possibility of defining negative properties of frames using rules has been explored in [56].

ACKNOWLEDGEMENTS

My thanks go in particular to Ian Hodkinson for his generous and detailed comments, which led to simplifications in the presentation; and to Yde Venema for many useful hints. All errors and omissions are my own responsibility.

PREFACE

This chapter is divided into two parts. The first (which consists of Sections 1–5) was written by Torben Braüner, and the second (which consists of Sections 6–11) was written by Silvio Ghilardi.

In the first part we give an introduction to first-order modal logic. We discuss a number of logics that make use of constant domain, increasing domain, and varying domain semantics, and also present a first-order intensional logic and a first-order version of hybrid logic. One criterion for selecting these logics has been the availability of sound and complete proof procedures for them, typically axiom systems and/or tableau systems. We compare the first-order modal logics discussed here to fragments of sorted first-order logic via appropriate versions of the standard translation.

In the second part of the chapter, we review both positive and negative results concerning fragment decidability, Kripke completeness and axiomatizability. Modal hyperdoctrines are then introduced, as a unifying tool for analyzing the alternative semantics proposed in the literature. These alternative semantics range from specific semantics for non-classical logics (like metaframes), to interpretations in well-established mathematical frameworks (like topological spaces and toposes). Finally, the strict relationship between topological semantics and D. Lewis's counterpart semantics is investigated in detail and an axiomatization is presented.

1 INTRODUCTION TO PART I

In Part I of this chapter we give an introduction to first-order modal logic. First-order modal logic is a big area with a great number of different logics. This has forced us to make a number of choices. The first choice we made was to concentrate on presenting an appropriate selection of logics rather than trying to be encyclopedic. This has allowed us to give reasonably detailed treatments of each of the selected logics. How did we select the logics in question? We wanted to present logics involving constant domains, increasing domains, and varying domains, and moreover, we wanted to present a first-order intensional logic as well as a first-order version of hybrid logic.

Given these overall requirements, one criteria for selecting particular logics for presentation has been the availability of sound and complete proof procedures, typically axiom systems and/or tableau systems. We have compared the first-order modal logics under consideration to fragments of sorted first-order logic via appropriate versions of the standard translation. The possibility of doing so in a straightforward and simple way has been another criteria for selecting a particular logic for presentation. In fact, we take such a simplicity as a sign of mathematical naturality. We have not included constant symbols in the presented logics, the reason being that constants (having a given sort of semantic values) from a mathematical, model-theoretic point of view are just variables (ranging over the same semantic values) that are not quantified over. In the interest of simplicity, we have not included function symbols either. Counterpart semantics, which can be considered an alternative to first-order intensional logics, is treated in Part II, Section 11 of this chapter.

So, which logics have been chosen? In Section 2 we shall present three first-order modal logics which we call the basic logics. In the basic logics, variables designate individual objects. The three basic logics have respectively constant domains, increasing

domains, and varying domains. In Section 3 we present first-order intensional logic. Beside objectual variables, this logic involves intension variables, that is, variables that designate functions from worlds to individual objects. Thus, there are two different types of semantic values, namely objects and functions from worlds to objects. First-order intensional logic allows quantification over both types of semantic values and predicates are allowed to take both types of semantic values as arguments. The logic includes so-called predicate abstraction which allows the functions from worlds to objects to be applied to arguments, that is, worlds, whereby objects are obtained. In Section 4 we present first-order hybrid logic which is obtained by adding to basic first-order modal logic further expressive power in the form of a new sort of propositional symbol called a nominal, and moreover, by adding so-called satisfaction operators and binders.

2 THE BASIC LOGICS

The syntax of the basic logics considered in this section is simply the syntax of ordinary (non-modal) first-order logic with equality, extended with a modal operator. Variables in the basic logics designate *rigidly*, that is, a variable designate the same object in all worlds. On the other hand, a predicate might have different extensions in different worlds, thus, predicates are relativised to worlds. This allows us to formalise natural language sentences involving predicates like for example "is a citizen of the United States". The fact that this predicate has different extensions in different worlds follows for example from the observation that Arnold Schwarzenegger is a citizen of the United States, but he might not have been so, for example if he had not emigrated to the United States. Predicates with different extensions in different worlds should be compared to predicates which naturally are taken to have the same extension in all worlds, one example being "is greater than five" since the extension of this predicate in any world naturally is taken to be the set of numbers greater than five. Predicates of the latter kind can be formalised in ordinary first-order logic.

One choice to make is whether quantified domains might be different in different worlds, that is, whether quantifier domains are relativised to worlds, and if they are relativised to worlds, whether any restrictions are imposed on this relativisation. In this section we present three different first-order modal logics corresponding to three different choices concerning relativisation, they have respectively constant domains (no relativisation), increasing domains (relativisation with the restriction that the domain of a world is included in the domain of any accessible world), and varying domains (unrestricted relativisation). Note that in all three cases an object might be a member of the quantified domains of more than one world, in fact, in the constant domain case all worlds have the same quantifier domain. In Subsection 2.8 we compare constant and varying domains using so-called *existence predicates*. The choice of relativisation of quantifier domains is related to the famous *Barcan* and *Converse Barcan* formulas, which we shall return to a number of times, in particular in Subsection 2.9.

Sound and complete proof procedures are available. In this section we give axiom systems for the constant, increasing, and varying domain basic logics. A tableau system for a version of the constant domain logic without equality can be found in Chapter 2 in the present handbook, and tableau systems for the constant and varying domain logics, including equality, can be found in the book [41]. For more on the model theory of first-order modal logic, see [30], [31], and [33].

2.1 Syntax of the basic logics

The three basic first-order modal logics have the same syntax, that is, the same formulas. The syntax is obtained by adding a modal operator $\Box$ to the syntax of ordinary first-order logic with equality. It is assumed that a countably infinite set of first-order variables is given. The metavariables x, y, z, ... range over variables. We do not consider function symbols or constants, so all terms are variables. It is also assumed that a set of predicate symbols is given. The metavariables P, Q, R, ... range over predicate symbols. Each predicate symbol comes together with a specification of its arity. Of course, 0-place predicate symbols correspond to propositional symbols. Formulas are defined by the grammar

$$S \ ::= \quad P(x_1, \ldots, x_n) \mid x = y \mid S \wedge S \mid \neg S \mid \Box S \mid \forall x S$$

where P is an n-place predicate symbol, x_1, ..., x_n as well as x and y are variables. Thus, formulas are built in the usual way using the connectives of ordinary first-order logic together with the modal operator. We allow parentheses to be inserted in formulas where needed and we shall assume the usual precedence rules for our logical connectives. In what follows, the metavariables ϕ, ψ, θ, ... range over formulas. Other propositional and first-order connectives such as $\top$, $\vee$, $\bot$, $\rightarrow$, $\leftrightarrow$, and $\exists$ are defined in the usual way. Also the modal operator $\Diamond$ is defined as usual. The notions of free and bound occurrences of variables are defined in the obvious way. Moreover, if $\overline{x}$ is a list of distinct variables and $\overline{y}$ is a list of variables of the same length as $\overline{x}$, then $\psi[\overline{y}/\overline{x}]$ is the formula ψ where the variables $\overline{y}$ have been simultaneously substituted for all free occurrences of the variables $\overline{x}$. It is assumed that no variable x_i in $\overline{x}$ occurs free in ψ within the scope of $\forall y_i$.

2.2 Constant domain semantics

We now define constant domain models and constant domain skeletons. Skeletons are first-order versions of the usual frames for propositional modal logics. We shall in many cases adopt the terminology of the books [11] and [41].

DEFINITION 1. A *constant domain model* is a tuple $\langle W, R, D, \{V_w\}_{w \in W}\rangle$ where

1. W is a non-empty set;
2. R is a binary relation on W;
3. D is a non-empty set; and
4. for each w, V_w is a function that to each n-place predicate symbol assigns a subset of D^n.

The tuple $\langle W, R\rangle$ is called a *frame* and the model is said to be *based* on this frame. The tuple $\langle W, R, D\rangle$ is called a *constant domain skeleton* and the model is said to be *based* on this constant domain skeleton.

As usual, the elements of the set W are called *worlds*, the relation R is called an *accessibility relation*, the set D is called the *domain of quantification*, and the function V_w is called the *valuation* at the world w.

DEFINITION 2. Given a constant domain model $\mathfrak{M} = \langle W, R, D, \{V_w\}_{w \in W}\rangle$, an *assignment* is a function that to each variable assigns an element of D. Given assignments g'

and g, $g' \overset{x}{\sim} g$ means that g' agrees with g on all variables save possibly x. The relation $\mathfrak{M}, g, w \models \phi$ is defined by induction, where w is a world, g is an assignment, and ϕ is a formula of first-order modal logic.

$$\begin{array}{rcl}
\mathfrak{M}, g, w \models P(x_1, \ldots, x_n) & \text{iff} & (g(x_1), \ldots, g(x_n)) \in V_w(P) \\
\mathfrak{M}, g, w \models x = y & \text{iff} & g(x) = g(y) \\
\mathfrak{M}, g, w \models \phi \wedge \psi & \text{iff} & \mathfrak{M}, g, w \models \phi \text{ and } \mathfrak{M}, g, w \models \psi \\
\mathfrak{M}, g, w \models \neg\phi & \text{iff} & \text{not } \mathfrak{M}, g, w \models \phi \\
\mathfrak{M}, g, w \models \Box\phi & \text{iff} & \text{for any } v \in W \text{ where } wRv,\ \mathfrak{M}, g, v \models \phi \\
\mathfrak{M}, g, w \models \forall x\phi & \text{iff} & \text{for any } g' \overset{x}{\sim} g,\ \mathfrak{M}, g', w \models \phi
\end{array}$$

A formula ϕ is said to be *true* at the world w if $\mathfrak{M}, g, w \models \phi$; otherwise it is said to be *false* at w. By convention $\mathfrak{M}, g \models \phi$ means $\mathfrak{M}, g, w \models \phi$ for every world w and $\mathfrak{M} \models \phi$ means $\mathfrak{M}, g \models \phi$ for every assignment g. A formula ϕ is *valid* in a frame (skeleton) if and only if $\mathfrak{M} \models \phi$ for any model $\mathfrak{M}$ that is based on the frame (skeleton) in question. A formula ϕ is *valid* in a class of frames (skeletons) $\mathfrak{F}$ if and only if ϕ is valid in any frame (skeleton) in $\mathfrak{F}$. A formula ϕ is *valid* if and only if ϕ is valid in the class of all frames (or equivalently, in the class of all skeletons).

Let us take a look at a natural language sentence that can be formalised using the machinery introduced so far. Consider the sentence

> Arnold Schwarzenegger is a citizen of the United States.

About Arnold Schwarzenegger, it says that he is a member of the set of persons who happen to be citizens of the United States. If the variable x stands for "Arnold Schwarzenegger" and the 1-place predicate symbol P stands for the predicate "is a citizen of the United States", then the formula $P(x)$ formalises the statement. Formally, $P(x)$ is true at a world w if and only if the designation of x belongs to the extension of the predicate symbol P at w. The relativisation of P to worlds formalises that the predicate "is a citizen of the United States" has different extensions in different worlds.

In ordinary (non-modal) first-order logic, the equality predicate is a designated primitive 2-place predicate symbol which is given a fixed interpretation, namely the identity relation on the domain of quantification. Note that the same pattern is followed in the case of first-order modal logic.

2.3 An axiom system for constant domains

In this subsection we shall give a Hilbert-style axiom system for the constant domain basic first-order modal logic. The axiom system is obtained as an extension of a Hilbert-style axiom system for the propositional modal logic **K** or another propositional modal logic. So we are actually giving a family of constant domain axiom systems, depending on a choice of the underlying propositional axiom system. In the definition of an axiom system we shall make use of *formula-schemas*. Informally, a formula-schema is like an ordinary formula except that it has metavariables for formulas instead of ordinary atomic formulas. Formally, a grammar for formula-schemas can be obtained from the grammar for formulas given in Subsection 2.1 by replacing the clauses for atomic formulas by a clause for metavariables. A *substitution-instance* of a formula-schema is a formula obtained by uniformly replacing all metavariables by ordinary formulas. Using this terminology, we

are able to talk formally about formulas having a specific common form (which is the form of an axiom schema).

We first give an axiom system for the propositional modal logic **K**. The axioms of the system are all the substitution-instances of tautologies of propositional logic (where propositional symbols are considered as metavariables) together with all substitution-instances of the following axiom schema

$$(K) \qquad \Box(\phi \to \psi) \to (\Box\phi \to \Box\psi)$$

The rules of the system are the following

$$\frac{\phi \to \psi \qquad \phi}{\psi}\,(\textit{Modus Ponens}) \qquad\qquad \frac{\phi}{\Box\phi}\,(\textit{Necessitation})$$

If there exists a derivation of a formula in the axiom system given above, then we say that the formula in question is *derivable*. This axiom system is sound and complete with respect to the standard possible-worlds semantics for propositional modal logic, see Chapter 2 in the present handbook. We here make use of the usual definition of soundness and completeness:

DEFINITION 3. An axiom system is *sound* with respect to a semantics if every derivable formula is valid and the axiom system is *complete* with respect to the semantics if every valid formula is derivable.

Further axiom schemas can be added to the axiom system for **K**, for example

$$\begin{array}{ll} (T) & \Box\phi \to \phi \\ (4) & \Box\phi \to \Box\Box\phi \\ (B) & \phi \to \Box\Diamond\phi \end{array}$$

whereby axiom systems for other propositional modal logics are obtained. If for example the axiom schema (T) is added, then an axiom system for the propositional modal logic **T** is obtained. Similarly, if (T) as well as (4) are added, then an axiom system for **S4** is obtained, and if all three axiom schemas above are added, the an axiom system for **S5** is obtained. It is straightforward to show that the axiom schemas above corresponds to the first-order conditions reflexivity, transitivity, and symmetry on the accessibility relation of a frame in the sense that a frame validates all substitution-instances of an axiom schema if and only if the accessibility relation of the frame satisfies the first-order condition corresponding to the axiom schema in question (for example, a frame validates all substitution-instances of the axiom schema (T) if and only if the accessibility relation of the frame is reflexive). Moreover, any axiom system obtained by adding some or all of the axiom schemas above can be proven to be sound and complete with respect to the semantics obtained by relativising validity to the class of frames where the accessibility relations satisfy the first-order conditions corresponding to the added axiom schemas, see Chapter 2 in the present handbook.

We are now ready to give the axiom system for the constant domain basic first-order modal logic. We choose **K** as the underlying propositional modal logic. The system is

obtained by extending the axiom system for propositional **K** with the axiom schemas

(*Reflexivity*)	$x = x$
(*Substitutivity*)	$(x = y \wedge \phi[x/z]) \rightarrow \phi[y/z]$
(*Necessary Distinctness*)	$x \neq y \rightarrow \Box(x \neq y)$
(*Barcan*)	$\forall x \Box \phi \rightarrow \Box \forall x \phi$
($\forall$ *Elimination*)	$\forall x \phi \rightarrow \phi[y/x]$

and the rule

$$\frac{\psi \rightarrow \phi[y/x]}{\psi \rightarrow \forall x \phi} \ (\forall \ \textit{Introduction})$$

where the rule is equipped with the side-condition that the variable y does not occur free in ψ or in $\forall x \phi$. This axiom system is sound and complete with respect to the constant domains semantics given in the previous subsection. A completeness proof can be found in the book [68]. See also the chapter [49] in *Handbook of Philosophical Logic*. This completeness result is essentially due to Saul Kripke, cf. the paper [75]. Soundness and completeness also holds for a number of other systems where further axiom schemas have been added and where the appropriate frame classes are considered, this is for example the case with the modal logics **T**, **S4**, and **S5** mentioned above, cf. the book [68].

The axiom (*Barcan*) is often simply called the Barcan formula. We shall return to it in Subsection 2.9. Note that ϕ in the axiom (*Substitutivity*) can be any formula of first-order modal logic, also a formula that involves modal operators. Thus, we here allow substitution of equals for equals in modal contexts, so for example the formula $x = y \rightarrow \Box(x = y)$ is derivable. This is justified by the fact that variables here designate rigidly. Thus, the variables x and y designating the same object in a world w imply that x and y designate the same object in any world, in particular any world accessible from w. This gives rise to a philosophical discussion which we shall return to in Subsection 3.2.

Note that the axiom ($\forall$ *Elimination*) together with the rule ($\forall$ *Introduction*) is a standard axiomatisation of quantifiers in ordinary (non-modal) first-order logic, and similarly, the axioms (*Reflexivity*) and (*Substitutivity*) together is a standard axiomatisation of equality in ordinary first-order logic, so the constant domain axiom system given above can be seen as obtained from the axiom system for the propositional modal logic **K** by adding standard non-modal axiomatic machinery for quantifiers and equality together with the axioms (*Necessary Distinctness*) and (*Barcan*). This motivates the following definition:

DEFINITION 4. The constant domain axiom system given above will (where such notation is needed) be denoted $\mathbf{QK}_{=}$+*ND*+*BF*. We will (again, where such notation is needed) use the same notation for the set of formulas derivable in the axiom system. The notation is adjusted as appropriate if another underlying propositional modal logic is chosen or if for example the axiom (*Barcan*) is omitted.

In Subsection 2.5 we shall consider the system $\mathbf{QK}_{=}$+*ND* without the axiom (*Barcan*). From Section 9 on in Part II of this chapter we shall treat logics along the lines of $\mathbf{QK}_{=}$, that is, logics with equality but without the axiom (*Necessary Distinctness*). In particular, a semantics for $\mathbf{QK}_{=}$ is given in the first example of Subsection 10.1.

Above we specified an axiom system by specifying the axiom schemas and the rules of the system. Given an axiom system, we could then talk about the set of formulas derivable in the axiom system. Sometimes we want to be more general in the sense that

we want talk about an arbitrary set of formulas containing all substitution instances of some axiom schemas and closed under some rules. To this end we need one more rule

$$\frac{\phi}{\phi[\psi/P(\overline{x})]}\ (\textit{Uniform Substitution})$$

where $\phi[\psi/P(\overline{x})]$ is the formula obtained by replacing every occurrence of $P(\overline{y})$ in ϕ by $\psi[\overline{y}/\overline{x}]$. It is assumed that $P(\overline{y})$ does not occur in ϕ within the scope of any quantifier $\forall z$ where z is a free variable of ψ which is not on the list $\overline{x}$. We shall call $\phi[\psi/P(\overline{x})]$ a *substitution-instance* of ϕ. It might be instructive to consider an example of a substitution-instance: If ϕ is the formula $\forall y(P(y) \wedge Q(y))$ and ψ is the formula $R(z, x)$ where z is distinct from x and y, then $\phi[\psi/P(x)]$ is the formula $\forall y(R(z, y) \wedge Q(y))$. Thus, $\forall y(R(z, y) \wedge Q(y))$ is a substitution-instance of $\forall y(P(y) \wedge Q(y))$. Note that the definition of a substitution-instance of a formula is more complicated than the definition of a substitution-instance of a formula-schema, the reason being that an atomic formula $P(\overline{x})$ has an inner structure whereas the metavariables in a formula-schema work as place-holders, that is, they are just indexes of places. Now, if L is a set of formulas which contains all substitution-instances of the axiom schemas of the axiom system $\mathbf{QK}_=$ and which is closed under the rules of $\mathbf{QK}_=$ together with the rule (*Uniform Substitution*), then the set L is called a *first-order modal system*. With this definition it is straightforward that $\mathbf{QK}_=$ is the least first-order modal system with respect to inclusion. We shall return to this in Section 8 in Part II of this chapter.

2.4 Increasing domain semantics

We now define increasing domain models and increasing domain skeletons. We do not repeat conventions and definitions that are the same as in the constant domain case.

DEFINITION 5. An *increasing domain model* is a tuple $\langle W, R, D, \{\delta_w\}_{w\in W}, \{V_w\}_{w\in W}\rangle$ where the tuple $\langle W, R, D, \{V_w\}_{w\in W}\rangle$ is a constant domain model as defined in Definition 1 and where for each w, δ_w is a subset of D such that $\delta_w \subseteq \delta_v$ whenever wRv. The tuple $\langle W, R, D, \{\delta_w\}_{w\in W}\rangle$ is called an *increasing domain skeleton* and the model is said to be *based* on this increasing domain skeleton.

The set δ_w is called the *domain of quantification* at the world w. Note that a constant domain model (skeleton) can be considered as an increasing domain model (skeleton) by letting $\delta_w = D$ for any element w of W (see Definition 1).

DEFINITION 6. Given an increasing domain model $\mathfrak{M} = \langle W, R, D, \{\delta_w\}_{w\in W}, \{V_w\}_{w\in W}\rangle$, the relation $\mathfrak{M}, g, w \models \phi$ is defined in the same way as in the constant domain case, that is, Definition 2, except that the clause for the quantifier is replaced by

$$\mathfrak{M}, g, w \models \forall x\phi \quad \text{iff} \quad \text{for any } g' \stackrel{x}{\sim} g \text{ where } g'(x) \in \delta_w,\ \mathfrak{M}, g', w \models \phi$$

The definition of validity is the same as in the constant domain case except that $\mathfrak{M} \models \phi$ now means $\mathfrak{M}, g, w \models \phi$ for every world w and every assignment g such that $g(x)$ is an element of δ_w for every variable x.

Of course, if $\delta_w = D$ for any element w of W, then the clause above for the increasing domain quantifier is equivalent to the clause for the constant domain quantifier (compare Definition 2). Note that in the increasing domain semantics, the only assignments considered are assignments where every variable is assigned an existent, that is, an element

of the quantifier domain. Also, note that if an assignment at some world has the property that it assigns existents to all variables, then the assignment also has that property at any accessible world, the reason being that the domain increases. This means that worlds with empty quantifier domains simply are ignored. In a similar way the semantics also ignores elements of D that are not elements of the set $\cup_{w\in W}\delta_w$.

2.5 An axiom system for increasing domains

In this subsection we shall consider a Hilbert-style axiom system for the increasing domain basic first-order modal logic. The system is obtained from the axiom system for constant domains of Subsection 2.3 simply by omitting the Barcan formula $\forall x\Box\phi \rightarrow \Box\forall x\phi$. This axiom system is sound and complete with respect to the increasing domain semantics given in the previous subsection, cf. the book [68]. Note that this axiom system can be seen as obtained from the axiom system for the propositional modal logic **K** by adding standard non-modal axiomatic machinery for quantifiers and equality together with the axiom (*Necessary Distinctness*). So in the terminology of Subsection 2.3, it is the system $\mathbf{QK}_{=}+ND$.

Now, the Barcan formula, which was taken as an axiom in the constant domain system, expresses interaction between first-order quantifiers and modal operators since it says that a quantifier and a modal operator can be permuted in one way. However, the Barcan formula is not taken as an axiom in the system considered here, and there are no other axioms or rules in the system that explicitly say that quantifiers and modal operators interact. It is therefore a surprise that the so-called Converse Barcan formula $\Box\forall x\phi \rightarrow \forall x\Box\phi$ is derivable in the system. In fact, the Converse Barcan formula has the very simple derivation

$$\cfrac{\cfrac{\dfrac{\forall x\phi \rightarrow \phi}{\Box(\forall x\phi \rightarrow \phi)} \qquad \Box(\forall x\phi \rightarrow \phi) \rightarrow (\Box\forall x\phi \rightarrow \Box\phi)}{\Box\forall x\phi \rightarrow \Box\phi}}{\Box\forall x\phi \rightarrow \forall x\Box\phi}$$

in the system. We shall return to the Barcan and Converse Barcan formulas in Subsection 2.9.

2.6 Varying domain semantics

We now define varying domain models and varying domain skeletons. Again, we do not repeat conventions and definitions that are the same as in the earlier cases.

DEFINITION 7. A *varying domain model* is a tuple $\langle W, R, D, \{\delta_w\}_{w\in W}, \{V_w\}_{w\in W}\rangle$ where the tuple $\langle W, R, D, \{V_w\}_{w\in W}\rangle$ is a constant domain model as defined in Definition 1 and where for each w, δ_w is a subset of D. The tuple $\langle W, R, D, \{\delta_w\}_{w\in W}\rangle$ is called a *varying domain skeleton* and the model is said to be *based* on this varying domain skeleton. A varying domain model (skeleton) has *increasing domains* if and only if $\delta_w \subseteq \delta_v$ whenever wRv, and similarly, it has *decreasing domains* if and only if $\delta_w \supseteq \delta_v$ whenever wRv.

Note that an increasing domain model (skeleton) is a varying domain model (skeleton) with increasing domains and vice versa (see Definition 5). A number of choices in the

definition of a varying domain model should be noted: We do not require that a predicate is false of non-existents, we do not require that a quantifier domain is non-empty and we do not require that each individual exists in some domain. Most combinations of these requirements can be found in the literature. One motivation for the choices made here is that they make the translation into two-sorted first-order logic very straightforward, see Subsection 2.10.

DEFINITION 8. Given a varying domain model $\mathfrak{M} = \langle W, R, D, \{\delta_w\}_{w\in W}, \{V_w\}_{w\in W}\rangle$, the relation $\mathfrak{M}, g, w \models \phi$ is defined as in the increasing domain case, that is, Definition 6. The definition of validity is the same as in the constant domain case, that is, Definition 2.

Note that validity is defined as in the constant domain case, not as in the increasing domain case. The resulting difference is that in the varying domain case all assignments are considered whereas in the increasing domain case the only assignments considered are assignments where every variable is assigned an existent. The reason why we make use of different definitions of validity is that straightforward and simple axiom systems are available with these choices.

2.7 Axiom systems for varying domains

In this subsection we shall give two different Hilbert-style axiom systems for the varying domain basic first-order modal logic. First note that the $\forall$ Elimination formula $\forall x\phi \rightarrow \phi[y/x]$ it is not valid with respect to the varying domain semantics (if the variable y designates a non-existent object, then the object is not a member of the domain of the quantifier, so the antecedent can be true but the succedent false) but it is valid with respect to the constant and increasing domain semantics (in both cases the object designated by y is a member of the quantifier domain, so if the antecedent is true, then the succedent is also true). Indeed, the $\forall$ Elimination formula is taken as an axiom in both the constant domain axiom system of Subsection 2.3 and the increasing domain axiom system of Subsection 2.5. Now, the $\forall$ Elimination formula can straightforwardly be modified in two ways such that it becomes valid with respect to the varying domain semantics. It is these two different modified versions of $\forall$ Elimination that give rise to the two varying domain axiom systems we shall give below.

Before giving the first axiom system we need to give a small definition: The so-called existence predicate is defined by the convention that $E(y)$ is an abbreviation for $\exists z(z = y)$ where z is a variable distinct from the variable y. We shall come back to the existence predicate in the next subsection. The first axiom system is obtained by extending the axiom system for the propositional modal logic **K** (see Subsection 2.3) with the axiom schemas

(*Reflexivity*)	$x = x$
(*Substitutivity*)	$(x = y \wedge \phi[x/z]) \rightarrow \phi[y/z]$
(*Necessary Distinctness*)	$x \neq y \rightarrow \Box(x \neq y)$
(*Free $\forall$ Elimination*)	$(\forall x\phi \wedge E(y)) \rightarrow \phi[y/x]$

and the rule

$$\frac{(\psi \wedge E(y)) \rightarrow \phi[y/x]}{\psi \rightarrow \forall x\phi}\ (\textit{Free } \forall \textit{ Introduction})$$

where the rule is equipped with the side-condition that the variable y does not occur free in ψ or in $\forall x\phi$. The axiom system is sound and complete with respect to the varying

domains semantics given in the previous subsection, cf. [49]. (Some of the axioms and rules above are formulated differently in [49], but these differences are not of significance here.)

Note that the axiom (*Free* $\forall$ *Elimination*) above is the result of adding a "guard" formula $E(y)$ to the antecedent of the $\forall$ Elimination formula $\forall x\phi \to \phi[y/x]$ such that the antecedent becomes false in the case where the variable y designates a non-existent. Note moreover that the rule (*Free* $\forall$ *Introduction*) above also makes use of such a guard formula. The axiomatic machinery for quantifiers in this axiom system is identical to the standard axiomatic machinery for quantifiers in so-called free logic which is a variant of ordinary first-order logic where quantifiers only range over a subset of the universe (but where variables might designate any member of the universe as in ordinary first-order logic). One original motivation for developing free logic was to avoid the assumption made in ordinary first-order logic that quantifier domains are non-empty as this assumption was found undesirable by a number of philosophers because of the associated "existential commitment". See [7] for more information on free logic.

We shall now give the second, alternative, axiom system for the varying domain basic first-order modal logic. This axiom system does not involve the existence predicate, in fact, the system is for a version of the basic logic without equality. This alternative system is obtained by extending the axiom system for the propositional modal logic **K** (see Subsection 2.3) with the axiom schemas

(*Vacuous* $\forall$)	$\forall x\phi \leftrightarrow \phi$
($\forall$ *Distributivity*)	$\forall x(\phi \to \psi) \to (\forall x\phi \to \forall x\psi)$
($\forall$ *Permutation*)	$\forall y\forall z\phi \to \forall z\forall y\phi$
(*Restricted* $\forall$ *Elimination*)	$\forall y(\forall x\phi \to \phi[y/x])$

and the rule

$$\frac{\phi}{\forall x\phi}\ (\forall\ \textit{Generalisation})$$

where the axiom (*Vacuous* $\forall$) is equipped with the side-condition that the variable x does not occur free in the formula ϕ. The axiom system is sound and complete with respect to the varying domains semantics given in Subsection 2.6, cf. the book [68]. (In the axiom system of [68], the formula $\forall y\forall z(\forall x\phi \to \phi[y/x])$ is taken as an axiom instead of the axioms ($\forall$ *Permutation*) and (*Restricted* $\forall$ *Elimination*) above, but this difference is not of significance here.) One might ask whether the axiom ($\forall$ *Permutation*) really is needed. This turns out to be the case which was pointed out in [34]. See the discussions of this issue in [68] and [41].

Note the way in which the $\forall$ Elimination formula $\forall x\phi \to \phi[y/x]$ has been modified in the system above: The variable y has been quantified over such that it only designates existents. The history of systems in line with this system goes back to [75].

2.8 Existence and quantification

In connection with varying domain models, the existence predicate is defined by the convention that $E(y)$ is an abbreviation for $\exists z(z = y)$ where z is a variable distinct from the variable y. With this definition it is straightforward to check that for any varying domain model $\mathfrak{M}$, any world w, and any assignment g, the relationship $\mathfrak{M}, g, w \models E(x)$ holds if and only if $g(x) \in \delta_w$. Thus, the existence predicate is true of the individual

designated by some variable if and only if the individual in question exists. So with this definition the existence predicate behaves as desired. But if the definition is adopted in connection with constant domain models, then the existence predicate is true of all individuals as expected.

However, in connection with constant domain models, the existence predicate is usually taken to be primitive, rather than defined. This brings us to an important definition.

DEFINITION 9. Given a varying domain model $\mathfrak{M} = \langle W, R, D, \{\delta_w\}_{w\in W}, \{V_w\}_{w\in W}\rangle$, a constant domain model $\mathfrak{M}^* = \langle W, R, D, \{V^*_w\}_{w\in W}\rangle$ for the language extended with a 1-place predicate symbol E is defined by letting V^*_w be the extension of V_w such that $V_w(E) = \delta_w$.

Clearly, the map $(\cdot)^*$ which maps $\mathfrak{M}$ to $\mathfrak{M}^*$ is bijective. Thus, from a mathematical point of view, giving a varying domain model is the same as extending the language with a 1-place predicate symbol E and then giving a constant domain model.

This observation is exploited in the translation below which translates any formula in the original language (that is, the language without the predicate symbol E) into a formula in the language extended with E.

$$\begin{array}{rcl}
(P(x_1,\dots,x_n))^E & = & P(x_1,\dots,x_n) \\
(x = y)^E & = & x = y \\
(\phi \wedge \psi)^E & = & \phi^E \wedge \psi^E \\
(\neg\phi)^E & = & \neg\phi^E \\
(\Box\phi)^E & = & \Box\phi^E \\
(\forall x\phi)^E & = & \forall x(E(x) \to \phi^E)
\end{array}$$

The translation gives rise to the following result.

PROPOSITION 10. *Let $\mathfrak{M}$ be a varying domain model. For any first-order modal-logical formula ϕ, any world w, and any assignment g, $\mathfrak{M}, g, w \models \phi$ if and only if $\mathfrak{M}^*, g, w \models \phi^E$.*

Proof. Induction in the structure of ϕ. ❑

See [68] and [41] for a more detailed discussion of the existence predicate.

The interpretation of a quantifier in a constant domain model is called *possibilist quantification* since the quantifier ranges over individuals that possibly exist (this terminology is a bit inaccurate if existence is formalised by extending the constant domain semantics with a primitive existence predicate as described above, the reason being that the quantifier then ranges over all individuals, not only those that possibly exist, that is, exist at some world, but we ignore this inaccuracy). On the other hand, the interpretation of a quantifier in a varying domain model is called *actualist quantification* since the quantifier in this case ranges over individuals that actually exist, that is, individuals that exist in the actual world.

The difference between actualist and possibilist quantification is very clear when the modal operator is given a temporal interpretation, that is, when worlds are taken to be instants and the modal operator is interpreted using the earlier-later relation on instants. In that case actualist quantification corresponds to quantifying over things that now exist whereas possibilist quantification corresponds to quantifying over things that exist at some time. This distinction was discussed already by Arthur Prior who rejected the temporal version of possibilist quantification:

> ... even if it be true that whatever exists at any time exists at all times, there is surely no *inconsistency* in denying it, and a *logic* of time-distinctions ought to be able to proceed without assuming it. ([98], p. 30)

Prior equated the statement "x exist" with "there are facts about x" and he found that facts can only be about whatever now exists. This view has the consequence that facts cannot be about things which have ceased to exist. Prior was uncomfortable about this consequence, but he found it unavoidable. Of course, the view also has the consequence that facts cannot be about things which do not yet exist, but Prior considered this less disputable. Since Prior, possibilist and actualist quantification has given rise to much philosophical discussion, see the book [41] for an account. See also the contributions to the discussion given in the papers [97] and [69].

2.9 The Barcan and Converse Barcan formulas

It is straightforward to show that the Barcan formula $\forall x \Box \phi \to \Box \forall x \phi$ is valid in any decreasing domain skeleton, and moreover, it can also be shown straightforwardly that if the Barcan formula is valid in a varying domain skeleton, then the skeleton in question has decreasing domains. Thus, the class of varying domain skeletons that validates the Barcan formula is exactly the class of decreasing domain skeletons. Prior rejected the Barcan formula for the same reasons as he rejected possibilist quantification, see the previous section. It can also be shown straightforwardly that the class of varying domain skeletons that validates the Converse Barcan formula $\Box \forall x \phi \to \forall x \Box \phi$ is exactly the class of increasing domain skeletons. Indeed, as we saw in Subsection 2.5, the Converse Barcan formula is derivable in the axiom system for increasing domains.

First-order modal logics can be seen as combinations of two distinct logics, namely propositional modal logic and ordinary first-order logic. The two logics, propositional modal logic and ordinary first-order logic, are combined in different ways in the constant, increasing, and varying domain logics. The interaction between modality and quantification is stronger in the constant domain logic than in the varying domain logic in the sense that the Barcan and Converse Barcan formulas (which together say that the order of quantifiers and modal operators does not matter) both are valid in the constant domain semantics but none of them are valid in the varying domain semantics. The Barcan formula is not valid in the increasing domain semantics, but the Converse Barcan formula is, so the increasing domain logic has a "medium" interaction between modality and quantification.

The semantical import of the Barcan and Converse Barcan formulas stems from the distinction between the semantics of the formulas $\forall x \Box \phi$ and $\Box \forall x \phi$. This distinction is an example of the so-called *de re*/*de dicto* distinction. In Latin *de re* means "about the thing" and *de dicto* means "about the proposition". To explain this difference, we instantiate the formula ϕ to $P(x)$. The formula $\Box \forall x P(x)$ says that

> it is necessary that each existing thing is P.

This is a *de dicto* interpretation since it says something about a proposition, namely the proposition that each existing thing is P. What it says about this proposition is that it is necessary. On the other hand, the formula $\forall x \Box P(x)$ says that

> each existing thing is necessarily P.

This is a *de re* interpretation since it says something about things, namely the things that exist. What it says about these things is that each of them is necessarily P. Se the book [41] for a much more thorough discussion of *de re* and *de dicto*. We shall return to the *de re*/*de dicto* distinction in Subsection 3.3 where we consider predicate abstraction. The history of formulas like the Barcan and Converse Barcan formulas goes back to the paper [6].

2.10 Translation into two-sorted first-order logic

The basic first-order modal logics can be translated into two-sorted first-order logic with equality. There is one sort for worlds and one sort for individuals. We consider two different translations, one which is truth-preserving with respect to the constant domain semantics and one which is truth-preserving with respect to the varying domain semantics. There is not much literature available on translations of first-order modal logic into sorted first-order logic. The translations we consider in this subsection are variations of a translation given in [127] and they are also considered in the chapter [91] in *Handbook of Automated Reasoning* which moreover considers a range of other non-classical logics. In [127] a semantic characterisation is given of the formulas of two-sorted first-order logic which have the same expressive power as formulas of a variant of the varying domain logic. The papers [63] and [65] consider a number of formulas in two-sorted first-order logic that express properties of models which are not expressible in first-order modal logic. The latter paper concentrates on a first-order version of the modal logic **S5**. A recent example of work in this area is the paper [123] which also concerns the expressive power of a first-order version of **S5**. See also that paper for an overview of the area.

We first consider the constant domain case. The two-sorted first-order language under consideration here is defined as follows. It is assumed that a countably infinite set of first-order variables for worlds and a countably infinite set of first-order variables for individuals are given. The sets are assumed to be disjoint. The metavariables a, b, c, ... range over first-order variables for worlds and the metavariables x, y, z, ... range over first-order variables for individuals. There are no function symbols or constants. Formulas of the two-sorted first-order language are defined by the grammar

$$S \ ::= \quad P^*(a, x_1, \ldots, x_n) \mid R(a, b) \mid x = y \mid S \wedge S \mid \neg S \mid \forall a S \mid \forall x S$$

where P is an n-place predicate symbol of first-order modal logic, a and b are variables for worlds, and x_1, ..., x_n as well as x and y are variables for individuals. Note that according to the grammar above, for each n-place predicate symbol P of the first-order modal language there is a corresponding $(n+1)$-place predicate symbol P^* in the two-sorted first-order language. The two-sorted $(n+1)$-place predicate symbol P^* will be interpreted such that it relativises the interpretation of the corresponding modal n-place predicate symbol P to worlds. In the grammar above R is a designated predicate symbol which will be interpreted using the accessibility relation (with the same name). In what follows, we shall identify first-order variables for individuals with first-order variables of modal logic. Note that the language contains two quantifiers, a quantifier for each sort, but the language only contains one equality predicate, namely an equality predicate for individuals.

We now give the translation. Given two new first-order variables for worlds, a and b, the translations ST_a and ST_b are defined by mutual induction. We just give the

translation ST_a.

$$\begin{array}{rcl} ST_a(P(x_1,\ldots,x_n)) & = & P^*(a,x_1,\ldots,x_n) \\ ST_a(x=y) & = & x=y \\ ST_a(\phi\wedge\psi) & = & ST_a(\phi)\wedge ST_a(\psi) \\ ST_a(\neg\phi) & = & \neg ST_a(\phi) \\ ST_a(\Box\phi) & = & \forall b(R(a,b)\rightarrow ST_b(\phi)) \\ ST_a(\forall x\phi) & = & \forall x ST_a(\phi) \end{array}$$

The definition of ST_b is obtained by exchanging a and b. What has been done is that the semantics of first-order modal logic has been formalised in terms of two-sorted first-order logic, note how each clause in the translation formalizes a clause in the definition of the semantics, Definition 2. The translation is an extension of the well-known *standard translation* from modal logic into first-order logic, see [127]. See Chapter 11 in the present handbook for a temporal version of the translation above.

To state formally that the translation given above is truth-preserving with respect to the constant domain semantics, we make use of the observation that a constant domain model for first-order modal logic can be considered as a model for two-sorted first-order logic and vice versa.

DEFINITION 11. Given a constant domain model $\mathfrak{M}=\langle W,R,D,\{V_w\}_{w\in W}\rangle$ for first-order modal logic, a model $\mathfrak{M}^*=\langle W,D,V^*\rangle$ for two-sorted first-order logic is defined by letting

- $V^*(R)=R$ and
- $(w,d_1,\ldots,d_n)\in V^*(P^*)$ if and only if $(d_1,\ldots,d_n)\in V_w(P)$.

It is straightforward to see that the map $(\cdot)^*$ which maps $\mathfrak{M}$ to $\mathfrak{M}^*$ is bijective. Moreover, if an assignment in the sense of first-order modal logic is extended such that it assigns a world to each first-order variable for worlds, then it can be considered an assignment as appropriate for two-sorted first-order logic and vice versa. See Chapter 11 in the present handbook for a temporal version of the above construction of a two-sorted first-order model from a modal model.

Given a model $\mathfrak{M}$ for two-sorted first-order logic, the relation $\mathfrak{M},g\models\phi$ is defined by induction in the standard way, where g is an assignment for two-sorted first-order logic and ϕ is a two-sorted first-order formula. The formula ϕ is said to be *true* if $\mathfrak{M},g\models\phi$; otherwise it is said to be *false*. By convention $\mathfrak{M}\models\phi$ means $\mathfrak{M},g\models\phi$ for every assignment g. A formula ϕ is valid if and only if $\mathfrak{M}\models\phi$ for any model $\mathfrak{M}$.

We are now ready to state formally that the translation is truth-preserving.

PROPOSITION 12. *Let a constant domain model $\mathfrak{M}$ be given. For any first-order modal-logical formula ϕ and any assignment g for $\mathfrak{M}$, it is the case that $\mathfrak{M},g,g^*(a)\models\phi$ if and only if $\mathfrak{M}^*,g^*\models ST_a(\phi)$ where g^* is any assignment extending g such that it assigns a world to each first-order variable for worlds (and the same for ST_b).*

Proof. Induction in the structure of ϕ. ❑

Thus, first-order modal logic, considered a language for talking about constant domain models, has the same expressive power as the fragment of two-sorted first-order logic obtained by taking the image of first-order modal logic under the translation ST_a.

We now briefly consider the translation which is truth-preserving with respect to the varying domain semantics. The two-sorted first-order language under consideration is the same as in the constant domain case except that the grammar for formulas is extended with a clause $E(a, x)$ for a new predicate symbol where a is a variable for worlds and x is a variable for individuals. Intuitively, the predicate symbol E is interpreted such that it relates a world to individuals existing at that world.

The translation is the same except that the clause for quantifiers is replaced by

$$ST_a(\forall x\phi) \quad = \quad \forall x(E(a, x) \rightarrow ST_a(\phi))$$

It is straightforward to modify Definition 11 to the varying domain case and it is also straightforward to check that Proposition 12 still holds.

Note that the correspondence between varying domain first-order modal models and two-sorted first-order models is very straightforward and simple due to the choices made in Subsection 2.6: We did not require predicates to be false of non-existents, we did not require quantifier domains to be non-empty, and we did not require that each individual exists in some domain.

3 FIRST-ORDER INTENSIONAL LOGIC

The logic we shall consider in this section is more complicated than the basic first-order modal logics we have considered in the previous section. Recall that variables in the basic logics designate rigidly, that is, a variable designates the same object in all worlds. So the assignment of objects to such variables is not relative to worlds. Compared to this, one new piece of machinery of first-order intensional logic is *intension variables* which are variables that designate *intensions*, that is, functions from worlds to objects. Thus, intension variables designate *non-rigidly* in the sense that intensions might map different worlds to different objects. Intensions are also called *individual concepts*. Intension variables can be motivated in a number of different ways. One very instructive motivation is that intension variables allow us to formalise natural language sentences involving non-rigidly designating terms like for example "the number of planets" and "the world champion in marathon running". The first example term designates non-rigidly as it designates the number nine (since there are nine planets in our world), but it might have designated another number (since there might have been another number of planets if natural history had been different). Similarly, the designation of the second example term is the winner of the world championship in marathon running, and the identity of the winning person is obviously also a contingent matter. Intension variables can be used for many different purposes, one example is that they can be used to give a solution to a famous philosophical problem, namely a modal version of Frege's puzzle about the morning star and the evening star. We shall return to this in Subsection 3.2. To sum up, in the previous section we took objects as semantic values, but in the present section we moreover take functions from worlds to objects as semantic values. In fact, first-order intensional logic allows quantification over both objects and intensions as well as predication of both objects and intensions. Thus, predicates are typed, that is, it is specified whether an argument-place is for an object term or an intension term. First-order intensional logic also includes so-called *predicate abstraction* which allows the function which is the interpretation of an intension variable to be applied to an

argument, that is, a world, whereby an object is obtained. Thus, predicate abstraction can be considered the "interface" between intensions and objects. We shall come back to the motivation for predicate abstraction in Subsection 3.3.

A number of versions of first-order intensional logic can be found in the literature. The version we give here is from the paper [40] where also a tableau system can be found which is sound and complete with respect to the semantics. See the book [68], the chapter [49] in *Handbook of Philosophical Logic*, and the papers [108] and [96] for other versions. See also [39] for a treatment of higher-order intensional logic. The history of first-order intensional logic goes back to the work of Richard Montague and Daniel Gallin, see [87] and [48]. See Chapter 21 in the present handbook for a historical account of intensional logic.

3.1 Syntax and semantics of first-order intensional logic

We now extend the formal syntax and semantics of the constant domain basic logic with first-order intensional machinery. Note that constant domains are just as general as varying domains in the sense that the varying domain semantics can be simulated by the constant domain semantics if a primitive existence predicate is added, cf. Subsection 2.8. Conventions and definitions that are the same as in the basic case are not repeated.

First the syntax. It is assumed that a countably infinite set of intension variables is given. The metavariables i, j, k, ... range over intension variables. It is assumed that the set of intension variables is disjoint from the set of ordinary variables for objects. A term is either an ordinary object variable or an intension variable. At this stage function symbols could have been included, but in the interest of simplicity we shall not do so. Predicate symbols are typed, that is, it is not only specified which arity a predicate symbol has, it is also specified which type each argument place has. Following the paper [40], the types of an n-place predicate symbol are specified by a list $T_1, \ldots, T_n$ where $T_i \in \{O, I\}$ for each T_i (the letter O stands for object and the letter I stands for intension). The syntax also includes predicate abstraction as mentioned above. Formulas are defined by the grammar

$$S \ ::= \quad P(t_1, \ldots, t_n) \mid x = y \mid S \wedge S \mid \neg S \mid \Box S \mid \forall x S \mid \forall i S \mid (\lambda x S)(i)$$

where P is an n-place predicate symbol and $t_1, \ldots, t_n$ are terms of the respective types $T_1, \ldots, T_n$ specified for P, x and y are object variables, and i is an intension variable. The free variable occurrences in the predicate abstraction $(\lambda x \phi)(i)$ are the free variable occurrences in the formula ϕ, except for occurrences of x, together with the variable occurrence i. Thus, all occurrences of x in ϕ are bound. Of course, the definition of substitution is modified in accordance with this extension of the language. We allow intension variables to occur in argument places for object variables in the sense that we abbreviate $(\lambda x P(\ldots, x, \ldots))(i)$ as $P(\ldots, i, \ldots)$, etc. This also applies to the equality predicate, so $i = j$ is an abbreviation for $(\lambda y(\lambda x(x = y))(i))(j)$. Now the semantics.

DEFINITION 13. A tuple $\langle W, R, D_O, D_I, \{V_w\}_{w \in W}\rangle$ where

1. W is a non-empty set;

2. R is a binary relation on W;

3. D_O is a non-empty set;

4. D_I is a non-empty set of functions from W to D_O; and
5. for each w, V_w is a function that to each n-place predicate symbol P assigns a subset of $D_{T_1} \times \ldots \times D_{T_n}$ where $T_1, \ldots, T_n$ are the types specified for P.

is a *constant domain intensional model.* The tuple $\langle W, R, D_O, D_I \rangle$ is called a *constant domain intensional skeleton* and the model is said to be *based* on this constant domain intensional skeleton.

Note that both the domain of objects D_O and the domain of intensions D_I are taken to be constant. A version of first-order intensional logic with varying intension domains can be found in [49] (that version also differs in other respects from the version presented here, however).

DEFINITION 14. Let $\mathfrak{M} = \langle W, R, D_O, D_I, \{V_w\}_{w \in W} \rangle$ be a constant domain intensional model. An assignment is a function that to each object variable assigns an element of D_O and to each intension variable assigns an element of D_I. The relation $\mathfrak{M}, g, w \models \phi$ is defined in the same way as in the basic constant domain case, that is, Definition 2, except that the clause for ordinary predicates is replaced by

$$\mathfrak{M}, g, w \models P(t_1, \ldots, t_n) \quad \text{iff} \quad (g(t_1), \ldots, g(t_n)) \in V_w(P)$$

and the following clauses

$$\begin{array}{lll} \mathfrak{M}, g, w \models \forall i \phi & \text{iff} & \text{for any } g' \overset{i}{\sim} g,\ \mathfrak{M}, g', w \models \phi \\ \mathfrak{M}, g, w \models (\lambda x \phi)(i) & \text{iff} & \mathfrak{M}, g', w \models \phi \text{ where } g' \overset{x}{\sim} g \text{ and } g'(x) = g(i)(w) \end{array}$$

for intensional quantification and predicate abstraction are added. Also the definition of validity is the same as in the basic constant domain case.

It is instructive to take a look at a couple of natural language sentences that can be formalised using intension variables. The examples involve the term "the President of the United States" which clearly designates non-rigidly. Consider the sentence

The President of the United States is a Republican.

It says something about the person who is the President of the United States, namely that the person in question is a Republican. If the intension variable i stands for “the President of the United States” and the objectual 1-place predicate symbol Q stands for the predicate “is a Republican”, then the formula $Q(i)$ formalises the statement (where $Q(i)$ is an abbreviation for $(\lambda x Q(x))(i)$). Formally, $Q(i)$ is true at a world w if and only if the designation of i at w belongs to the extension of the predicate Q at w, that is, if and only if the extension of Q at w contains the object obtained by applying the intension designated by i to w. On the other hand, consider the sentence

The President of the United States is an important concept in politics.

This sentence is not about the person who happens to be the President of the United States, rather it is about the concept of the President of the United States. What the sentence says about this concept, is that it is politically important. If the intensional 1-place predicate symbol R stands for the predicate “is a politically important concept”, then the formula $R(i)$ formalises the statement in question. Formally, $R(i)$ is true at

a world w if and only if the extension of R at w contains the intension, that is, the function, designated by i. Clearly, the statement is true, but if "the President of the United States" is replaced by for example "the world champion in marathon running", then it becomes false.

According to the clause above for predicate abstraction, the formula $(\lambda x\phi)(i)$ is true at a world w if and only ϕ is true at w when the variable x is assigned the object obtained by applying the intension designated by i to w. Note that from a mathematical point of view, an intension is just a relation between the sets W and D_O of a particular kind, namely what we usually call the graph of a function, and given such a relation together with an element of W, predicate abstraction is the only built-in machinery in the logic that allows us to perform the mathematical operation we usually call applying a function to an argument, thereby obtaining an element of D_O. Incidentally, in [68] a result is proved according to which a formula in the language of the basic first-order modal logic (see Subsection 2.1) is valid in the basic constant domain semantics (see Subsection 2.2) if and only if the formula is valid in a variant of the intensional semantics given above where all variables designate intensions and all predicates (including the equality predicate) are intensional. The point here is that in such an intensional logic there is no machinery to apply intensions to worlds, that is, there is no machinery that can detect that arguments to predicates have a paarticular inner structure, thus, from a mathematical point of view it does not matter whether the intensional semantics or the basic constant domain semantics is chosen (although the choice of semantics may be of philosophical or metaphysical significance, as pointed out in [68]).

Note that the intensional quantifiers in the semantics above range over elements of the set D_I which is an arbitrary non-empty subset of the set of all functions from W to D_O. An alternative semantics can be obtained by letting D_I be the set of all functions from W to D_O. Contrary to the original semantics, this alternative semantics validates the formula $\Box\exists x P(x) \rightarrow \exists i \Box P(i)$ (note that the 1-place predicate symbol P is objectual, so $P(i)$ is an abbreviation for $(\lambda x P(x))(i)$). Roughly, this formula says that if an object is associated with each accessible world, then there exists an intension which maps each accessible world to the object associated with it. A criticism often raised against this property of being able to make an intension out of any association of objects with worlds is that the choices of objects in such an intension need not in any sense be coherent, contrary to what is intuitively expected. In general, logics along the lines of the alternative logic are unaxiomatisable (although it should be mentioned that no proof is available of unaxiomatisability of the alternative logic described here). See [68] and [49] for proofs of unaxiomatisability of other such logics.

It can be remarked that predicate abstraction plays a role in the modal version of Herbrand's theorem given in the paper [37]. The logic under consideration there is essentially the increasing domain logic of Subsection 2.4 extended with non-rigid constant and function symbols as well as predicate abstraction. The role of predicate abstraction is to enable appropriate Skolemisation of formulas involving modal operators, for example, the formula $\Box\exists x P(x)$ is in the terminology of first-order intensional logic Skolemised as $\Box(\lambda x P(x))(i)$ (abbreviated $\Box P(i)$). In the case of ordinary first-order logic, Herbrand's theorem gives rise to a semi-decision procedure by a reduction to the search for a tautology in a countably infinite set of propositional formulas. A similar result can be proved in the modal case, see [37] and also [38]. We shall come back to predicate abstraction in Subsection 3.3.

3.2 Equality and intensions

Equality in first-order modal logic has given rise to a heated philosophical debate. This debate was initiated by a series of papers where W.V.O. Quine criticised quantified modal logic, see for example [101]. See also Chapter 21 in the present handbook for an account of Quine's criticism. Central in the debate initiated by Quine's papers is the issue of substitution of equals for equals in modal contexts. This is not the place to enter into a detailed philosophical discussion of the problem involved in substitution of equals for equals, so we only give a brief sketch of the problem, and we also only give a brief sketch of how a solution to the problem can be given using intensional variables. See the book [41] for a detailed account of the discussion. Now, consider the statement

> If the morning star is identical to the evening star, then it is necessary that the morning star is identical to the evening star.

which is a modal version of Frege's famous puzzle. This statement is naturally taken to be false (the morning star is the same celestial body as the evening star but this is a contingent fact). How can this statement be formalised in the basic first-order modal logic given in the previous section? An obvious candidate is the formula $x = y \to \Box(x = y)$ where the variables x and y respectively stand for the terms "the morning star" and "the evening star". But this does not work since this formula is valid (whether we take the basic varying domain semantics or the basic constant domain semantics).

Given that the equality predicate is objectual, the diagnosis of the problem is that the variables x and y designate rigidly whereas the terms "the morning star" and "the evening star" designate non-rigidly. Therefore the solution to the problem is to replace the object variables x and y by intension variables i and j since intension variables designate non-rigidly. The resulting formula $i = j \to \Box(i = j)$ is not valid, as i and j designating the same object at a world w does not imply that i and j designate the same object in any world accessible from w. Thus, the significant difference is that object variables designate rigidly whereas intension variables designate non-rigidly.

The fact that the formula $i = j \to \Box(i = j)$ is not valid shows that we cannot substitute equals for equals in modal contexts as far as intension variables are concerned. In fact, the failure of substitution of equals for equals in modal contexts is often taken as a criteria for identifying intensional terms. However, note that the formula is valid if objectual equality is replaced by intensional equality, also called *synonymy*, which takes two intensions to be equal if and only if they have the same graph.

To sum up, the formula $x = y \to \Box(x = y)$ is valid as it is, but it is invalid if the rigidly designating object variables x and y are replaced by the non-rigidly designating intension variables i and j. Thereby a solution can be given to the problem of formalizing the modal version of Frege's puzzle. Another solution is to keep the language as it is, but instead generalise the models for the basic first-order modal logic to encompass so-called counterpart relations. This also makes the formula invalid. The history of counterpart relations goes back to the papers [79] and [80] by David Lewis. After the publication of these papers, a number of generalised versions of Lewis' counterpart semantics have been introduced, one example being the semantics given in the paper [72]. See the discussion in the paper [40] where first-order intensional logic is compared to Lewis' counterpart semantics as well as to a variation of the semantics given in [72]. Another formalization of Lewis's counterpart semantics is the semantics considered in Section 11 of Part II of this chapter.

3.3 Predicate abstraction

The motivation for predicate abstraction is closely related to the *de re/de dicto* distinction described in Subsection 2.9. The history of predicate abstraction goes back to the papers [122] and [126]. See also the paper [35]. See [41] for a recent treatment of predicate abstraction. Many natural language sentences are ambiguous as they can be given two distinct readings, a *de re* reading and a *de dicto* reading. Predicate abstraction can be used to distinguish formally between such readings. Consider for example the sentence

> The number of planets is necessarily greater than five.

which is taken from Quine's paper [101]. On one reading, this sentence says that

> it is necessary that the number of planets is greater than five.

This is the *de dicto* reading since it says something about a proposition, namely the proposition that the number of planets is greater than five. It says about this proposition that it is necessary. However, on another reading, the sentence says that

> the number designated by the term "the number of planets" is necessarily greater than five.

This is the *de re* reading since it says something about a thing, namely a number. It says about this number that it is necessarily greater than five. Note that the *de re* reading of Quine's example sentence is naturally taken to be true (since there are nine planets and the number nine is necessarily greater than five) whereas the *de dicto* reading is naturally taken to be false (since there might have been five planets or fewer if natural history had been different). The point here is that the term "the number of planets" designates non-rigidly.

In what follows, the intension variable i stands for "the number of planets" and the objectual 1-place predicate symbol P stands for the predicate "is greater than five". (The term "the number of planets" is actually a so-called definite description. We ignore this additional structure since it is not of significance for the discussion here, but we remark that the term alternatively could have been formalised by a definite description operator, see [41].) The formula $\Box P(i)$ (which is an abbreviation for $\Box(\lambda x P(x))(i)$ since P is objectual) then formalises the *de dicto* reading of Quine's sentence since this formula expresses that

> it is necessary that the thing designated by i is P.

That is, it says something about the proposition that the thing designated by i is P, namely that this proposition is necessary. Formally, $\Box P(i)$ is true at a world w if and only if for each world v accessible from w, the designation of i at v belongs to the extension of the predicate P at v. Thus, in the *de dicto* case the predicate P and its argument, the variable i, are interpreted at the same world, namely the new world v. How about the *de re* reading of Quine's sentence? We want a formula which expresses that

> the thing designated by i is necessarily P.

That is, we want a formula which says something about the thing that i designates, namely that it is necessarily P. So, formally we want the variable i to be interpreted

at the original world w, not at the new world v where the predicate P is interpreted. It is straightforward that the formula $(\lambda x \Box P(x))(i)$ does the job since it is true at the world w exactly under the condition we want, namely under the condition that the designation of i at the world w belongs to the extension of the predicate P at each world v accessible from w. We have used predicate abstraction to indicate that the variable i has to be interpreted at w, not v (note that this is a formally significant difference exactly because we allow non-rigid designation, that is, the interpretations of i at the worlds w and v might not be the same). Thus, predicate abstraction enables us to separate the interpretation of a predicate from the interpretation of its arguments.

3.4 Translation of first-order intensional logic

In Subsection 2.10 it was shown that the basic constant domain logic can be translated into two-sorted first-order logic. In a similar way first-order intensional logic can be translated into three-sorted first-order logic with equality. There is one sort for worlds, one sort for objects, and one sort for intensions. It should be mentioned that the material presented in this subsection has not been presented elsewhere.

The three-sorted first-order language under consideration here is defined as follows. It is assumed that countably infinite sets of first-order variables for respectively worlds, objects, and intensions are given. The three sets are assumed to be pairwise disjoint. As in Subsection 2.10, the metavariables a, b, c, ... range over variables for worlds, and x, y, z, ... range over variables for objects. The metavariables i, j, k, ... range over variables for intensions. There is only one function symbol, namely the 2-place function symbol ℓ which is of type objects and whose argument places are of types intensions and worlds respectively. Thus, a term for worlds is a variable, a term for intensions is a variable, and a term for objects is either a variable or of the form $\ell(i,a)$ where i is a variable for intensions and a is a variable for worlds. Formulas of the three-sorted first-order language are defined by the grammar

$$S \ ::= \quad P^*(a,t_1,\ldots,t_n) \mid R(a,b) \mid t = u \mid i = j \mid S \wedge S \mid \neg S \mid \forall a S \mid \forall x S \mid \forall i S$$

where P is an n-place predicate symbol of first-order intensional logic and t_1, ..., t_n are terms of the respective types T_1, ..., T_n specified for P, a and b are variables for worlds, t and u are terms for objects, i and j are variables for intensions, and x is a variable for objects. As in Subsection 2.10, we identify first-order variables for objects with object variables of modal logic. Similarly, we identify first-order variables for intensions with intension variables of modal logic.

We now give the translation. The translation is obtained by modifying the constant domain version of ST_a given in Subsection 2.10 by replacing the clause for ordinary predicates by

$$ST_a(P(t_1,\ldots,t_n)) \quad = \quad P^*(a,t_1,\ldots,t_n)$$

and by adding the clauses

$$\begin{aligned} ST_a(\forall i \phi) \quad &= \quad \forall i ST_a(\phi) \\ ST_a((\lambda x \phi)(i)) \quad &= \quad ST_a(\phi)[\ell(i,a)/x] \end{aligned}$$

for intensional quantification and predicate abstraction. The translation ST_b is modified in the same way.

In Subsection 2.10 we had a bijective correspondence between models for first-order modal logic and models for two-sorted first-order logic. We do not have a bijective correspondence between models for first-order intensional logic and models for three-sorted first-order logic in general, but we do have a bijective correspondence if a very natural class of models for three-sorted first-order logic is considered instead of the class of all such models. Below we shall make this more precise.

DEFINITION 15. Let $\mathfrak{M} = \langle W, R, D_O, D_I, \{V_w\}_{w \in W}\rangle$ be a constant domain intensional model. A three-sorted first-order model $\mathfrak{M}^* = \langle W, D_O, D_I, V^*\rangle$ is defined by letting

- $V^*(R) = R$,
- $(w, d_1, \ldots, d_n) \in V^*(P^*)$ if and only if $(d_1, \ldots, d_n) \in V_w(P)$, and
- $V^*(\ell)(f, w) = f(w)$.

Thus, the construction of a three-sorted first-order model is straightforward: We use the recipe from Definition 11, and besides that, we take the domain of intensions D_I as it is and we interpret the function symbol ℓ as the application function. Clearly, the map $(\cdot)^*$ is injective.

DEFINITION 16. Let $\mathfrak{M} = \langle W, D_O, D_I, V\rangle$ be a three-sorted first-order model which satisfies the condition that $\mathfrak{M} \models \forall i \forall j(\forall a(\ell(i,a) = \ell(j,a)) \rightarrow i = j)$. A function σ from D_I to the set of functions from W to D_O is defined by letting $\sigma(d)(w) = V(\ell)(d, w)$ (note that σ is injective and therefore has an inverse σ^{-1} on the image $\sigma(D_I)$ of D_I under σ). A constant domain intensional model $\mathfrak{M}^\sharp = \langle W, R^\sharp, D_O, D_I^\sharp, \{V_w^\sharp\}_{w \in W}\rangle$ is defined by letting

- $R^\sharp = V(R)$,
- $D_I^\sharp = \sigma(D_I)$, and
- $(d_1, \ldots, d_n) \in V_w^\sharp(P)$ if and only if $(w, d_1', \ldots, d_n') \in V(P^*)$.

where in the last item $d_i' = d_i$ if $T_i = O$ and $d_i' = \sigma^{-1}(d_i)$ if $T_i = I$ (recall that $T_1, \ldots, T_n$ are the types specified for P). Moreover, given an assignment g for $\mathfrak{M}$, an assignment $g^\sharp$ for $\mathfrak{M}^\sharp$ is defined by letting $g^\sharp(x) = g(x)$ for any object variable x and by letting $g^\sharp(i) = \sigma(g(i))$ for any intension variable i (note that the values of the assignment g on world variables are ignored).

So the construction of a constant domain intensional model is also straightforward: We define $R^\sharp$ in the obvious way and we take the domain of intensions $D_I^\sharp$ to contain any function f from worlds to objects that is "encoded" by some element d of D_I in the sense that f is identical to the function that maps a world w to $V(\ell)(d, w)$. Moreover, we use the bijection σ to move forwards and backwards between D_I and $D_I^\sharp$. The condition $\mathfrak{M} \models \forall i \forall j(\forall a(\ell(i,a) = \ell(j,a)) \rightarrow i = j)$ ensures that different elements of D_I encode different functions from worlds to objects, so the code of an encoded function is uniquely determined. Also, note that $D_I^\sharp$ is non-empty since D_I is non-empty. The map $(\cdot)^\sharp$ is not injective since there is no restriction on the way in which an element of D_I encodes a function from worlds to objects, in particular, an element of D_I need not be identical to the function from worlds to objects that it encodes. However, if D_I is a set of functions

from W to D_O and each such function encodes itself, that is, $V(\ell)$ is the application function, then $(\cdot)^\sharp$ clearly is injective.

The mapping $\mathfrak{M}^*$ of any constant domain intensional model $\mathfrak{M}$ satisfies the condition of Definition 16, and moreover, it is straightforward that $(\mathfrak{M}^*)^\sharp = \mathfrak{M}$. It follows that $((\mathfrak{M}^*)^\sharp)^* = \mathfrak{M}^*$. So if the map $(\cdot)^\sharp$ is restricted to the image of the class of all first-order intensional models under the map $(\cdot)^*$, which of course is the class of all models where D_I is a set of functions from W to D_O and $V(\ell)$ is the application function, then the maps $(\cdot)^*$ and $(\cdot)^\sharp$ are each others' inverses.

Now, given a model $\mathfrak{M}$ for three-sorted first-order logic, the relation $\mathfrak{M}, g \models \phi$ is defined by induction in the standard way, where g is an assignment for three-sorted first-order logic and ϕ is a three-sorted first-order formula. This leads to two propositions. The first concerns the map $(\cdot)^*$.

PROPOSITION 17. *Let $\mathfrak{M}$ be a constant domain intensional model. For any formula ϕ of first-order intensional logic and any assignment g for $\mathfrak{M}$, it is the case that $\mathfrak{M}, g, g^*(a) \models \phi$ if and only if $\mathfrak{M}^*, g^* \models ST_a(\phi)$ where g^* is any assignment extending g such that it assigns a world to each first-order variable for worlds (and the same for ST_b).*

Proof. Induction in the structure of ϕ. ❑

The second proposition concerns the map $(\cdot)^\sharp$.

PROPOSITION 18. *Let $\mathfrak{M}$ be a three-sorted first-order model having the property that $\mathfrak{M} \models \forall i \forall j (\forall a(\ell(i,a) = \ell(j,a)) \to i = j)$. For any formula ϕ of first-order intensional logic and any assignment g for $\mathfrak{M}$, it is the case that $\mathfrak{M}^\sharp, g^\sharp, g(a) \models \phi$ if and only if $\mathfrak{M}, g \models ST_a(\phi)$ (and the same for ST_b).*

Proof. Induction in the structure of ϕ. ❑

We are now ready to prove that validity in first-order intensional logic can be simulated by validity in three-sorted first-order logic.

THEOREM 19. *Any formula ϕ of first-order intensional logic is valid if and only if the formula*

$$\forall i \forall j (\forall a(\ell(i,a) = \ell(j,a)) \to i = j) \to ST_a(\phi)$$

of three-sorted first-order logic is valid.

Proof. By Proposition 17 and Proposition 18. ❑

4 FIRST-ORDER HYBRID LOGIC

First-order hybrid logic is obtained by adding to first-order modal logic further expressive power in the form of a new sort of propositional symbol called a *nominal*, and moreover, by adding so-called *satisfaction operators*. It is stipulated that a nominal is true at exactly one world, so in this sense a nominal refers to a world. If a is a nominal and ϕ is an arbitrary formula, then a new formula $a : \phi$ called a *satisfaction statement* can be formed. The part $a :$ of the satisfaction statement $a : \phi$ is called a satisfaction operator. The satisfaction statement $a : \phi$ expresses that the formula ϕ is true at one particular world,

namely the world at which the nominal a is true. Furthermore, the so-called *binders* $\forall$ and $\downarrow$ might be added. The two binders bind nominals to worlds in two different ways: The binder $\downarrow$ binds a nominal to the actual world whereas the binder $\forall$ quantifies over worlds (but it is not to be confused with the first-order quantifier $\forall$ that has been used earlier in the chapter). The $\downarrow$ binder is definable in terms of $\forall$. Here we shall concentrate on the $\downarrow$ binder.

The history of hybrid logic goes back to Prior's work, more precisely, it goes back to what he called four grades of tense-logical involvement. They were presented in the book [100], Chapter XI (also Chapter XI in the new edition [62]). See also [99] Chapter V.6 and Appendix B.3–4. The stages progress from what can be regarded as pure first-order earlier-later logic to what can be regarded as pure tense logic; the goal being to be able to consider the tense logic of the fourth stage as encompassing the earlier-later logic of the first stage. In other words, the goal was to be able to translate the first-order logic of the earlier-later relation into tense logic. With this in mind, Prior introduced so-called instant-propositions:

> What I shall call the third grade of tense-logical involvement consists in treating the instant-variables a, b, c, etc. as also representing propositions. ([100], p. 122–123)

In the context of modal logic, Prior called such propositions possible-world-propositions. Of course, this is what we here call nominals. Prior also introduced the binder $\forall$ and what we here call satisfaction operators. See the paper [92] and the handbook chapter [93] for accounts of Prior's work. Moreover, see the very recent paper [10] as well as the book [21].

It is notable that hybridisation of propositional as well as first-order modal logics enables the formulation of uniform proof-rules for wide classes of logics. See the papers [9] and [12] for tableau systems and see the papers [16] and [17] for natural deduction systems. The classes of logics considered in [17] correspond to first-order conditions on the accessibility relations and quantifier domains expressed by so-called *geometric theories*. Natural deduction systems corresponding to different geometric theories are obtained in a uniform way simply by adding inference rules as appropriate. It is also notable that first-order hybrid logic offers precisely the features needed to prove interpolation theorems: While interpolation fails in a number of well-known first-order modal logics, see [32], their hybridised counterparts have this property, see the papers [3] and [13]. See Chapter 14 of the present handbook for a detailed introduction to hybrid logic.

4.1 Syntax and semantics of first-order hybrid logic

We now extend the formal syntax and semantics of first-order modal logic with hybrid machinery. We hybridise the varying domain basic logic given in Section 2.6 since proof procedures are available for this logic, namely the tableau and natural deduction systems of respectively [12] and [17] mentioned above. Moreover, an axiom system is available which we shall cover in Section 4.2.

First the syntax. It is assumed that a countably infinite set of nominals is given. The metavariables a, b, c, ... range over nominals. Note that nominals are the only sort of propositional symbols, since ordinary propositional symbols are represented by 0-place predicate symbols. We also add satisfaction operators and the binder $\downarrow$ as mentioned

above. We furthermore assume that a set of non-rigid constant symbols is given, and we follow [12] in overloading the notation for the satisfaction operator by defining a term to be either a first-order variable or an expression of the form $a : f$ where a is a nominal and f is a non-rigid constant symbol. Of course, the term $a : f$ denotes the value of f at the world where a is true. Such terms are called *grounded definite descriptions*. The formulas of first-order hybrid logic are defined by the grammar

$$S \ ::= \quad P(t_1, \ldots, t_n) \mid t = u \mid a \mid S \wedge S \mid \neg S \mid \Box S \mid a : S \mid \forall x S \mid \ \downarrow a S$$

where P is an n-place predicate symbol, $t_1, \ldots, t_n$ as well as t and u are terms, a is a nominal, and x is an ordinary first-order variable. The free nominal occurrences in the formula $a : \phi$ is the occurrence of a together with the free nominal occurrences in ϕ. The free nominal occurrences in $\downarrow a\phi$ are the free nominal occurrences in ϕ, except for occurrences of a. Substitution of nominals for nominals is defined accordingly. Substitution of terms for first-order variables is modified to take into account that terms might contain nominals (that can be bound). Now the semantics.

DEFINITION 20. A *varying domain hybrid model* is a varying domain model as defined in Definition 7, that is, a tuple, $\langle W, R, D, \{\delta_w\}_{w\in W}, \{V_w\}_{w\in W}\rangle$, where for each w, the valuation V_w is extended such that to each non-rigid constant symbol it assigns an element of D.

Thus, hybridisation does not change the notion of a varying domain model except that interpretations of the non-rigid constants are added.

DEFINITION 21. Given a model $\mathfrak{M} = \langle W, R, D, \{\delta_w\}_{w\in W}, \{V_w\}_{w\in W}\rangle$, an assignment is a function that to each first-order variable assigns an element of D and to each nominal assigns an element of W. Given an assignment g, each term t is assigned an element $t^{\mathfrak{M},g}$ of D as follows: If t is of the form $a : f$, then $t^{\mathfrak{M},g} = V_{g(a)}(f)$, otherwise t is a variable, in which case $t^{\mathfrak{M},g} = g(t)$. The relation $\mathfrak{M}, g, w \models \phi$ is defined in the same way as in the basic varying domain case, that is, Definition 8, except that the clauses for predicates are replaced by

$$\begin{array}{rcl} \mathfrak{M}, g, w \models P(t_1, \ldots, t_n) & \text{iff} & (t_1^{\mathfrak{M},g}, \ldots, t_n^{\mathfrak{M},g}) \in V_w(P) \\ \mathfrak{M}, g, w \models t = u & \text{iff} & t^{\mathfrak{M},g} = u^{\mathfrak{M},g} \end{array}$$

and clauses

$$\begin{array}{rcl} \mathfrak{M}, g, w \models a & \text{iff} & w = g(a) \\ \mathfrak{M}, g, w \models a : \phi & \text{iff} & \mathfrak{M}, g, g(a) \models \phi \\ \mathfrak{M}, g, w \models \downarrow a\phi & \text{iff} & \mathfrak{M}, g', w \models \phi \text{ where } g' \stackrel{a}{\sim} g \text{ and } g'(a) = w \end{array}$$

for hybrid machinery are added. Also the definition of validity is the same as in the basic varying domain case.

Propositional hybrid logic has a number of notable features: We can express that a formula ϕ is true at a world a (by the formula $a : \phi$), that a world a is identical to a world c (by the formula $a : c$), and that a world a is R-related to a world c (by the formula $a : \Diamond c$). In the first-order case we can moreover express that an individual t exists at a world a (by the formula $a : E(t)$). These features are exactly what enable the formulation of uniform natural deduction rules for the class of first-order hybrid logics corresponding to conditions expressed by geometric theories, cf. the paper [17].

Grounded definite descriptions can be motivated by the fact that they give an alternative way to formalise the two distinct readings of Quine's example sentence considered in Subsection 3.3. Recall that the *de dicto* reading of the sentence in question was formalised as the formula $\Box(\lambda x P(x))(i)$ in first-order intensional logic whereas the *de re* reading was formalised as $(\lambda x \Box P(x))(i)$. If the non-rigid designator f is considered instead of the intension variable i, then the two readings can be formalised in first-order hybrid logic as respectively $\Box \downarrow a P(a : f)$ and $\downarrow a \Box P(a : f)$. This is no coincidence: If first-order intensional logic is extended with the hybrid-logical machinery of this section and non-rigid designators are replaced by intension variables, then predicate abstractions are eliminable since a formula $(\lambda x \phi)(i)$ is equivalent to $\downarrow a \phi[a : i/x]$ where the nominal a is new.

4.2 Axioms for first-order hybrid logic

In this subsection we give a Hilbert-style axiom system for first-order hybrid logic. The axioms of the system are all substitution-instances of tautologies of propositional logic together with all substitution-instances of the following axiom schemas

(: *Distributivity*)	$a : (\phi \to \psi) \leftrightarrow (a : \phi \to a : \psi)$
(*Falsum*)	$a : \bot \to \bot$
(*Scope*)	$a : b : \phi \leftrightarrow b : \phi$
(*Reflexivity 1*)	$a : a$
(*Reflexivity 2*)	$t = t$
(*Transfer*)	$a : (t = u) \to c : (t = u)$
(: *Introduction*)	$(a \wedge \phi) \to a : \phi$
(*Nominal*)	$a : c \to (a : q) = (c : q)$
(*Substitutivity*)	$(t = u \wedge \phi[t/x]) \to \phi[u/x]$
($\Box$ *Elimination*)	$(\Box\phi \wedge \Diamond e) \to e : \phi$
(*Free* $\forall$ *Elimination*)	$(\forall x \phi \wedge E(t)) \to \phi[t/x]$
($\downarrow$ *Elimination*)	$(\downarrow b \phi \wedge e) \to e : \phi[e/b]$

The rules of the system are the following

$$\frac{\phi \to \psi \qquad \phi}{\psi}\ (\textit{Modus Ponens}) \qquad\qquad \frac{\phi}{a : \phi}\ (:\ \textit{Necessitation})$$

$$\frac{a : \phi}{\phi}\ (\textit{Naming}) \qquad\qquad \frac{(\psi \wedge \Diamond c) \to c : \phi}{\psi \to \Box\phi}\ (\Box\ \textit{Introduction})$$

$$\frac{(\psi \wedge E(y)) \to \phi[y/x]}{\psi \to \forall x \phi}\ (\textit{Free}\ \forall\ \textit{Introduction}) \qquad\qquad \frac{(\psi \wedge c) \to c : \phi[c/b]}{\psi \to \downarrow b \phi}\ (\downarrow\ \textit{Introduction})$$

where the rule (*Naming*) is equipped with the side-condition that the nominal a does not occur in the formula ϕ, the rule (*Free* $\forall$ *Introduction*) is equipped with the side-condition that y does not occur free in $\forall x \phi$ or ψ, the rule ($\Box$ *Introduction*) is equipped with the side-condition that c does not occur free in ϕ or ψ, and the rule ($\downarrow$ *Introduction*) is equipped with the side-condition that c does not occur free in $\downarrow b \phi$ or ψ. The axiom system is sound and complete with respect to the semantics given in Subsection 4.1. A

completeness proof can be found in the paper [17]. The axiom system can be extended with rules corresponding to geometric theories, again see [17]. The system is an extension of an axiom system for propositional hybrid logic given in the paper [18] where also further references on axiom systems for hybrid logic can be found.

Note that the axiom (*Free* $\forall$ *Elimination*) and the rule (*Free* $\forall$ *Introduction*) above are the same as the axiom and the rule for quantifiers of Subsection 2.7. It is instructive to compare these rules to the axiom ($\Box$ *Elimination*) and the rule ($\Box$ *Introduction*) for the modal operator. As described in Subsection 2.7, the idea in the rule (*Free* $\forall$ *Introduction*) is that the guard formula $E(y)$ in the antecedent ensures that the antecedent is false in the case where the variable y refers to an individual outside the range of the quantifier. This is analogous to the idea in the rule ($\Box$ *Introduction*) for hybrid logic which is that the guard formula $\Diamond c$ in the antecedent ensures that the antecedent is false in the case where the nominal c refers a world that is not accessible. A similar remark applies in connection with the pair of rules (*Free* $\forall$ *Elimination*) and ($\Box$ *Elimination*). In fact, such analogies can be found in connection with all pairs of Elimination rules and all pairs of Introduction rules.

4.3 Translation of first-order hybrid logic

First-order hybrid logic can be translated into two-sorted first-order logic by an extension of the varying domain version of the translation of Subsection 2.10.

The two-sorted first-order language under consideration here is a straightforward modification of the varying domain version of the language of Subsection 2.10. A term for worlds is still a variable but now a term for individuals is either a variable or of the form $f(a)$ where f is a constant symbol of first-order hybrid logic. Formulas of the language are defined by the grammar

$$S \ ::= \quad P^*(a, t_1, \ldots, t_n) \mid R(a, b) \mid a = b \mid t = u \mid E(a, t) \mid S \wedge S \mid \neg S \mid \forall a S \mid \forall x S$$

where P is an n-place predicate symbol of first-order modal logic, a and b are variables for worlds, and $t_1, \ldots, t_n$ as well as t and u are terms for individuals. Note that the clause $a = b$ has been added. We shall identify first-order variables for worlds with nominals in the same way as we have identified first-order variables for individuals with first-order variables of modal logic.

A term t of first-order hybrid logic is translated by the translation ST defined as follows: If t is of the form $a : f$, then $ST(t) = f(a)$, otherwise t is a variable, in which case $ST(t) = t$. Note that the translation ST of terms is not relative to a variable for worlds. A formula is translated by a translation obtained by modifying the varying domain version of ST_a given in Subsection 2.10 by replacing the clauses for predicates by

$$\begin{array}{rcl} ST_a(P(t_1, \ldots, t_n)) & = & P^*(a, ST(t_1), \ldots, ST(t_n)) \\ ST_a(t = u) & = & ST(t) = ST(u) \end{array}$$

and by adding the clauses

$$\begin{array}{rcl} ST_a(c) & = & a = c \\ ST_a(c : \phi) & = & ST_a(\phi)[c/a] \\ ST_a(\downarrow c\phi) & = & ST_a(\phi)[a/c] \end{array}$$

The translation ST_b is modified in the same way. A similar translation can be found in the paper [3].

It is straightforward to adapt the varying domain version of Definition 11 to the hybrid-logical case by extending it to encompass non-rigid constant symbols, so we still have a bijective correspondence between models for first-order hybrid logic and models for the two-sorted first-order logic under consideration here. Moreover, the notions of assignments are the same. Given this, it is also straightforward to adapt the varying domain version of Proposition 12 to the hybrid-logical case.

It turns out that a fragment of two-sorted first-order logic can be translated back into first-order hybrid logic. This fragment is defined by the grammar

$$\begin{array}{rl} S \ ::= & P^*(a, t_1, \ldots, t_n) \mid R(a, c) \mid E(a, t) \mid a = c \mid t = u \mid S \wedge S \mid \neg S \mid \\ & \forall b(R(a, b) \to S) \mid \forall x(E(a, x) \to S) \end{array}$$

where the variables a and b are distinct. A term t of two-sorted first-order logic is translated back into first-order hybrid logic by the translation HT defined as follows: If t is of the form $f(a)$, then $HT(t) = a : f$, otherwise t is a variable, in which case $HT(t) = t$. So HT and the translation ST given above are simply inverses to each other. A formula is translated by the translation given below.

$$\begin{array}{rcl} HT(P^*(a, t_1, \ldots, t_n)) & = & a : P(HT(t_1), \ldots, HT(t_n)) \\ HT(R(a, c)) & = & a : \Diamond c \\ HT(E(a, t)) & = & a : E(HT(t)) \\ HT(a = c) & = & a : c \\ HT(t = u) & = & HT(t) = HT(u) \\ HT(\phi \wedge \psi) & = & HT(\phi) \wedge HT(\psi) \\ HT(\neg\phi) & = & \neg HT(\phi) \\ HT(\forall b(R(a, b) \to \phi)) & = & a : \Box \downarrow b HT(\phi) \\ HT(\forall x(E(a, x) \to \phi)) & = & a : \forall x HT(\phi) \end{array}$$

The propositional version of this translation was originally given in [2] where the associated fragment of ordinary one-sorted first-order logic is called the *bounded fragment*. In [2] a number of independent semantic characterisations of the bounded fragment are given. See also [3].

The translation HT is truth-preserving as is shown by the proposition below (where $\mathfrak{M}^*$ is the model for two sorted first-order logic defined in the hybrid-logical version of Definition 11).

PROPOSITION 22. *Let a varying domain hybrid model $\mathfrak{M}$ be given. For any formula ϕ of the two-sorted version of the bounded fragment and any assignment g for $\mathfrak{M}$, it is the case that $\mathfrak{M}^*, g \models \phi$ if and only if $\mathfrak{M}, g \models HT(\phi)$.*

Proof. Induction in the structure of ϕ. ❑

Thus, in the sense of the proposition above and the hybrid-logical version of Proposition 12, first-order hybrid logic has the same expressive power as the two-sorted version of the bounded fragment (note that for any formula ϕ of first-order hybrid logic, the formula $ST_a(\phi)$ is in this fragment).

5 OTHER SURVEY ARTICLES AND BOOKS

Below we point out a number of survey articles and books that contain material on first-order modal logic not covered by the present handbook chapter. First the survey articles.

- *Philosophical perspectives on quantification in tense and modal logic*, N.B. Cocchiarella [20], in *Handbook of Philosophical Logic.* Discusses a range of philosophical issues.

- *Basic modal logic*, M. Fitting [36], in *Handbook of Logic in Artificial Intelligence and Logic Programming.* Contains a condensed introduction to first-order modal logic including tableau systems.

- *Quantification in modal logic*, J.W. Garson [49], in *Handbook of Philosophical Logic.* An introduction to first-order modal logic that gives a good overview of the whole area. Contains a detailed discussion of completeness and incompleteness.

- *Correspondence theory*, J. van Benthem [129], in *Handbook of Philosophical Logic.* Contains a section on correspondence theory for first-order modal logic.

Below is the list of books.

- *First-Order Modal Logic*, M. Fitting and R. Mendelsohn [41]. A detailed introduction to first-order modal logic that covers technical as well as philosophical issues. Includes tableau systems.

- *Temporal Logic: Mathematical Foundations and Computational Aspects (Volume 1)*, D. Gabbay and I. Hodkinson and M. Reynolds [43]. Contains a chapter on first-order temporal logic.

- *Quantification in Nonclassical Logic*, D. Gabbay and V. Shehtman and D. Skvortsov [44]. A detailed mathematical treatment of first-order modal logic and other first-order non-classical logics.

- *Modal Logics and Philosophy*, R. Girle [58]. Gives an introduction to first-order modal logic from a philosophical point of view.

- *The Logics of Time and Computation*, R. Goldblatt [59]. Has some material on first-order dynamic logic.

- *Dynamic Logic*, D. Harel, D. Kozen, and J. Tiuryn [61]. Gives a detailed introduction to first-order dynamic logic.

- *A New Introduction to Modal Logic*, G.E. Hughes and M.J. Cresswell [68]. Contains an introduction to first-order modal logic that covers a broad range of topics. Compares intensions and counterparts. A follow-up to the books [67] and [66] by the same authors.

- *Modal Logic and Classical Logic*, J. van Benthem [127]. Contains a chapter on first-order modal logic which includes translational issues.

6 INTRODUCTION TO PART II

In this second part of the chapter, we first deal with more specific topics concerning *decision, completeness and axiomatizability* issues. We shall see in Section 7 that the extension to modal languages of a number of well-known decidability results for fragments of classical logic is hopeless; however, less naive extensions (limiting the kind of subformulas occurring within the scope of modal operators) still keep decidability over classical fragments. This is a remarkable fact, because the expressivity of such combined fragments is indeed quite rich, thanks to the contribution of the modal operators.

Completeness analysis of normal systems over **QS4** will reveal in Section 8 the intrinsic limits of Kripke semantics; in addition, rather natural classes of frames will turn out to be non-axiomatizable. However, unlike undecidability and non-axiomatizability results, incompleteness results cannot properly be seen as negative results: on the contrary, they seem to indicate that modal logic cannot be reduced to possible worlds semantics and that extra motivations for it can be found elsewhere, in alternative (non-Kripkean) semantics.

Such *alternative semantics* will be investigated in the remaining sections, using the hyperdoctrinal point of view as a unifying tool. Modalities arising from geometric morphisms of toposes will be studied in Subsection 10.1 and in Subsection 10.2 we shall exploit the isomorphism between counterpart frames and preordered topological bundles in order to find the relevant hints for the axiomatization of counterpart semantics. The axiomatization of counterpart semantics is presented in Section 11 (this section is independent from the rest of the chapter, the reader can have *direct access* to it after reading only Subsection 9.1).

We summarize here basic syntactic and semantic ingredients, just to fix notation (for more information, consult Section 2 in the First Part of this chapter). We fix a first-order language $\mathcal{L}$ (without identity, functions and constant symbols, for simplicity)[1] containing infinitely many predicate symbols for each arity $n \geq 0$ (a special 0-ary predicate symbol $\perp$ denoting syntactic falsehood is included in $\mathcal{L}$). Formulas are built up using countably many variables, propositional implication $\rightarrow$, the quantifier $\forall$ and the modal connective $\Box$ (the other operators $\top, \wedge, \vee, \neg, \leftrightarrow, \exists, \Diamond$ are defined in the usual way). Notations like $\phi(x_1, \dots, x_n)$ (or, for short, $\phi(\underline{x})$) means that ϕ contain free variables only among the tuple of distinct variables $\underline{x} := x_1, \dots, x_n$.

A *first-order modal system* **S** is a set of formulas closed under necessitation, modus ponens, universal generalization and uniform substitution rules (for the definition of uniform substitution in the predicate case, consult Subsection 2.3 of Part I); since we deal only with normal extensions of **QK**, we assume also that **S** contains, in addition to all classically valid formulas, also the formulas **K**, namely the formulas of the kind $\Box(\phi \rightarrow \psi) \rightarrow (\Box\phi \rightarrow \Box\psi)$. If **L** is a propositional modal logic (i.e., a set of propositional formulas closed under modus ponens, necessitation, uniform substitution and containing all classical tautologies and the formulas **K**), we denote by **QL** the minimum first-order modal system containing **L**; by **BF**.**L** we mean the minimum first order modal system containing both **L** and **BF**, where **BF** is the Barcan schema $\forall y \Box\phi \rightarrow \Box\forall y\phi$ of Subsection 2.9.

We briefly review Kripke semantics (with increasing and with constant domains). A Kripke *frame* $\mathfrak{F} = (W, R)$ is a graph, that is a set W endowed with a binary relation R. A

[1]Languages containing identity, functions and constant symbols will be considered only from Section 9 on.

Kripke $\mathfrak{F}$-domain (or simply a Kripke domain) D based on the Kripke frame $\mathfrak{F} = (W, R)$ is a collection of (non empty) sets $D = \{D_w \mid w \in W\}$ such that $D_v \subseteq D_w$ holds whenever vRw (i.e., whenever w is 'accessible' from v). The Kripke domain D is *constant* iff we have $D_v = D_w$ for all $v, w \in W$; for a constant Kripke domain D, the indexes $v, w, \ldots$ in $D_v, D_w, \ldots$ are usually suppressed. A Kripke *skeleton* is a pair $(\mathfrak{F}, D)$ (written also as (W, R, D)), where $\mathfrak{F} = (W, R)$ is a frame and D is a Kripke $\mathfrak{F}$-domain.

A *Kripke model* $\mathfrak{M} = (\mathfrak{F}, D, \mathcal{I})$ is a triple given by a Kripke frame $\mathfrak{F} = (W, R)$, a Kripke $\mathfrak{F}$-domain D and an *interpretation* (or valuation) function $\mathcal{I}$ mapping every n-ary predicate symbol P to a collection of subsets $\mathcal{I}(P) = \{\mathcal{I}(P)_w \subseteq D_w^n \mid w \in W\}$. For $n = 0$, by D^0 we mean a singleton Kripke $\mathfrak{F}$-domain (that is, D_w^0 contains just the empty tuple of elements from D_w); we assume that in a Kripke model, $\mathcal{I}(\bot)$ is always the collection of the empty subsets $\{\emptyset \subseteq D_w^0 \mid w \in W\}$. The Kripke model $\mathfrak{M} = (\mathfrak{F}, D, \mathcal{I})$ is said to be a *constant domain model* iff D is constant as a Kripke domain.

Given a Kripke model $\mathfrak{M} = (\mathfrak{F}, D, \mathcal{I})$, a world $w \in W$, a w-assignment g (that is a map from the set of variables to D_w) and a formula ϕ, the forcing relation $\mathfrak{M}, g, w \models \phi$ (written from now on as $g \models_w^{\mathfrak{M}} \phi$) is defined as in in Part I, Subsection 2.4. We say that ϕ is valid in $\mathfrak{M}, w$ (written $\models_w^{\mathfrak{M}} \phi$) iff $g \models_w^{\mathfrak{M}} \phi$ holds for all g and we say that ϕ is valid in $\mathfrak{M}$ (written $\models^{\mathfrak{M}} \phi$) iff $\models_w^{\mathfrak{M}} \phi$ holds for all w. We also use the notation $\models_w^{\mathfrak{M}} \phi(a_1, \ldots, a_n)$ to mean $g \models_w^{\mathfrak{M}} \phi(x_1, \ldots, x_n)$, where g is any assignment such that $g(x_1) = a_1, \ldots, g(x_n) = a_n$.

A formula ϕ is *valid in a Kripke skeleton* $(\mathfrak{F}, D)$ iff it is valid in any Kripke model of the kind $\mathfrak{M} = (\mathfrak{F}, D, \mathcal{I})$. For instance, for a given $(\mathfrak{F}, D)$, we have that **BF** is valid in $(\mathfrak{F}, D)$ iff D is constant as a Kripke domain. A modal system **S** is valid in $(\mathfrak{F}, D)$ iff all $\phi \in$ **S** are valid in $(\mathfrak{F}, D)$. The set of formulas valid in a Kripke skeleton $(\mathfrak{F}, D)$ is actually a modal system that is denoted $\mathbf{S}(\mathfrak{F}, D)$. We finally recall from Part I that **QK** (resp. **BF**.**K**) coincides with the set of formulas which are valid in all Kripke skeletons (resp. in all constant domain Kripke skeletons).

7 DECISION PROBLEMS

Although classical first-order logic is known to be undecidable, there are interesting fragments which are actually decidable: among them, we have the fragment containing only monadic predicate symbols [81], the fragment with two individual variables [107], [88], [109], the guarded and the packed guarded fragments [1], [60], [86]. The border between decidability and undecidability is, however, quite subtle: three variables and binary predicate letters are sufficient, for instance, to cross the border and consequently to get an undecidable fragment [124] (a great deal of information on the subject can be found in the monograph [15] and in [29]).

As the notion of 'one-more dimension' is implicit in modal formalisms, there is no surprise in the fact that full modal extensions of classically decidable fragments are usually no longer decidable. We first give an account of such negative results, but in the second part of this section we also investigate remarkable positive results coming from recent literature.

Recall that we already fixed a modal language $\mathcal{L}$ containing infinitely many predicate symbols of any arity, but no identity nor function or constant symbols. A *fragment* of $\mathcal{L}$ is a set F of $\mathcal{L}$-formulas; for instance, the *classical fragment* $\mathcal{L}_C$ of $\mathcal{L}$ consists of the $\Box$-free $\mathcal{L}$-formulas. If a modal system **S** and a fragment F are given, by the F-fragment

of $\mathbf{S}$ we mean the set $\mathbf{S} \cap F$ of formulas which belong to both $\mathbf{S}$ and F. Notice that this definition leaves aside interesting questions concerning the axiomatizability of $\mathbf{S} \cap F$ in terms of axiom schemata and inference rules operating only on formulas belonging to F.

A Kripke skeleton (W, R, D) is said to be *countably large* iff (i) D is constant and countable; (ii) for some $w \in W$, the set of possible worlds $R(w) := \{v \mid wRv\}$ is infinite.

The first fragment we consider is the *monadic fragment* F_m formed by the formulas of $\mathcal{L}$ containing only unary predicate symbols. The following negative result is due to Kripke [73]:

THEOREM 23. *Let $\Sigma \subseteq F_m$ be a set of sentences such that:*

(i) Σ *contains all formulas ψ such that $\psi \in F_m$ and ψ is a substitution instance of a classically valid formula of $\mathcal{L}_C$;*

(ii) $\Sigma \subseteq \mathbf{S}(W, R, D)$ *for a countably large Kripke skeleton* (W, R, D).

Then Σ is undecidable.

Proof. A formula $\psi \in \mathcal{L}_C$ is said to be dyadic iff it contains only the binary relation symbol S. Classically valid dyadic formulas form an undecidable class, so our strategy consists of reducing the decision problem for classically valid dyadic formulas to the decision problem for Σ. For dyadic ψ, let ψ^t be the formula obtained from ψ by replacing the atomic subformulas $S(x, y)$ by $\Diamond(P(x) \wedge Q(y))$, where P, Q are distinct unary predicate letters (clearly $\psi^t \in F_m$). We show that a dyadic sentence ϕ is classically valid iff $\phi^t \in \Sigma$. One direction is just by the assumption (i); for the other side, suppose that ϕ is not classically valid. By standard model theory, there is a countable classical first-order structure $\mathcal{S} = (D, I)$ such that $\mathcal{S} \not\models \phi$ (here D is the countable domain of $\mathcal{S}$ and I is the related interpretation function). Let $w \in W$ be such that $R(w)$ is infinite and let $\rho : R(w) \longrightarrow D$ be any surjection. We define a Kripke model $\mathfrak{M} = (W, R, D, \mathcal{I})$ in the following way: for $v \notin R(w)$, we let $\mathcal{I}(P)_v := \mathcal{I}(Q)_v := \emptyset$ and for $v \in R(w)$, we let $\mathcal{I}(P)_v := \{\rho(v)\}$ and $\mathcal{I}_v(Q) = \{b \in D \mid \mathcal{S} \models S(\rho(v), b)\}$. Now it is sufficient to show by induction that for every dyadic formula $\psi(\underline{x})$ and $\underline{a} \in D$, we have $\models_w^{\mathfrak{M}} \psi^t(\underline{a})$ iff $\mathcal{S} \models \psi(\underline{a})$ (in particular, ϕ^t fails in $\mathfrak{M}$ and hence cannot belong to Σ by assumption (ii)). The proof is easy: for the atomic formulas case, we have $\models_w^{\mathfrak{M}} \Diamond(P(a_1) \wedge Q(a_2))$ iff there is $v \in R(w)$ s.t. $\models_v^{\mathfrak{M}} P(a_1) \wedge Q(a_2)$ iff there is $v \in R(w)$ s.t. $\rho(v) = a_1$ & $\mathcal{S} \models S(\rho(v), a_2)$ iff there is $v \in R(w)$ s.t. $\rho(v) = a_1$ & $\mathcal{S} \models S(a_1, a_2)$ iff (ρ being surjective) $\mathcal{S} \models S(a_1, a_2)$. ❑

In particular, Theorem 23 means that any subsystem of **QS5** has an undecidable monadic fragment. The second fragment we consider is the *two-variable fragment* F_2: this is formed by the formulas of $\mathcal{L}$ containing at most two (bound or free) variables. The following negative result was obtained quite recently [71] (it generalizes previous results in [46] for systems with the Barcan formula):

THEOREM 24. *Let $\Sigma \subseteq F_2$ be a set of sentences such that*

$$\mathbf{QK} \cap F_2 \ \subseteq \ \Sigma \ \subseteq \ \mathbf{S}(W, R, D),$$

for a countably large Kripke skeleton (W, R, D). Then Σ is undecidable.

Proof. We sketch the argument of [71], which uses a reduction of an undecidable tiling problem [8]. The problem is the following: we are given a finite set T, whose members

$t = \langle u(t), d(t), r(t), l(t)\rangle$ are 4-tuple of 'colours', and we are asked about the existence of a $\mathbb{N} \times \mathbb{N}$-tiling function, i.e., of a function $\tau : \mathbb{N} \times \mathbb{N} \longrightarrow T$ such that for all $i, j \in \mathbb{N}$ we have:

$$u(\tau(i,j)) = d(\tau(i,j+1)) \quad \text{and} \quad r(\tau(i,j) = l(\tau(i+1,j)).$$

Given a finite T, let χ_T be the F_2-sentence obtained as a conjunction of (1)-(8) below:

$$\begin{array}{lr}
\forall x \bigvee_{t\in T}(P_t(x) \wedge \bigwedge_{t'\neq t} \neg P_{t'}(x)), & (1)\\
\forall x\, \forall y\, (succ_H(x,y) \to \bigwedge_{r(t)\neq l(t')} \neg(P_t(x) \wedge P_{t'}(y))), & (2)\\
\forall x\, \forall y\, (succ_V(x,y) \to \bigwedge_{u(t)\neq d(t')} \neg(P_t(x) \wedge P_{t'}(y))), & (3)\\
\forall x\, \exists y\, succ_H(x,y) \wedge \forall x\, \exists y\, succ_V(x,y), & (4)\\
\forall x\, \forall y\, (succ_H(x,y) \to \Box succ_H(x,y)) \;\wedge\; \forall x\, \forall y\, (succ_V(x,y) \to \Box succ_V(x,y)), & (5)\\
\forall x\, \forall y\, (\Diamond succ_V(x,y) \to succ_V(x,y)), & (6)\\
\forall x\, \Diamond Q(x), & (7)\\
\Box \forall x\, \forall y\, [succ_V(x,y) \wedge \exists x(Q(x) \wedge succ_H(y,x)) \to & \\
\qquad \forall y(succ_H(x,y) \to \forall x(Q(x) \to succ_V(y,x)))]. & (8)
\end{array}$$

We show that there is a tiling function $\tau : \mathbb{N} \times \mathbb{N} \longrightarrow T$ if and only if $\neg\chi_T \notin \Sigma$.

Suppose in fact that there is such a tiling τ; let $w \in W$ be a world such that $R(w)$ is infinite and let $\rho : R(w) \longrightarrow \mathbb{N} \times \mathbb{N}$ be any surjective function. Since D is countable, we can identify it with $\mathbb{N} \times \mathbb{N}$ and define a Kripke model $\mathfrak{M} = (W, R, D, \mathcal{I})$ as follows:

- $\mathcal{I}(Q)_v = \{\rho(v)\}$ if $v \in R(w)$ and $\mathcal{I}(Q)_v = \emptyset$ if $v \notin R(w)$;
- $\mathcal{I}(P_t)_v = \{\langle i,j\rangle \mid \tau(i,j) = t\}$;
- $\mathcal{I}(succ_H)_v = \{\langle (i_1,j),(i_2,j)\rangle \mid i_2 = i_1 + 1\}$ and $\mathcal{I}(succ_V)_v = \{\langle (i,j_1),(i,j_2)\rangle \mid j_2 = j_1 + 1\}$.

Since it is easy to check that $\models_w^{\mathfrak{M}} \chi_T$, we have that $\neg\chi_T \notin \mathbf{S}(W,R,D)$, i.e., $\neg\chi_T \notin \Sigma$.

Conversely, suppose that $\neg\chi_T \notin \Sigma$: this means that $\neg\chi_T \notin \mathbf{QK}$, i.e., that χ_T is satisfiable in a world v of a certain Kripke model $\mathfrak{M}$. Now the conjunction of the two-variable formulas (4)-(8) is easily seen to imply in $\mathbf{QK}$ the (three-variable) formula

$$(9) \quad \forall x\, \forall y\, \forall z\, [succ_H(x,y) \wedge succ_V(x,z) \to \exists x\, (succ_H(z,x) \wedge succ_V(y,x))].$$

Thus (9) is also true at v in the model $\mathfrak{M}$. The truth of (9) and of (4) implies that for every $i, j \in \mathbb{N}$ there are individuals a_{ij} living in v, such that $\models_v^{\mathfrak{M}} succ_H(a_{ij}, a_{i+1,j})$ and $\models_v^{\mathfrak{M}} succ_V(a_{ij}, a_{i,j+1})$. From the fact that formulas (1)-(3) hold in v, it is easily seen that the function defined by

$$\tau(i,j) = t \quad \text{iff} \quad \models_v^{\mathfrak{M}} P_t(a_{ij})$$

tiles $\mathbb{N} \times \mathbb{N}$. ❑

Since one-variable fragments of standard quantified modal systems are usually decidable [110], one may suspect that the source of undecidability is the application of modal operators to formulas with two free variables. A modal formula ϕ is said to be *monodic* iff all subformulas of ϕ whose main connective is $\Box$ contain at most one free variable. Roughly speaking, we shall prove that the decision problem for validity in the fragment

F_{mon} formed by the monodic formulas can be reduced to the decision problem for validity in the classical fragment $\mathcal{L}_C$; the proof of such a result will entail that validity in fragments like $F_m \cap F_{mon}$, $F_2 \cap F_{mon}$ is decidable. More generally, classically decidable well-behaved fragments do not loose decidability if they are extended to the modal monodic fragment (for a recent precise formulation of this fact in a general combination context, see [57]).

For simplicity, we restrict our attention to the monodic fragment over **BF**.**QK**, that is we deal with the problem of deciding whether a monodic formula is valid in all Kripke models with constant domains. It should be noticed that there are various unnecessary restrictions in this approach: (a) results can be extended to models with increasing domains and to standard systems based on $\mathbf{T}, \mathbf{S4}, \mathbf{K4}, \ldots$ (instead of $\mathbf{K}$); (b) the addition of rigid designator constants is harmless; (c) more complicated modal operators (like reflexive-transitive closures in **PDL**-style, binary temporal operators like 'since' and 'until' for some standard temporal flows semantics) can be considered, without affecting the results to be illustrated in this subsection. In some cases (like (a)-(b)), rather trivial modifications in the proofs below are required, in some other cases (like those in (c)) the extension is not straightforward at all, however the method is basically the same. The interested reader is referred to [47] for an almost complete picture of the existing results.

Let us fix for the remaining part of this subsection a monodic sentence ϕ. Let $sub(\phi)$ be the set of the subformulas of ϕ together with their negations: this set is finite, provided we 'define' $\neg\neg\psi$ to be ψ. By $sub_z(\phi)$ (where z is a variable not occurring in ϕ) we mean $\{\psi(z/x) \mid \psi(x) \in sub(\phi)$, for some variable $x\}$.[2]

For any subformula $\Box\chi$ of ϕ containing at most one free variable, let $P_{\Box\chi}$ be a predicate symbol not occurring in ϕ: the arity of $P_{\Box\chi}$ is 1 if χ contains a free variable, it is 0 (i.e., $P_{\Box\chi}$ is a propositional letter) otherwise. $P_{\Box\chi}$ is called the *surrogate* of $\Box\chi$. For any subformula ψ of ϕ, let $\overline{\psi}$ be the result of replacing the outermost subformulas of ψ whose main connective is $\Box$, by their surrogates. Clearly $\overline{\psi} \in \mathcal{L}_C$.

DEFINITION 25. A *1-type* t is any subset of $sub_z(\phi)$ such that $\{\overline{\psi} \mid \psi \in t\}$ is maximal consistent. A *world-candidate* for ϕ is any non empty set $\mathcal{T}$ of 1-types; a world-candidate is *realizable* iff the formula

$$(\alpha_{\mathcal{T}}) \qquad \bigwedge_{t\in\mathcal{T}} \exists z(\bigwedge_{\psi(z)\in t} \overline{\psi}(z)) \wedge \forall z(\bigvee_{t\in\mathcal{T}} \bigwedge_{\psi(x)\in t} \overline{\psi}(z))$$

is classically consistent.

Notice that all types belonging to the same realizable world candidate must contain the same sentences (i.e., the same subformulas of ϕ not containing free variables), by the maximality request on the definition of a 1-type. Any world w in a Kripke model $\mathfrak{M} = (\mathfrak{F}, D, \mathcal{I})$ gives rise to a realizable world-candidate, by taking the set of 1-types that are realized in it (where t is said to be realized in w iff there is $a \in D$ such that $\models_w^{\mathfrak{M}} \bigwedge_{\psi(z)\in t} \psi(a)$).

DEFINITION 26. Let $\mathfrak{F} = (W, R)$ be a Kripke frame. A *domain-candidate* is a function δ associating with every $w \in W$ a realizable world-candidate δ_w. A *run* in a domain-candidate δ, is a map r associating with every $w \in W$ a 1-type $r(w) \in \delta_w$, satisfying the

[2]Recall that we use the notation $\psi(x)$ to express the fact that in ψ *at most* the variable x is free (thus the notation $\psi(x)$ does not prevent ψ from being a sentence).

following condition for every $\Box\psi \in sub_z(\phi)$:

$$\Box\psi \in r(w) \quad \text{iff} \quad \forall v\,(wRv \;\Rightarrow\; \psi \in r(v)).$$

Finally, a *quasi-model* is a domain-candidate δ such that for every $w \in W$ and $t \in \delta_w$ there is a run r such that $r(w) = t$.

We say that ϕ is satisfied in a quasi-model (W, R, δ) iff for some $w \in W$ and $t \in \delta_w$, we have that $\phi \in t$. This notion turns out to coincide with standard satisfiability in Kripke models:

PROPOSITION 27. *ϕ is satisfied in a constant domain Kripke model $\mathfrak{M} = (W, R, D, \mathcal{I})$ iff it is satisfied in a quasi-model (W, R, δ), based on the same Kripke frame (W, R).*

Proof. One direction is trivial: if ϕ is satisfied in $\mathfrak{M} = (W, R, D, \mathcal{I})$, then it is satisfied in the quasi-model (W, R, δ), where δ_w is the function associating with $w \in W$ the set of 1-types that are realized in w.

Conversely, suppose that ϕ is satisfied in (W, R, δ). For every $w \in W$, let $\mathcal{S}_w$ be a classical first-order structure which is a model of the formula $(\alpha_{\delta(w)})$ from Definition 25; by standard classical model theory (since we are considering languages without identity), we can raise the cardinality of the support of $\mathcal{S}_w$ to any chosen infinite cardinal. Better, we may freely suppose that the support of all the $\mathcal{S}_w$ is constantly equal to $D := \kappa \times \mathcal{R}$, where $\mathcal{R}$ is the set of all runs in (W, R, δ) and κ is any infinite cardinal bigger than the cardinality of $\mathcal{R}$. Notice that any $a \in D$ is in this way a pair (a^r, a^c), where a^r is a run in (W, R, δ) and $a^c < \kappa$. Also, we can raise in $\mathcal{S}_w$ the cardinality of the set of elements satisfying each 1-type of δ_w to κ and freely suppose that, for $a \in D$, we have

(1) $\quad \mathcal{S}_w \models \overline{\psi}(a) \quad \text{iff} \quad \psi(z) \in a^r(w)$

for all $\psi(z) \in sub_z(\phi)$.

Now we can define the desired Kripke model $\mathfrak{M} = (W, R, D, \mathcal{I})$, by taking, for every n-ary predicate letter, $\mathcal{I}_w(P) := \{(a_1, \ldots, a_n) \mid \mathcal{S}_w \models P(a_1, \ldots, a_n)\}$. It is now sufficient to show, by induction, that for every subformula $\psi(x_1, \ldots, x_n)$ of ϕ and for every $a_1, \ldots, a_n \in D$, we have

(2) $\quad \models^{\mathfrak{M}}_w \psi(a_1, \ldots, a_n) \quad \text{iff} \quad \mathcal{S}_w \models \overline{\psi}(a_1, \ldots, a_n).$

We just show the $\Box$-case: since ϕ is monodic, we can suppose $n = 1$.[3] Hence we have:

$$\begin{aligned} &\mathcal{S}_w \models \overline{\Box\psi}(a_1) \;\Leftrightarrow\; \Box\psi(z) \in a_1^r(w) \Leftrightarrow \forall v(wRv \Rightarrow \psi(z) \in a_1^r(v)) \;\Leftrightarrow \\ \Leftrightarrow\;& \forall v(wRv \Rightarrow \mathcal{S}_v \models \overline{\psi}(a_1)) \;\Leftrightarrow \forall v(wRv \Rightarrow \models^{\mathfrak{M}}_v \psi(a_1)) \;\Leftrightarrow\; \models^{\mathfrak{M}}_w \Box\psi(a_1). \end{aligned}$$

(1) and (2) show, in particular, that ϕ is satisfiable in $\mathfrak{M}$, being satisfiable in (W, R, δ). ❑

The next step is to represent quasi-models satisfying ϕ as structures repeating a finite set of special patterns, called blocks. We denote by $\mathfrak{F}_n = (W_n, R_n)$ the finite Kripke frame given by $W_n := \{0, 1, \ldots, n\}$, $R_n := \{(0, i) \mid 1 \leq i \leq n\}$ (this is a finite rooted tree containing only the root 0 and the leaves $1, \ldots, n$).

[3]For $n = 0$, take an arbitrary $a_1 \in D$ (if ψ is a sentence, both relations $\models^{\mathfrak{M}}_w \psi(a_1)$ and $\mathcal{S}_w \models \overline{\psi}(a_1)$ are not influenced by the choice of a_1).

DEFINITION 28. Let $(\mathfrak{F}_n, \delta)$ be a domain candidate based on $\mathfrak{F}_n$. A *root-pseudo-run* in it is a map r associating with every $w \in W_n$ a 1-type $r(w)$ satisfying the following condition for every $\Box\psi \in sub_z(\phi)$:

$$\Box\psi \in r(0) \quad \text{iff} \quad \forall v \in W_n \ (0Rv \Rightarrow \psi \in r(v)).$$

We say that $(\mathfrak{F}_n, \delta)$ is a *block* iff for every $w \in W_n$ and $t \in \delta_w$ there is a root-pseudo-run r such that $r(w) = t$.

Again, we say that ϕ is satisfied in a block (W_n, R_n, δ) iff for some $w \in W_n$ and $t \in \delta_w$, we have that $\phi \in t$.

DEFINITION 29. A set $\mathcal{B}$ of blocks is a *satisfying set* for ϕ iff $\mathcal{B}$ contains a satisfying block for ϕ and moreover for every world w in a block $(\mathfrak{F}_n, \delta)$ belonging to $\mathcal{B}$, there is a block $(\mathfrak{F}_{n'}, \delta')$, again in $\mathcal{B}$, such that $\delta(w) = \delta'(0)$.

THEOREM 30. *ϕ is satisfiable in a Kripke model (with constant domains) iff there a satisfying set for ϕ whose blocks contain at most $2k \cdot 2^k$ worlds, where k is the cardinality of $sub_z(\phi)$.*

Proof. If there is a satisfying set for ϕ, it is not difficult to 'glue' together the various blocks in it, thus forming a satisfying quasi-model for ϕ based on an intransitive tree:[4] then Proposition 27 applies.

Conversely, if ϕ is satisfied in a Kripke model with constant domains, then (by standard modal techniques, like unravelling, or directly by the subordination frame technique of [67]) ϕ is satisfied in a model based on an intransitive tree $\mathfrak{F} = (W, R)$. By Proposition 27, ϕ is satisfied in a quasi-model $(\mathfrak{F}, \delta)$ based on $\mathfrak{F}$. By 'duplicating' some worlds, if needed, we can also suppose that if wRv holds in $\mathfrak{F}$, then there is a 'twin' of v, namely a world $v' \neq v$ such that wRv' and $\delta_v = \delta_{v'}$. We now extract from $(\mathfrak{F}, \delta)$ a satisfying set for ϕ: this is done by associating with any $w \in W$ a suitable block, matching the required cardinality conditions. For every 1-type $t \in \delta_w$ and for every $\Box\psi \in sub_z(\phi)$ with $\Box\psi \notin t$, select twin worlds v_1, v_2 such that wRv_1, wRv_2 and a 1-type $t' \in \delta_{v_1} = \delta_{v_2}$ such that: (i) $\psi \notin t'$ and (ii) for all $\Box\chi \in sub_z(\phi)$, if $\Box\chi \in t$, then $\chi \in t'$ (this is possible for instance by considering any run r in $(\mathfrak{F}, \delta)$ such that $r(w) = t$ and by taking $v_1 := v$, $v_2 :=$ a twin of v_1 and $t' := r(v)$, where v is any world such that wRv and $\psi \notin r(v)$, see the definition of a run in a quasi-model).

Consider now the subframe $\mathfrak{F}_w = (W_w, R)$ of $\mathfrak{F}$ formed by w and by the worlds so selected: as $\mathfrak{F}$ is an intransitive tree, this is isomorphic to a frame of the kind $\mathfrak{F}_n$ for $n \leq 2k \cdot 2^k$. If we show that this subframe $\mathfrak{F}_w$ is a block $\mathcal{B}_w$ (with respect to the restriction of δ), the theorem is proved (the required satisfying set for ϕ is formed by the various blocks $\mathcal{B}_w$, varying $w \in W$). Take a type $t \in \delta_v$ for a possible world v in $\mathcal{B}_w = (W_w, R, \delta)$; let r be a run in $(\mathfrak{F}, \delta)$ such that $r(v) = t$. Consider now the 1-type $r(w)$: by the above construction of W_w, for each $\Box\psi \in sub_z(\phi)$ with $\Box\psi \notin r(w)$, there is a possible world $v_\psi \in W_w$ with wRv_ψ and a 1-type $t_\psi \in \delta_{v_\psi}$ such that: (i) $\psi \notin t_\psi$ and (ii) for all $\Box\chi \in sub_z(\phi)$, if $\Box\chi \in r(w)$, then $\chi \in t_\psi$. As in fact there are such twin v_ψs to choose between, we can assume that $v_\psi \neq v$ for every ψ. Define now the root-pseudo-run s by letting $s(u) := t_\psi$ if $u = v_\psi$ for some ψ, $s(u) := r(u)$, otherwise. Since v is not among the v_ψ's, this implies $s(v) = r(v) = t$, as required. ❑

[4]A Kripke frame (W, R) is said to be an intransitive tree iff there is a world $w_0 \in W$ such that for every $v \in W$, there is exactly one path $w_0 R w_1 R \cdots R w_n = v$ ($n \geq 0$) from w_0 to v.

COROLLARY 31. *Let $F \subseteq F_{mon}$ be a subfragment of the monodic fragment; suppose that for a sentence $\phi \in F$ there is an algorithm that decides whether a world-candidate for ϕ is realizable or not. Then the set of sentences in $F \cap$ **BF.K** is decidable.*

Thus, in particular, $F_m \cap F_{mon} \cap$ **BF.K** and $F_2 \cap F_{mon} \cap$ **BF.K** are decidable, because for $\phi \in F_m \cap F_{mon}$ (resp. $\phi \in F_2 \cap F_{mon}$), the formulas of the kind $(\alpha_{\mathcal{T}})$ are still in $F_m \cap F_{mon}$ (resp. in $F_2 \cap F_{mon}$). Corollary 31 applies also to the monodic guarded fragment (see [47]). It should be noticed that, although the monodic fragment of **BF.K** has the finite frame property [130] (i.e., a monodic satisfiable formula can be satisfied in a Kripke model based on a finite frame), the same does not apply e.g. to **BF.S4**: for this system it is impossible to extract a finite transitive model from the construction of Theorem 30, because e.g. the formula (3) from Section 8 requires infinitely many worlds to be falsified. Notice also that, for more sophisticated systems, most (although not all) of the proofs of the incompleteness results of next section apply already to the one-variable fragment.

8 COMPLETENESS, INCOMPLETENESS AND NON-AXIOMATIZABILITY

A first-order modal system **S** is complete with respect to a class $\mathcal{K}$ of Kripke skeletons iff **S** is valid in every Kripke skeleton belonging to $\mathcal{K}$ and, moreover, every formula $\phi \notin$ **S** fails in a Kripke model $\mathfrak{M} = (\mathfrak{F}, D, \mathcal{I})$ such that $(\mathfrak{F}, D)$ belongs to $\mathcal{K}$. **S** is said to be *K(ripke)-complete* iff it is complete with respect to some class $\mathcal{K}$ of Kripke skeletons.

Basic quantified systems like **QK**, **QT**, **QK4**, **QS4**, **QS5**, etc., as well as their variants with the Barcan formula, are all Kripke complete (see [25], [68] or Chapter 2 of this Handbook). However, despite the simplicity of the definition of a K-complete modal system, we shall show that K-completeness (contrary to the propositional case) is not as frequent as one might expect.

We first mention a couple of examples of K-complete systems, whose completeness proofs are not immediate (and which were open problems till the late eighties). Recall that **S4** is obtained from **K** by adding it the axiom schemata $\Box\phi \to \phi$, $\Box\phi \to \Box\Box\phi$; from the semantic side, **S4** is valid and complete with respect to Kripke frames $(W, \leq)$ in which the accessibility relation $\leq$ is a *preorder*, i.e., it is reflexive and transitive (when the letter $\leq$ is used for the accessibility relation of a frame, it is implicitly assumed that such an accessibility relation is a preorder). Recall also that **S4.2** is the extension of **S4** axiomatized by the schema $\Diamond\Box\phi \to \Box\Diamond\phi$ and that **S4.3** is the extension of **S4** axiomatized by the schema $\Box(\Box\phi \to \psi) \vee \Box(\Box\psi \to \phi)$.[5]

THEOREM 32. *The systems* **QS4.2** *and* **QS4.3** *are both K-complete.*

In the case of **QS4.2** the completeness proof is obtained in [24] by adapting the subordination frame technique from [67], whereas in the case of **QS4.3**, one needs more sophisticated methods, like Fine's diagrams [22] (but see also [118]). However, the following theorem seems to suggest that K-incompleteness is the rule for many systems extending **QS4**:

THEOREM 33. [52] *Let* $\mathbf{L} \supseteq$ **S4** *be a propositional logic such that* $\mathbf{L} \not\supseteq$ **S5** *and such that* **QL** *is K-complete. Then* $\mathbf{L} \subseteq$ **S4.3** *and, if* $\mathbf{L} \neq$ **S4.3**, *then* **L** *is an unbounded width logic*

[5] See Chapter 7 for more information about the propositional systems we mention here.

(that is, for every n, there is a rooted frame[6] *for* **L** *containing n mutually incomparable states).*

The proof of Theorem 33 requires some powerful alternative semantics, like presheaf semantics (over an arbitrary category). The latter is analyzed in more detail in the topos-theoretic context of Subsection 10.1, here we use a simple formulation in terms of functional frames. Following [128], we call *functional frame* a pair $(W, \mathcal{R})$, where W is a family $\{D_w \mid w \in W\}$ of individual domains and $\mathcal{R}$ is a family of maps between such domains. Since we want **S4**-axioms to be valid,[7] we ask for $\mathcal{R}$ to contain identities and to be closed under compositions. A functional frame $(W, \mathcal{R})$ becomes a *functional model* $\mathfrak{M} = (\mathfrak{F}, D, \mathcal{I})$ upon addition of an interpretation function $\mathcal{I}$, mapping n-ary predicates P to families of subsets $\mathcal{I}_w(P) \subseteq D_w^n$. Truth of a formula ϕ in the model $\mathfrak{M}$ at a world w under the w-assignment g (in symbols $g \models_w^{\mathfrak{M}} \phi$) is defined in the expected way:[8] for instance, $g \models_w^{\mathfrak{M}} \Box\phi$ holds iff $f \circ g \models_v^{\mathfrak{M}} \phi$ holds for all $f \in \mathcal{R}$ having domain D_w and codomain D_v. Thus functional models and frames differ from the corresponding Kripke models and frames because, given two possible worlds w and v, there are many different ways of making a transition from w to v: the difference with Kripke semantics is sensible, both from a philosophical and from a mathematical point of view.

For space reasons, we cannot report here the full proof of Theorem 33, however we can illustrate the method by sketching in some detail the proof a weaker (but still informative) result. The key idea is to use an indirect kind of reduction of functional frames to ordinary Kripke frames. Let us call *frame representation* $\mathfrak{F}(W, \mathcal{R})$ of a functional frame $(W, \mathcal{R})$ the frame having the $f \in \mathcal{R}$ as states and as accessibility relation the divisibility relation (namely $f_1 \leq f_2$ holds in $\mathfrak{F}(W, \mathcal{R})$ iff we have $f_2 = h \circ f_1$, for some domain and codomain matching function $h \in \mathcal{R}$).

LEMMA 34. *Let a functional frame $(W, \mathcal{R})$ be given; if $\mathfrak{F}(W, \mathcal{R}) \models \psi$ holds for some modal propositional formula ψ, then every predicate-logical substitution instance $\sigma(\psi)$ of ψ is valid in all the functional models based on $(W, \mathcal{R})$.*

Proof. We argue by contraposition: suppose that we have $g \not\models_w^{\mathfrak{M}} \sigma(\psi)$ for some w, g in a model $\mathfrak{M}$ based on $(W, \mathcal{R})$. Define a propositional valuation V on $\mathfrak{F}(W, \mathcal{R})$ by setting (for every propositional variable p) $V(p) := \{f : D_w \longrightarrow D_v \mid f \circ g \models_v^{\mathfrak{M}} \sigma(p)\}$. By induction, it is easy to see that, for all $f \in \mathcal{R}$ having domain D_w and for all propositional modal formula χ, we have that χ is true at f in the propositional Kripke model $(\mathfrak{F}(W, \mathcal{R}), V)$ iff $f \circ g \models_v^{\mathfrak{M}} \sigma(\chi)$ holds (here D_v is the codomain of f). In particular, we get that ψ fails at id_w in $(\mathfrak{F}(W, \mathcal{R}), V)$. ❑

Let $\mathbf{L} \supseteq \mathbf{S4}$ be a propositional logic such that $\mathbf{L} \not\supseteq \mathbf{S5}$ and such that **QL** is K-complete: *we shall prove that* $\mathbf{L} \subseteq \mathbf{S4.3.Grz}$ (equivalently, that every finite chain is a frame for **L**). Bearing this aim in mind, consider the following formula ϕ

(3) $\Box\forall x(P(x) \to \Box P(x)) \to \Diamond\forall x(\Diamond P(x) \to P(x))$.

Now, if $\mathbf{QL} \not\vdash \phi$, by the Kripke completeness for **QL**, it is clear that there exists a Kripke skeleton $(\mathfrak{F}, D)$ (based on a Kripke frame $\mathfrak{F}$ for **L**) containing a generated subframe

[6] A preordered set $(W, \leq)$ is rooted iff for some $\rho \in W$, we have $\rho \leq v$ for all v.

[7] This is a simplified analysis, in fact correspondence theory for functional frames still needs full investigation (for some subtleties arising here, see [128] again).

[8] In particular, quantification at w ranges over the domain D_w only.

that can be p-morphically mapped onto any finite linear chain,[9] which means that $\mathbf{L} \subseteq \mathbf{S4.3.Grz}$, as claimed. Thus, it is sufficient to show that $\mathbf{QL} \vdash \phi$ implies $\mathbf{L} \supseteq \mathbf{S5}$: here functional models comes into the picture.

Consider the following functional frame $(W, \mathcal{R})$: W contains just one world w, the unique individual domain is $D_w := \{1, 2\}$ and the functions in $\mathcal{R}$ are the identity function and the constant function with value 2. The formula ϕ is not valid in a functional model $\mathfrak{M}$ based on $(W, \mathcal{R})$ (take $\mathcal{I}_w(P) := \{2\}$); since we supposed $\mathbf{QL} \vdash \phi$ and functional models semantics is obviously valid, some predicate-logical substitution instance of an axiom of $\mathbf{L}$ fails in $\mathfrak{M}$. By Lemma 34, we must conclude that $\mathfrak{F}(W, \mathcal{R})$ is not a frame for $\mathbf{L}$. However, $\mathfrak{F}(W, \mathcal{R})$ is the two-element chain and consequently $\mathbf{L} \supseteq \mathbf{S5}$, as claimed.

The full statement of Theorem 33 is obtained by repeating again and again the above schema (find a formula that functional models prove to be independent through Lemma 34 and identify some necessary condition for it to be false in a Kripke skeleton). Additional incompleteness results can be found in [111]; we mention just one of them: the system axiomatized by adding to $\mathbf{QS4}$ the modal translation of the 'constant domain' superintuitionistic axiom schema $\forall y\, (\psi(y, \underline{x}) \vee \phi(\underline{x})) \to (\forall y\, \psi(y, \underline{x})) \vee \phi(\underline{x})$ is unable to prove the Barcan formula and hence it is not K-complete.

For constant domain semantics, a general completeness/incompleteness theorem is available, by combining the results from [125] and [113]:

THEOREM 35. *If* $\mathbf{L} \supseteq \mathbf{S4}$ *is a subframe logic, then* $\mathbf{BF.L}$ *is K-complete iff* $\mathbf{L}$ *has the finite embedding property.*[10]

However, it seems to be problematic to get positive results beyond the subframe logics case: the system $\mathbf{BF.S4.2}$ is not K-complete [111], [50] and $\mathbf{BF.S4.1}$ (namely $\mathbf{BF.S4}$ plus $\Box\Diamond\phi \to \Diamond\Box\phi$) is incomplete as well [68].

K-completeness can be re-gained by axiomatizing Kripke completions: the *Kripke completion* of a modal system $\mathbf{S}$ is the modal system $\mathbf{S_K}$ containing the formulas which are valid in all the Kripke skeletons in which $\mathbf{S}$ is valid. Some work has been done for the axiomatization of Kripke completions within the related field of Kripke semantics for *intermediate* predicate logics: for instance, an axiomatization of the intuitionistic first-order formulas which are valid in Kripke models based on posets not exceeding a preassigned bounded height is given in [131], where the insufficient propositional axioms are suitably strengthened. If one restricts to the intuitionistic first-order formulas which are valid in Kripke models based on a given *single finite poset*, then general reasons (which apply to any first-order axiomatizable class of Kripke skeletons) guarantee recursive enumerability, whereas nothing can be said about existence of a finite axiomatization: the latter exists for the constant domain case (where it can be shown that propositional axioms suffice [112]), but not always for the nested domain case, see [95], [115], [116], [117] for existing results on the subject.

The problem of axiomatizing an (even quite natural) given class of Kripke skeletons might be a tremendous task, as exemplified by the case of constant domain skeletons based on $(\mathbb{N}, \leq)$:[11]

[9]Starting from any world w falsifying ϕ, we can in fact find an infinite strictly ascending chain of worlds over w, thus p-morphisms from the w-upper cone onto finite linear chains easily obtain.

[10]See Chapter 7 for the definition of a subframe logic. $\mathbf{L}$ is said to have the finite embedding property iff every frame in which $\mathbf{L}$ is not valid contains a finite subframe in which $\mathbf{L}$ is not valid as well.

[11]Theorem 36 comes from unpublished work by D. Scott. Scott's method is outlined in [45] (here we give a similar, but simplified argument).

THEOREM 36. *The set of modal formulas which are valid in constant domain models based on the frame* $(\mathbb{N}, \leq)$ *is not arithmetical (hence, a fortiori, not recursively enumerable).*

Proof. We reduce true arithmetic to validity in constant domain models based on $(\mathbb{N}, \leq)$. For the purposes of this proof only, let us assume for simplicity that our language $\mathcal{L}$ contains equality, constant and function symbols[12] (these are treated rigidly in models, contrary to the extensions of predicates which are allowed to vary). Let $\mathcal{L}_R$ be the sublanguage of $\mathcal{L}$ containing equality, a constant $\overline{0}$, a unary function symbol s and binary function symbols $+, \cdot$; $\mathcal{L}_R$ can be used in order to introduce Robinson's arithmetic (see e.g. [90]): this is the first-order theory obtained from Peano's arithmetic by replacing the induction schema by the formula $\forall x(x = \overline{0} \vee \exists y(x = s(y)))$. Robinson arithmetic is a finitely axiomatized theory (let ρ be the conjunction of the related axioms), in which recursive functions and predicates are formally representable. In particular, for all $n, m \in \mathbb{N}$, we have (we use $\vdash$ for provability in classical logic):

$$n \neq m \quad \Rightarrow \quad \vdash \rho \to \overline{n} \neq \overline{m}; \tag{4}$$

$$\vdash \rho \to \overline{n} + \overline{m} = \overline{n+m}; \tag{5}$$

$$\vdash \rho \to \overline{n} \cdot \overline{m} = \overline{n \cdot m}. \tag{6}$$

Moreover, if we define $x \leq y$ as $\exists z(z + x = y)$, it is well-known (and easily proved by metatheoretical induction over m) that we have:

(7) $\vdash \rho \to \forall x\,(x \leq \overline{m} \leftrightarrow (x = \overline{0} \vee \cdots \vee x = \overline{m}))$.

Let N be a unary predicate (not in $\mathcal{L}_R$) and let τ be the conjunction of the following three formulas

$$\forall x \forall y(y \leq x \leftrightarrow \Box(N(x) \to N(y))), \quad \forall x \Box(N(x) \to \Box N(x)), \quad \forall x \Diamond N(x).$$

For every ($\Box$-free) sentence ϕ in $\mathcal{L}_R$, we show that ϕ is true in the standard model $\mathbb{N}$ of arithmetic iff $\rho \wedge \tau \wedge \phi$ is satisfiable in a constant domain model based on $(\mathbb{N}, \leq)$ (hence, $\neg\phi$ is a true arithmetical statement iff $\neg(\rho \wedge \tau \wedge \phi)$ is valid in our semantics). One direction is easy: if ϕ is a true arithmetical sentence, let us define $D := \mathbb{N}$ and $\mathcal{I}_n(N) := \{0, 1, \dots, n\}$ (obviously, $\mathcal{I}_n(\overline{0})$, $\mathcal{I}_n(s)$, $\mathcal{I}_n(+)$, $\mathcal{I}_n(\cdot)$ are number 0, successor, sum and product, respectively). For this $\mathfrak{M} = (\mathbb{N}, \leq, D, \mathcal{I})$, we clearly have that $\models_0^{\mathfrak{M}} \rho \wedge \tau \wedge \phi$.

Conversely, assume $\rho \wedge \tau \wedge \phi$ is satisfied in a constant domain model $\mathfrak{M} = (\mathbb{N}, \leq, D, \mathcal{I})$ (without loss of generality, we may suppose that $\models_0^{\mathfrak{M}} \rho \wedge \tau \wedge \phi$). Then $(D, \mathcal{I}_0)$ is a classical first-order structure which is a model of Robinson arithmetic. Because of that, the map associating $\mathcal{I}_0(\overline{n})$ with n is an injective homomorphism of the standard model $\mathbb{N}$ into $(D, \mathcal{I}_0)$ (see (4)-(6)). Thus, to show that ϕ is indeed a true arithmetical sentence, we only need to check that D does not contain non-standard elements, i.e., that for any $b \in D$ there is n such that $b = \mathcal{I}_0(\overline{n})$. Here we use the fact that $\models_0^{\mathfrak{M}} \tau$ holds. Notice first that, because of this, we have $D = \bigcup_{n \in \mathbb{N}} \mathcal{I}_n(N)$ and moreover $\mathcal{I}_n(N) \subseteq \mathcal{I}_m(N)$, whenever $n \leq m$. Also, $\models_0^{\mathfrak{M}} \tau$ forces, in the world 0, the relation $x \geq y$ to be $\Box(N(x) \to N(y))$

[12] This assumption makes the arguments below more transparent, but it is not essential: one can use $n+1$-ary predicate symbols instead of n-ary function symbols, select a binary predicate symbol $\approx$ in $\mathcal{L}$ and let it play the role of equality (this means that suitable rigidity, congruence and functionality axioms for the symbols of $\mathcal{L}_R$ w.r.t. $\approx$ are included in the conjuncts of the formula ρ below).

(that is, the relation $x \geq y$ holds iff x is added to the extension of the predicate N at the same time or after y is added).

Let now k_0 be the minimum $k_0 \in \mathbb{N}$ such that $\mathcal{I}_{k_0}(N)$ is not empty: from $c \in \mathcal{I}_{k_0}(N)$, we get that c is the $\leq$-smallest element in D, hence in particular $\models_0^{\mathfrak{M}} c \leq \overline{0}$, i.e., $c = \mathcal{I}_0(\overline{0})$ by (7). Then, let $k_1 > k_0$ be the minimum number such that $\mathcal{I}_{k_1}(N)$ is a proper superset of $\mathcal{I}_{k_0}(N)$: here just $\mathcal{I}_0(\overline{1})$ is the new element entering into $\mathcal{I}_{k_1}(N)$, because from $c \in \mathcal{I}_{k_1}(N)$, we get that c is $\leq$-smaller than every element of D different from $\mathcal{I}_0(\overline{0})$, hence in particular $\models_0^{\mathfrak{M}} c \leq \overline{1}$, i.e., $c = \mathcal{I}_0(\overline{0})$ or $c = \mathcal{I}_0(\overline{1})$, by (7) again. If we proceed in this way, we identify an infinite sequence of natural numbers $k_0 < k_1 < k_2 \cdots$ such that for all n

$$\mathcal{I}_{k_n}(N) = \mathcal{I}_{k_n+1}(N) = \cdots = \mathcal{I}_{k_{n+1}-1}(N) = \{\mathcal{I}_0(\overline{0}), \ldots, \mathcal{I}_0(\overline{n})\}.$$

Let now $b \in D$: from $\models_0^{\mathfrak{M}} \Diamond N(b)$, it follows that $b = \mathcal{I}_0(\overline{n})$, for some n. ❑

Theorem 36 is just an example of a non-axiomatizable natural class of Kripke models: for non-axiomatizability of Kripke models based on finite frames, see [5], [4], [26]. Further very strong results have been reached in [119], [120], where it is shown in particular that *for any infinite family Y of finite rooted posets*, the set of valid formulas in models based on members of Y (both with constant and with nested domains) is not recursively enumerable. For non recursive enumerability of valid formulas on every noetherian frame (both with increasing and constant domains), see [105], [106].

The reader might have the impression that incompleteness and non-axiomatizability arise only in rather specific situations and that common standard semantic classes are on the contrary nicely behaved. This is not the case: so far, we examined only unary monomodal systems, but if we drop such a restriction, negative results arise even more easily. The following sample illustrates what happens to quantified extensions of **PDL**-like propositional systems. Let us consider the bimodal language $\mathcal{L}^*$ obtained from $\mathcal{L}$ by adding it an extra box operator $\Box^*$. At the semantical level, we do not need to modify the definitions of a frame, of a skeleton and of a model we gave in Section 6 for monomodal systems over **QK**, we simply add the truth-clause

$$g \models_{w_0}^{\mathfrak{M}} \Box^* \phi \qquad \text{iff} \qquad \forall n \geq 0, \forall w_1, \ldots, w_n \; (\bigwedge_{i=0}^{n-1} w_i R w_{i+1} \;\Rightarrow\; g \models_{w_n}^{\mathfrak{M}} \phi),$$

saying that $\Box^*$ is interpreted by using the reflexive-transitive closure of R. Here not only the standard propositional axioms (those listed e.g. in Chapter 12) are insufficient, but once again incompleteness cannot be repaired:

THEOREM 37. *The set of $\mathcal{L}^*$-formulas which are valid in the above semantics (both with increasing and with constant domains) is not recursively enumerable.*

The proof of this theorem is obtained in [130] by reduction of the $\mathbb{N} \times \mathbb{N}$-recurrent tiling problem. Actually, Theorem 37 applies to the two-variable monadic fragment, but *not* to the monodic fragment. The latter is nicely axiomatizable: to this end, it is sufficient [47] to join a propositionally complete set of axiom schemata with the standard quantifier laws (proofs in the resulting system are restricted to formulas belonging to the monodic fragment).

9 TOWARDS MORE POWERFUL SEMANTICS

In this section, we begin our investigation of alternative semantics, starting from an appropriate algebraic framework, namely hyperdoctrines (traditional algebraic semantics [102] is inadequate because, contrary to the propositional case, it is not complete [94]). From hyperdoctrines, we derive the most powerful existing semantics for modal first-order logic, namely metaframes; we postpone to Section 10 the analysis of suitable mathematical frameworks giving rise to further very natural extended semantics. Finally, in Section 11, we analyze counterpart semantics.

9.1 Typed Languages and Systems

Types are commonly used in higher order formalisms, where they are needed to deal with constructors like exponentiation and powerset, see e.g. [76]. The reason why we introduce them in a first order framework is different. It is well-known that a first-order formula ϕ, once interpreted in a model $\mathfrak{M}$, defines a subset $[\![\phi]\!]^{\mathfrak{M}}$ of a suitable cartesian power of the domain (of the domains, in the many-sorted case). What exactly this cartesian power is, however, is not specifically indicated in the formula itself: if ϕ contains n free variables, then $[\![\phi]\!]^{\mathfrak{M}}$ can be seen as a subset of any m-th cartesian power of the domain, where $m \geq n$. Thus, varying m, $[\![x = 0]\!]^{\mathfrak{M}}$ may denote in analytic geometry a point, a straight line, a plane, and so forth: logicians usually argue that this confusion is harmless, because infinitary assignments (not finitary assignments) are commonly used in the inductive definition of truth of a formula in a model. There is however something artificial in this choice of leaving the 'dimension' unspecified: in fact, there is an implicit notion of dimension even in contexts which are far from mathematics (for instance, dimension seems to naturally arise in linguistics, in relation to indexicals [19], see also Section 11 below). Although ordinary untyped languages are more manageable from a proof-theoretic point of view, we shall adopt typed languages from now on, because using such languages it is *easier* to interpret first-order formulas in the extended semantics that have been proposed in the literature. Typed languages will also be *indispensable* for the counterpart semantics of Section 11. We formally introduce the notion of a typed formula (i.e., of a 'formula-with-dimension').

For simplicity, we shall give the definition of a typed language in the one-sorted case only: extensions to the many-sorted case [51] are important, but straightforward and will be left to the experienced reader. Given that only one sort is allowed, types (i.e., 'dimensions') are formal cartesian products of that unique sort and can hence be identified with natural numbers greater or equal to 0.

We suppose that a first-order *language* $\mathcal{L}$ is given, where a language is now a set of *functions* and of *predicate* symbols, both endowed with a specified arity. We assume that $\mathcal{L}$ always contains a 0-ary predicate symbol $\perp$ (the 'falsehood') and a 2-ary predicate symbol $=$ (the 'equality predicate').

Terms are built up in the customary way, using countably many variables $x_1, x_2, \ldots$. A term of type n (briefly an *n-term*) is a term t in which at most the variables $x_1, \ldots, x_n$ occur; we write $t : n$ to mean that t is an n-term. If $t : n$ is an n-term and if $v_1 : m, \ldots, v_n : m$ are m-terms, $t[v_1, \ldots, v_n] : m$ is the m-term resulting from t by replacing x_i by v_i ($i = 1, \ldots, n$).

DEFINITION 38. The notion of a formula of type n (briefly an *n-formula*) $\phi : n$ is so

defined:

(i) if P is a predicate symbol of arity k and if $t_1 : n, \ldots, t_k : n$ are n-terms, then $P(t_1, \ldots, t_k) : n$ is an (atomic) n-formula;

(ii if $\phi : n$ and $\psi : n$ are n-formulas, so is $(\phi \to \psi) : n$;

(iii) if $\phi : n{+}1$ is an $n{+}1$-formula, then $(\forall x_{n+1}\phi) : n$ is an n-formula;

(iv) if $\phi : n$ is an n-formula, then $(\Box\phi) : n$ is an n-formula.

Thus quantification is allowed only with respect to the maximum index variable (this limitation does not cause any loss of expressivity, only alphabetic variants are lost). The inductive definition of an n-formula in the $\Box$-case will be modified in Section 11 in order to make it suitable for counterpart semantics. The remaining logical operators (namely $\top, \wedge, \vee, \neg, \leftrightarrow, \exists, \Diamond$) are defined in the usual way. We formally introduce *substitutions*:

DEFINITION 39. If $\phi : n$ is an n-formula and if $\underline{v} : m$ is an n-tuple of m-terms, the m-formula $\phi[\underline{v}] : m$ is so defined, by induction on $\phi : n$:

(a) if $\phi : n$ is the atomic formula $P(t_1, \ldots, t_k) : n$, then $\phi[\underline{v}] : m$ is $P(t_1[\underline{v}], \ldots, t_k[\underline{v}]) : m$;

(b) if $\phi : n$ is $\psi_1 \to \psi_2 : n$, then $\phi[\underline{v}] : m$ is $(\psi_1[\underline{v}]) \to (\psi_2[\underline{v}]) : m$;

(c) if $\phi : n$ is $\forall x_{n+1}\psi : n$, then $\phi[\underline{v}] : m$ is $\forall x_{m+1}\ (\psi[\underline{v}, x_{m+1}]) : m$;

(d) if $\phi : n$ is $\Box\psi : n$, then $\phi[\underline{v}] : m$ is $\Box(\psi[\underline{v}]) : m$.

Thus bound variables are systematically renamed in substitutions (observe also that Definition 39(c) is correct, because if the $\underline{v}$'s are m-terms, then they are also $m+1$-terms).[13] The following compatibility condition between substitutions into terms and substitutions into formulas can be easily proved by induction:

$$(\phi[t_1, \ldots, t_k])[\underline{v}] : m \ = \ \phi[t_1[\underline{v}], \ldots, t_k[\underline{v}]] : m.$$

We can emphasize the fact that a given $n{+}1$-formula does not contain occurrences of a variable, say x_{n+1}, by writing it in the form $\phi[x_1, \ldots, x_n] : n{+}1$, for a suitable n-formula $\phi : n$. Notice also that in order to take the implication of $\phi : n$ and $\psi : n{+}1$, one must e.g. use $\phi[x_1, \ldots, x_n] \to \psi : n{+}1$ (the $n+1$-formula $\phi[x_1, \ldots, x_n] : n{+}1$ differs from the n-formula $\phi : n$ because the bound variables x_i, for $i > n$, are suitably renamed). In order to make notation easier, we shall also make the following convention: by $\underline{x}$ we indicate a list of variables like $x_1, \ldots, x_n$ (for some $n \geq 0$) and, whenever the notation $\underline{x}$ is used, y stands for x_{n+1}, whereas z_1, z_2 stand for x_{n+1}, x_{n+2}, etc.

We shall make use of modal systems formulated within typed languages; from now on, we shall also consider *only systems on a propositional* **S4** *basis*. The latter choice is due to simplicity and uniformity reasons: mathematical 'topological-like' semantics require **S4**-axioms to be valid and certain arguments would look unnatural and distorted if 'topological-like' conditions would systematically be weakened in the style of neighborhood semantics for propositional modal logic. On the other hand, we shall explicitly

[13]In order to make clearer the comparison with the Beck-Chevalley property below, notice that the right-most formula $\forall x_{m+1}\ (\psi[\underline{v}, x_{m+1}]) : m$ of Definition 39(c) can also be written as $\forall x_{m+1}(\psi[\underline{v}[x_1, \ldots, x_m], x_{m+1}]) : m$, because $\underline{v}[x_1, \ldots, x_m] = \underline{v}$.

alert the reader whenever the adaptation of the semantics we introduce to systems weaker than **S4** is non trivial or problematic.

The quantified (typed) deductive system **QS4** is explained in Table 1. The instantiation rule (*Inst*) can be avoided by closing under instantiation the axiom schemata ($\forall$-*Ex*), (*Refl*), (*Repl*) (that is, one may use e.g. the schema $\forall y\phi \to \phi[\underline{x}, t] : n$ instead of ($\forall$-*Ex*)), however we prefer to keep rule (*Inst*) in order to make next subsections proofs smoother.

If we need to consider modal first-order systems **S** stronger than **QS4**, we simply add to Table 1 a set of formulas Φ *closed under uniform substitution* as extra **S**-axioms.[14] In particular, if Φ is the set of first-order instances of the formulas provable in a propositional modal logic $\mathbf{L} \supseteq \mathbf{S4}$, we get the system **QL** (this is the typed version with equality of the system **QL** of Section 6).

Typed systems and untyped ordinary systems are *equivalent formalisms*: since untyped formulas have alphabetic variants that can be typed, we have syntactic translations in both directions which reduce to identity (up to provability) in case they are sequentially applied. This result is not difficult to prove (see [51] for the details); notice however that in order to get it, the extra single axiom $\exists x_1 \top : 0$ must be added to Table 1, in case the language does not contain any constant symbol (this is because the calculus of Table 1 is sound with respect to empty domain models and consequently it cannot prove any theorem of the kind $\exists x_1 \phi : 0$ if no constant is available).

Table 1.

Axiom Schemata

$\phi : n$ (*Taut*)

(provided ϕ is an instance of a propositional **S4**-valid formula)

$(\forall y\, \phi)[\underline{x}] \to \phi : n{+}1$ ($\forall$-*Ex*)

$x_1 = x_1 : 1$ (*Refl*)

$z_1 = z_2 \to (\phi[\underline{x}, z_1] \to \phi[\underline{x}, z_2]) : n{+}2$ (*Repl*)

Inference Rules

$$\frac{\psi : n \qquad \psi \to \phi : n}{\phi : n} \quad (MP)$$

$$\frac{\phi : n}{\Box\phi : n} \quad (Nec)$$

$$\frac{\phi[\underline{x}] \to \psi : n{+}1}{\phi \to \forall y\, \psi : n} \quad (\forall\text{-}In)$$

$$\frac{\phi : n}{\phi[\underline{t}] : k} \quad (Inst)$$

(where $\underline{t}$ is an n-tuple of k-terms).

[14] The definition of uniform substitution $\phi[\psi/P]$ from Subsection 2.3 of Part I can be easily adapted to typed languages.

9.2 Cartesian and Lex Categories

We shall use hyperdoctrines in order to introduce all the alternative semantics from a unitary point of view: this will greatly simplify proofs and will be useful to explain appropriately the main phenomena arising from the interplay of modalities, substitutions, quantifiers and equality. Since we do not assume from the reader previous knowledge about basic category-theoretic concepts, we shall briefly introduce them in this subsection (more examples and motivations can be found in textbooks like [83], [14]).

A *category* $\mathbf{T}$ consists of two classes T_0 and T_1, the class of the objects and the class of the arrows of $\mathbf{T}$, respectively. To each arrow $f \in T_1$, two objects $d(f)$ and $c(f)$ are assigned (we write $f \in Hom(Y, X)$ or $f : Y \longrightarrow X$ or $Y \xrightarrow{f} X$ to mean that $d(f) = Y$ and $c(f) = X$). Moreover for each object X an arrow id_X of domain and codomain X is given and finally to each pair of arrows g, f such that $c(g) = d(f)$ an arrow $f \circ g$ of domain $d(g)$ and codomain $c(f)$ is assigned, as schematized in the following picture:

$$(Z \xrightarrow{g} Y \xrightarrow{f} X) \qquad \longmapsto \qquad Z \xrightarrow{f \circ g} X.$$

The following associativity and unity requirements must be satisfied by the above data:

$$(f \circ g) \circ h \ = \ f \circ (g \circ h), \qquad id_X \circ f \ = \ f \ = \ f \circ id_Y$$

for $W \xrightarrow{h} Z \xrightarrow{g} Y \xrightarrow{f} X$. The typical example of a category is the category **Set** of sets and functions; notice however that also a single monoid is a category (in fact monoids can be identified with categories having just one object) and that a single preordered set is a category (preordered sets can be identified with categories in which, for given objects X, Y, there is at most one arrow $f \in Hom(Y, X)$).

Objects in a category are abstract entities, hence they 'do not have elements'; however we show how the formalism of elements can be re-gained, so that it is possible up to a certain extent to work in an arbitrary category $\mathbf{T}$ as if $\mathbf{T}$ were just **Set**. For given objects U, X of $\mathbf{T}$, an U*-element* of X is, by definition, an arrow $x : U \longrightarrow X$.[15] To emphasize that $x : U \longrightarrow X$ is a 'generalized element of X', we may write $x \in X$; for $f : X \longrightarrow Y$, the notation $f(x)$ may be used to indicate the U-element $x \circ f \in Y$.

The *product* of a pair of objects X, Y in $\mathbf{T}$ is a further object $X \times Y$ endowed with two arrows $\pi_X : X \times Y \longrightarrow X$ and $\pi_Y : X \times Y \longrightarrow Y$, such that for every pair of U-elements $x : U \longrightarrow X$, $y : U \longrightarrow Y$, there exists a unique U-element $\langle x, y\rangle : U \longrightarrow X \times Y$ such that $\pi_X(\langle x, y\rangle) = x$ and $\pi_Y(\langle x, y\rangle) = y$. Thus this definition is a way of saying that '$X \times Y$ is formed by the set of ordered pairs of elements from X and Y', like a honest set-theoretic cartesian product. Similarly, a *terminal object* $\mathbf{1}$ in $\mathbf{T}$ is any object having just one U-element (for every U). By a *cartesian* category, we mean a category with products of pairs of objects and a terminal object. In a cartesian category, by iteration, it is possible to define the product of $X_1 \times \cdots \times X_n$ of n objects $X_1, \ldots, X_n$. For $n = 0$, $X_1 \times \cdots \times X_n$ is the terminal object $\mathbf{1}$ and, whenever $X_1 = \cdots = X_n := X$, the product $X_1 \times \cdots \times X_n$ is noted as X^n and called the n-th cartesian power of X.

Given arrows $Y_1 \xrightarrow{f_1} X \xleftarrow{f_2} Y_2$, the pullback P of f_1, f_2 is 'formed by the pairs' of U-elements $y_1 \in Y_1, y_2 \in Y_2$ such that $f_1(y_1) = f_2(y_2)$. This means that we have a commutative square

[15] The technique of generalized elements is common folklore in the category-theoretic community; we nevertheless wish to thank A. Carboni for pointing out the opportunity of introducing it at a very early stage.

$$\begin{tikzcd} P \arrow[r, "p_1"] \arrow[d, "p_2"'] & Y_1 \arrow[d, "f_1"] \\ Y_2 \arrow[r, "f_2"'] & X \end{tikzcd}$$

such that, for all U-elements $y_1 \in Y_1, y_2 \in Y_2$, if $f_1(y_1) = f_2(y_2)$, then there is a unique $y : U \longrightarrow P$ such that $p_1(y) = y_1$ and $p_2(y) = y_2$. A *left exact* (or just lex) *category* is a category with pullbacks, terminal object and products (actually, requiring products turns out to be redundant).

As happens with all category-theoretic notions, products, terminal objects, pullbacks, etc. are uniquely determined only *up to isomorphism* (where an isomorphism among objects X, Y is a pair of arrows $f : X \longrightarrow Y, g : Y \longrightarrow X$ such that $f \circ g = id_Y$ and $g \circ f = id_X$).

An arrow $m : A \hookrightarrow X$ is mono iff 'it is injective', i.e., iff $f(a_1) = f(a_2)$ implies $a_1 = a_2$, for every pair of U-elements of A. If x is a U-element of X and $m : A \hookrightarrow X$ is mono, we say that $x \in_X A$ iff[16] there is $a : U \longrightarrow A$ such that $m(a) = x$. We can compare monos $A_1 \hookrightarrow X$, $A_2 \hookrightarrow X$ by defining a suitable 'inclusion': formally, $A_1 \leq A_2$ holds iff for every U, for every U-element $x \in X$ ($x \in_X A_1 \Rightarrow x \in_X A_2$). Moreover $A_1 \sim A_2$ holds iff we have both $A_1 \leq A_2$ and $A_2 \leq A_1$; a *subobject* of X is then defined as an equivalence class (under $\sim$) of monos of codomain X. The relation $\leq$ gives the set of subobjects of X a partial order structure $(Sub(X), \leq)$: in fact, reflexivity, transitivity and antisymmetry of $\leq$ are immediately checked through generalized elements.

It is easily seen that in a pullback diagram

$$\begin{tikzcd} f^{-1}(A) \arrow[r] \arrow[d, tail] & A \arrow[d, tail, "m"] \\ Y \arrow[r, "f"'] & X \end{tikzcd}$$

the left vertical arrow is mono in case the right vertical arrow is mono. Notice that $f^{-1}(A)$, as a subobject of Y, is precisely inverse image, in the sense that we have $\forall y \in Y(y \in_Y f^{-1}(A) \Leftrightarrow f(y) \in_X A)$. Relations like

$$A \leq B \Rightarrow f^{-1}(A) \leq f^{-1}(B), \qquad id_X^{-1}(A) = A \qquad (f \circ g)^{-1}(A) = g^{-1}(f^{-1}(A))$$

for $A, B \in Sub(X)$ and $Z \xrightarrow{g} Y \xrightarrow{f} X$ can be easily established by using U-elements again. Such relations say that, for a given category $\mathbf{T}$, the correspondence associating with X the partial order $(Sub(X), \leq)$ and with $f : Y \longrightarrow X$ the order-preserving map $f^{-1} : (Sub(Y), \leq) \longrightarrow (Sub(X), \leq)$ is in fact a contravariant functor (see below) from $\mathbf{T}$ to the category of partial orders and order-preserving maps. This functor is called the *subobject functor* and plays a central role in the categorical analysis of logic.

If $\mathbf{T}$ is lex, it is easily seen that the subobject functor takes values into the category of semilattices and related morphisms (the meet of $A_1 \hookrightarrow X$, $A_2 \hookrightarrow X$ is their pullback). For rich $\mathbf{T}$, subobjects have further structure: for instance, in **Set**, subobjects are Boolean

[16] It is customary, by abuse, to name a mono $m : A \hookrightarrow X$ by A instead of by m (often m is not even mentioned).

algebras, moreover not only inverse but also direct image of a subobject (=subset) along an arrow (=function) can be defined. Understanding these richer structures is the goal of categorical logic and can be achieved mainly in two ways. The first (even from a historical point of view) approach is perhaps more empirical, but more flexible: this is the *hyperdoctrinal* method which tries to abstractly axiomatize the desired properties of the pair (category $\mathbf{T}$, subobject functor). The second approach, the *logical categories* approach, is exemplified in the book [85] and tries to understand what conditions on $\mathbf{T}$ itself lead precisely the subobject functor (not just an abstract 'subobject-like' functor) to have the desired structure. The philosophical effect of the logical categories program, if accomplished, is that of *explaining all the logical constructors* in terms of properties of the notion of composition of two arrows in a category. In the sequel, we take the hyperdoctrinal point of view, but we report also the achievements [84] of the logical categories analysis of modal logic.

We conclude this section by giving the definition of a *functor* $F : \mathbf{T_1} \longrightarrow \mathbf{T_2}$ between categories $\mathbf{T_1}$ and $\mathbf{T_2}$: this is a correspondence associating with every object X in $\mathbf{T_1}$ an object $F(X)$ in $\mathbf{T_2}$ and with every arrow $f : Y \longrightarrow X$ in $\mathbf{T_1}$ an arrow $F(f) : F(Y) \longrightarrow F(X)$ in $\mathbf{T_2}$. Identity and composition should be preserved, in the sense that we must have:

$$F(id_X) = id_{F(X)}, \qquad F(f \circ g) = F(f) \circ F(g),$$

for $Z \xrightarrow{g} Y \xrightarrow{f} X$ in $\mathbf{T_1}$. The functor F is said to preserve products, terminal objects, pullbacks iff it sends a product, terminal object, pullback diagram to a product, terminal object, pullback diagram, respectively. A *cartesian functor* is a functor among cartesian categories preserving products and terminal object, whereas a *left exact* (or just lex) *functor* is a cartesian functor among lex categories preserving also pullbacks. Notice that, since an arrow m is mono iff the pullback of m with itself is the identity, a lex functor preserves monos (and also the partial order among subobjects). Finally, a contravariant functor from $\mathbf{T_1}$ to $\mathbf{T_2}$ is a functor $F : \mathbf{T_1} \longrightarrow \mathbf{T_2}^{op}$, where $\mathbf{T_2}^{op}$ (the opposite category of $\mathbf{T_2}$) is the category obtained from $\mathbf{T_2}$ by 'reversing arrow directions'.

9.3 Hyperdoctrines

Hyperdoctrines were introduced by F.W. Lawvere in [78]; they were adapted to the counterpart semantics of Section 11 in [55], [56] and to standard first-order non classical logics in [114]. Recall that *interior algebras* are the algebraic models of propositional **S4**: an interior algebra is a Boolean algebra $(B, \wedge, \vee, \top, \bot, \neg)$ endowed with an operator $\Box$ satisfying the equations $\Box(a \wedge b) = \Box a \wedge \Box b$, $\Box\top = \top$, $\Box\Box a = \Box a$, $\Box a \leq a$ (recall that inequations like $c \leq d$ are defined as $c \wedge d = c$ in lattices). Interior algebras and the appropriate morphisms form the category **Int**.

DEFINITION 40. A *modal hyperdoctrine*, based on the cartesian category $\mathbf{T}$, is a contravariant functor $\mathcal{A} : \mathbf{T} \longrightarrow \mathbf{Int}^{op}$ satisfying the following two requirements.

(i) For any arrow $f : Y \longrightarrow X$ in $\mathbf{T}$, the 'inverse image' morphism $\mathcal{A}(f) : \mathcal{A}(X) \longrightarrow \mathcal{A}(Y)$ has a left adjoint (the 'direct image along f') $\exists_f : \mathcal{A}(Y) \longrightarrow \mathcal{A}(X)$ and a right adjoint (the 'dual image along f') $\forall_f : \mathcal{A}(Y) \longrightarrow \mathcal{A}(X)$.[17] This means that the

[17] As we are in a Boolean context, these adjoints are interdefinable, e.g. we have $\exists_f(A) = \neg\forall_f(\neg A)$.

following conditions must be satisfied for all $A \in \mathcal{A}(Y)$ and $B \in \mathcal{A}(X)$ (we write f^{-1} instead of $\mathcal{A}(f)$):

$$\begin{array}{ll} B \leq f^{-1}(A) \Rightarrow \exists_f(B) \leq A, & B \leq f^{-1}(\exists_f(B)) \\ f^{-1}(A) \leq B \Rightarrow A \leq \forall_f(B), & f^{-1}(\forall_f(B)) \leq B. \end{array}$$

(ii) The Beck-Chevalley condition holds; this means that for every term/projection pullback, i.e., for every pullback of the kind[18]

$$\begin{tikzcd} Y \times Z \arrow[r, "f \times id_Z"] \arrow[d, "\pi_Y"'] & X \times Z \arrow[d, "\pi_X"] \\ Y \arrow[r, "f"'] & X \end{tikzcd}$$

the following two identities are satisfied for all $A \in \mathcal{A}(X \times Z)$:

$$f^{-1}(\exists_{\pi_X}(A)) = \exists_{\pi_Y}((f \times id_Z)^{-1}(A)), \qquad f^{-1}(\forall_{\pi_X}(A)) = \forall_{\pi_Y}((f \times id_Z)^{-1}(A)).$$

The meaning of Definition 40 is better explained through the corresponding Lindenbaum construction: given a language $\mathcal{L}$, we take as $\mathbf{T}_{\mathcal{L}}$ the category whose objects are natural numbers $n \geq 0$ and whose arrows $n \longrightarrow m$ are m-tuples of n-terms (composition is substitution). For a given modal first-order system $\mathbf{S}$, let $\mathcal{A}_{\mathbf{S}}(n)$ be the set of equivalence classes of n-formulas (equivalence is meant with respect to provability of bi-implication in $\mathbf{S}$). For an m-tuple of n-terms $\underline{t} = (t_1, \ldots, t_m) : n \longrightarrow m$, the inverse image interior algebras morphism $\mathcal{A}(\underline{t})$ maps the equivalence class of $\psi : m$ to the equivalence class of $\psi[\underline{t}] : n$. Moreover $\exists_{\underline{t}}$ is 'syntactic direct image', that is the operation of taking the equivalence class of a formula $\phi : n$ to the equivalence class of the formula (let z_i be x_{m+i})

$$\exists z_1 \cdots \exists z_n (\phi[z_1, \ldots, z_n] \wedge \bigwedge_{i=1}^{m} t_i[z_1, \ldots, z_n] = x_i) : m.$$

Thus, when $n = m+1$ and $\underline{t} = x_1, \ldots, x_m$, $\exists_{\underline{t}}$ applied to $\phi : m+1$ is just the equivalence class of $\exists x_{m+1}\phi : m$. Beck-Chevalley conditions hold because of Definition 39(c), hence it is easily seen that $\mathcal{A}_{\mathbf{S}}$ is a modal hyperdoctrine over $\mathbf{T}_{\mathcal{L}}$ (called the 'Lindenbaum hyperdoctrine' of $\mathbf{S}$).

In fact, there is a sense in which every (small) modal hyperdoctrine is equivalent to a Lindenbaum hyperdoctrine (of a multi-sorted theory, rather than of a system). Thus (small) modal hyperdoctrines may be seen as syntactic, rather than semantic frameworks. This is why the following definition of a hyperdoctrinal model becomes really significant only after the next subsections introduction of suitable special 'semantic' modal hyperdoctrines.

DEFINITION 41. Let a language $\mathcal{L}$ be given; a hyperdoctrinal model $\mathfrak{M} = (\mathbf{T}, \mathcal{A}, D, \mathcal{I})$ consists of the following data:

- a modal hyperdoctrine $\mathcal{A}$ over the cartesian category $\mathbf{T}$;

[18]The arrow $f \times id_Z$ is defined as $\langle f \circ \pi_Y, \pi_Z \rangle$.

- an object D of $\mathbf{T}$ (the domain of $\mathfrak{M}$);
- an interpretation $\mathcal{I}$ mapping every function symbol f to an arrow $\mathcal{I}(f) : D^n \longrightarrow D$ of $\mathbf{T}$ and every predicate symbol P to an element $\mathcal{I}(P) \in \mathcal{A}(D^n)$ (here n is the arity of f, P).

In Definition 41, it is assumed also that $\mathcal{I}(\bot) := \bot$ and that $\mathcal{I}(=) := \exists_{\Delta_D}(\top)$, where Δ_D is the diagonal map $\langle id_D, id_D\rangle : D \longrightarrow D^2$.

DEFINITION 42. Given a hyperdoctrinal model $\mathfrak{M} = (\mathbf{T}, \mathcal{A}, D, \mathcal{I})$ and an n-term $t : n$, the term $[\![t]\!]^{\mathfrak{M}} : D^n \longrightarrow D$ is so defined by induction:

- if $t = x_i$ $(i = 1, \dots, n)$, then $[\![t]\!]^{\mathfrak{M}}$ is the i-th projection $\pi_i : D^n \longrightarrow D$;
- if $t = f(t_1, \dots, t_k)$, then $[\![t]\!]^{\mathfrak{M}}$ is given by the composition

$$D^n \xrightarrow{\langle [\![t_1]\!]^{\mathfrak{M}}, \dots, [\![t_k]\!]^{\mathfrak{M}}\rangle} D^k \xrightarrow{\quad \mathcal{I}(f) \quad} D.$$

DEFINITION 43. Given a hyperdoctrinal model $\mathfrak{M} = (\mathbf{T}, \mathcal{A}, D, \mathcal{I})$ and an n-formula $\phi : n$, we define $[\![\phi]\!]^{\mathfrak{M}} \in \mathcal{A}(D^n)$ as follows, by induction:

(i) if $\phi : n$ is $P(t_1, \dots, t_k)$, then $[\![\phi]\!]^{\mathfrak{M}} := \langle [\![t_1]\!]^{\mathfrak{M}}, \dots, [\![t_k]\!]^{\mathfrak{M}}\rangle^{-1}(\mathcal{I}(P))$;

(ii) if $\phi : n$ is $\phi_1 \to \phi_2 : n$, then $[\![\phi]\!]^{\mathfrak{M}} := [\![\phi_1]\!]^{\mathfrak{M}} \to [\![\phi_2]\!]^{\mathfrak{M}}$ (this is the Boolean relative complement operation in $\mathcal{A}(D^n)$);

(iii) if $\phi : n$ is $\forall y \psi : n$, then $[\![\phi]\!]^{\mathfrak{M}} := \forall_{\langle \pi_1, \dots, \pi_n\rangle}([\![\psi]\!]^{\mathfrak{M}})$ (this is the dual image along the n-tuple of the first n projections of domain D^{n+1} and of codomain D);

(iv) if $\phi : n$ is $\Box\psi : n$, then $[\![\phi]\!]^{\mathfrak{M}} := \Box[\![\psi]\!]^{\mathfrak{M}}$ (this is the Box operator in the interior algebra $\mathcal{A}(D^n)$).

An n-formula $\phi : n$ is *valid in* $\mathfrak{M}$ iff $[\![\phi]\!]^{\mathfrak{M}} = \top$.

We can now prove that the system **QS4** of Table 1 is sound with respect to hyperdoctrinal models. The proof is indeed simple (it would be much more tedious for untyped systems); we first need an instantiation lemma, which is immediate by Definition 39, by the fact that inverse image in a modal hyperdoctrine is an interior algebra morphism and by Beck-Chevalley condition:

LEMMA 44. *In every modal hyperdoctrinal* $\mathfrak{M}$, *we have*

$$[\![\phi[t_1, \dots, t_k]]\!]^{\mathfrak{M}} = \langle [\![t_1]\!]^{\mathfrak{M}}, \dots, [\![t_k]\!]^{\mathfrak{M}}\rangle^{-1}([\![\phi]\!]^{\mathfrak{M}}),$$

for every k-formula $\phi : k$ and for every k-tuple of n-terms $t_1 : n, \dots, t_k : n$.

THEOREM 45. *(Validity) If the n-formula $\phi : n$ is provable in* **QS4**, *then it is valid in every hyperdoctrinal model* $\mathfrak{M}$.

Proof. The **S4**-propositional tautologies and the rules (MP) and (Nec) are valid by interior algebras axioms; the instantiation rule $(Inst)$ is valid by Lemma 44. The rule $(\forall\text{-}In)$ and the axiom schemata $(\forall\text{-}Ex)$ are just logical translations of the adjointness

conditions. Take for instance the case of ($\forall$-*Ex*): by Lemma 44, we have $[\![(\forall y\, \phi)[\underline{x}]]\!]^{\mathfrak{M}} = ([\![\underline{x}]\!]^{\mathfrak{M}})^{-1}([\![\forall y \phi]\!]^{\mathfrak{M}})$, which is equal to $\langle \pi_1, \ldots, \pi_n\rangle^{-1}(\forall_{\langle \pi_1, \ldots, \pi_n\rangle}([\![\phi]\!]^{\mathfrak{M}}))$; this is less or equal to $[\![\phi]\!]^{\mathfrak{M}}$ by adjointness.

We finally justify the validity of the equality axiom schemata. Now $[\![x_1 = x_2]\!]^{\mathfrak{M}}$ is $\exists_{\Delta_D}(\top)$, hence $[\![x_1 = x_1]\!]^{\mathfrak{M}}$ is equal to $\Delta_D^{-1}(\exists_{\Delta_D}(\top))$, i.e., to $\top$ by adjointness. Similarly, the axiom schemata (*Rep*) is equivalent (using the remaining rules and axioms of Table 1) to

$$x_1 = x_2 \to \forall x_3 \cdots \forall x_{n+2}(\phi[x_1, x_3, \ldots, x_{n+2}] \to \phi[x_2, x_3, \ldots, x_{n+2}]) : 2.$$

Now, by adjointness, we can move $\exists_{\Delta_D}$ in the antecedent of the implication to $\Delta_D^{-1} = \langle [\![x_1]\!]^{\mathfrak{M}}, [\![x_1]\!]^{\mathfrak{M}}\rangle^{-1}$ in the consequent, apply instantiation Lemma 44, Definition 39(c) and get a tautology. ❑

Let $\mathcal{K}$ be a class of modal hyperdoctrines (e.g. the class of modal hyperdoctrines arising from metaframes, presheaves, etc., see next subsections). We say that a modal system $\mathbf{S}$ is *complete with respect to $\mathcal{K}$-semantics* (or simply with respect to $\mathcal{K}$) iff every formula which is not provable in $\mathbf{S}$ fails in a hyperdoctrinal model $\mathfrak{M} = (\mathbf{T}, \mathcal{A}, D, \mathcal{I})$, such that: (i) $(\mathbf{T}, \mathcal{A}) \in \mathcal{K}$; (ii) all formulas provable from $\mathbf{S}$ are valid not only in $\mathfrak{M}$, but also in every model of the kind $\mathfrak{M} = (\mathbf{T}, \mathcal{A}, D, \mathcal{I}')$ (varying $\mathcal{I}'$).[19]

Thus, for instance, every modal system $\mathbf{S}$ is complete with respect to the class $\mathcal{K}$ formed by all the modal hyperdoctrines [114]: to prove it, it is sufficient to work in the Lindenbaum hyperdoctrine of $\mathbf{S}$.

However, given an arbitrary hyperdoctrine $(\mathbf{T}, \mathcal{A})$ and an object D from $\mathbf{T}$, it is not always the case that the set of formulas valid in all the models of the kind $\mathfrak{M} = (\mathbf{T}, \mathcal{A}, D, \mathcal{I})$ is a modal system. This set of formulas is closed only under modus ponens, generalization, necessitation and *exact* uniform substitutions.[20] This phenomenon is common to most of the extended semantics proposed in the literature (such as Kripke bundles, presheaves or metaframes): thus, in order to define *the modal system of* $(\mathbf{T}, \mathcal{A}, D)$, one should take the set of formulas whose substitution instances are all valid in the models of the kind $(\mathbf{T}, \mathcal{A}, D, \mathcal{I})$.

9.4 Metaframes

Metaframes [121] can be easily introduced (and understood) through the hyperdoctrinal approach [114]. Notice first that preordered sets and *open* maps form a category $\mathbf{F}$. Here a map $f : (W, \leq) \longrightarrow (W', \leq')$ is said to be open iff it is order-preserving and moreover satisfies the condition $f(w) \leq' w' \;\Rightarrow\; \exists v\,(w \leq v \;\&\; f(v) = w')$, for all $w \in W, w' \in W'$. For a given preordered set $\mathfrak{F} = (W, \leq)$, the powerset Boolean algebra $\mathcal{P}(W)$ can be turned into an interior algebra by defining, for $S \subseteq W$, $\Box S = \{w \in W \mid \forall v\,(w \leq v \;\Rightarrow\; v \in S)\}$. Similarly, taking inverse image along an open map $f : (W, \leq) \longrightarrow (W', \leq')$ is an interior algebras morphism $\mathcal{P}(f) := f^{-1} : \mathcal{P}(W') \longrightarrow \mathcal{P}(W)$. In this way, we actually defined a contravariant functor $\mathcal{P} : \mathbf{F} \longrightarrow \mathbf{Int}^{op}$.

Given a cartesian category $\mathbf{T}$, a $\mathbf{T}$-*metaframe* is a functor $M : \mathbf{T} \longrightarrow \mathbf{F}$ such that the composite functor $\mathcal{A}_M : \mathbf{T} \xrightarrow{M} \mathbf{F} \xrightarrow{\mathcal{P}} \mathbf{Int}^{op}$ is a modal hyperdoctrine over $\mathbf{T}$.

[19] A stronger (yet unexplored) variant of this definition would allow also D to vary.

[20] An exact uniform substitution [121] of $\phi : n$ is a formula of the kind $\phi[\psi/P] : n$, where $\psi : k$ is a k-formula replacing the predicate symbol P of arity k.

This definition can be equivalently stated directly in terms of the functor $M : \mathbf{T} \longrightarrow \mathbf{F}$ as follows. Notice that set-theoretic inverse image along f always has both adjoints (namely, direct image and dual image), so in order for M to be a $\mathbf{T}$-metaframe, only the Beck-Chevalley condition has to be considered. However, in this setting, f^{-1}, $\exists_f$ and $\forall_f$ can be conveniently treated as modal (two-sorted) operators and, as Beck-Chevalley condition is in Sahlqvist form, standard correspondence machinery applies. Thus it is not difficult to see that M is a $\mathbf{T}$-metaframe iff for the term-projections pullbacks of Definition 40(ii), the following 'lifting' condition is satisfied, for all $a \in M(X \times Z), b \in M(Y)$:

$$M(\pi_X)(a) = M(f)(b) \;\Rightarrow\; \exists c \in M(Y \times Z)\; (M(f \times id)(c) = a \;\&\; M(\pi_Y)(c) = b).$$

If M is a $\mathbf{T}$-metaframe, a *metaframe model* on M can be defined as a hyperdoctrinal model over $(\mathbf{T}, \mathcal{A}_M)$,[21] so that all the semantic definitions of the previous subsection apply to metaframes as special cases. Metaframes define a powerful semantics, as is shown by the following result:

THEOREM 46. [121] *Let* **L** *be a canonical propositional modal logic. Then:*

(i) **QL** *is complete in metaframes semantics;*

(ii) **BF**.**QL** *is complete in metaframes semantics.*

The proof essentially uses the composition of the Lindenbaum functor $\mathcal{A}_{\mathbf{QL}}$ with the 'canonical frame functor': notice, in fact, that propositional axioms transfer to canonical frames by assumption and that both Beck-Chevalley condition and the Barcan formula are 'in Sahlqvist form', so they transfer too.

The distinguishing feature of modal metaframes semantics is that 'products are not preserved', i.e., for a $\mathbf{T}$-metaframe M, we have that $M(X \times Y)$ is not even a subset of $M(X) \times M(Y)$: this has the consequence that a, say binary, predicate symbol is not interpreted as a set of pairs of individuals, but just as a set of 'abstract pairs'.

One may wonder whether Theorem 46 holds for other ('product-preserving') semantics: by applying saturated model-theory techniques, [53] *proves Theorem 46(i) for presheaf semantics*[22] in the case of intermediate logics. The related extension to **S4**-modal logics holds, provided **L** is assumed to be not only canonical, but also closed under a 'cluster-expansion' semantic condition (see [53] for details)

10 MATHEMATICAL MODELS FOR MODALITIES

The aim of this section is to show that modalities naturally arise in well-established mathematical frameworks. The related analysis will give us new insight for the axiomatization of D. Lewis' counterpart semantics.

[21] Taking into consideration the special case in which the language does not contain constant or function symbols, $\mathbf{T}$ is (equivalent to) the opposite of the category of finite sets and the domain of the model is a singleton set, this substantially agrees with the definition of [121] (but our interpretation of the equality predicate in a metaframe model is different).

[22] This is the semantics explained in the Example 4 of Subsection 10.1 below.

10.1 Geometric Morphisms and Modal Logic

An (elementary) topos $\mathbf{E}$ is a lex cartesian closed category with subobject classifier. In the sequel, we shall directly mention the relevant consequences that can be drawn from this definition that matter for our purpose of interpreting first-order systems in a topos. For the moment, let us just mention a couple of examples of toposes that are used in intensional semantics.

Example 1. Kripke-like universes: fix a preordered Kripke frame $\mathfrak{F} = (W, \leq)$. A presheaf on $\mathfrak{F}$ is a contravariant functor into the category $\mathbf{Set}$ of sets. That is, D associates with $w \in W$ a set D_w (the set of 'individuals' living in it) and, whenever the relation $v \leq w$ holds, D_{vw} is a function $D_w \longrightarrow D_v$; such data should satisfy the requirements $D_{ww} = id$ and $D_{vw} \circ D_{wz} = D_{vz}$. These presheaves on preordered sets (investigated also in some textbooks on intuitionistic logic like [27]) are sometimes called *Kripke frames with equality*: they differ from the standard Kripke $\mathfrak{F}$-domains of Section 6 because the inclusion $D_w \subseteq D_v$ is replaced by an arbitrary function (we also reversed the direction of such a function in accordance with current topos-theoretic literature).[23]

A natural transformation $f : D \longrightarrow D'$ among our presheaves is a collection of functions $\{f_w : D_w \longrightarrow D'_w \mid w \in W\}$ such that for $v \leq w$ the square

$$\begin{tikzcd} D_w \arrow[r, "f_w"] \arrow[d, "D_{vw}"'] & D'_w \arrow[d, "D'_{vw}"] \\ D_v \arrow[r, "f_v"'] & D'_v \end{tikzcd}$$

commutes.[24] Presheaves and natural transformations are the 'Kripkean' topos $\mathbf{Set}^{\mathfrak{F}^{\mathbf{op}}}$.

The generalization to the case in which $\mathfrak{F}$ is a category (and not simply a preordered set) is straightforward: if $\mathfrak{F}$ is a category, a presheaf on it is a contravariant functor from $\mathfrak{F}$ to $\mathbf{Set}$, a morphism among such presheaves is a natural transformation (=family of maps indexed by the objects of $\mathfrak{F}$ making the obvious squares to commute), these presheaves and natural transformations are a category which is a topos, the latter is called $\mathbf{Set}^{\mathfrak{F}^{\mathbf{op}}}$ again. Usually, in the literature, when people deal with presheaf semantics, they actually refer to *presheaves over an arbitrary category.* Notice also that functional frames of Section 8 can be easily turned into presheaves on a category.

Example 2. Etale spaces: fix a topological space S. A local homeomorphism $e : E \longrightarrow S$ (or etale space, or sheaf over S) is a continuous map among topological spaces such that for every $a \in E$ there are open neighborhoods N of a and M of $e(a)$ such that e restricts to a homeomorphism $e_{|N} : N \longrightarrow M$. A map among etale spaces $e : E \longrightarrow S$ and $e' : E' \longrightarrow S$ is a continuous map $f : E \longrightarrow E'$ such that $e' \circ f = e$. Etale spaces and related maps are the topos $Sh(S)$.

Recall the subobject functor Sub from Subsection 9.2: this functor associates with an object X in a topos $\mathbf{E}$ the equivalence classes of monos $A \hookrightarrow X$; moreover, for every arrow $f : Y \longrightarrow X$ in $\mathbf{E}$, $Sub(f) = f^{-1} : Sub(X) \longrightarrow Sub(Y)$ takes pullback. As

[23] As pointed out in [111], Kripke frames with equality are semantically stronger than standard Kripke $\mathfrak{F}$-domains, even for systems without equality.

[24] In case $D = \mathbf{1}$ is the one-point terminal presheaf, the commutativity of the square just expresses a kind of 'rigid designator' condition for the global constant $f : \mathbf{1} \longrightarrow D'$.

the categorical structure of a topos is quite rich, we have the following lemma (see any textbook like [83], [70] for the proof):

LEMMA 47. *Every topos* $\mathbf{E}$ *is a Heyting category, meaning that the subobject functor*

$$Sub : \mathbf{E} \longrightarrow \mathbf{Heyt}^{op}$$

endows $\mathbf{E}$ *with an intuitionistic hyperdoctrinal structure.*

The notion of an intuitionistic (resp. classical) hyperdoctrine, is obtained from Definition 40 by replacing in it the category **Int** by the category **Heyt** of Heyting algebras (resp. by the category **Bool** of Boolean algebras). Whenever the intuitionistic hyperdoctrinal structure mentioned in Lemma 47 is in fact a classical hyperdoctrinal structure, the topos $\mathbf{E}$ is said to be *Boolean*.

In order to extend the above analysis from intuitionistic to modal logic, we must first understand in a general topos-theoretic context an evident anomaly that characterizes Kripke semantics for first-order modal logic (when compared with the corresponding semantics for intuitionistic logic). In first-order Kripke semantics for modal logic, sorts are interpreted as presheaves and terms are interpreted as natural transformations (at least in the rigid designators case). What is peculiar is the interpretation of predicates: in fact a, say unary, predicate P is interpreted as a collection of subsets $\{P_w \subseteq D_w \mid w \in W\}$ which is *not* a subpresheaf (i.e., it is not a subobject of D in the topos $\mathbf{Set}^{\mathfrak{F}^{\mathbf{op}}}$). Thus, the categorical structure of a topos seems to be unable to give a full account of modal logic. There is however a quite simple and beautiful solution to this problem for our **S4** systems: we only need to consider *two* toposes and a geometric morphism connecting them.[25]

The most obvious notion of a morphism $F : \mathbf{E}_1 \longrightarrow \mathbf{E_2}$ among toposes is the so-called 'logical' notion: F is taken to be a functor that preserves the topos structure (i.e., finite limits, exponentials and subobject classifier). However, geometry suggests another notion, which is the good one for modal logic too. In fact, a continuous map $f : S \longrightarrow T$ among topological spaces, induces two functors $F_* : Sh(S) \longrightarrow Sh(T)$ and $F^* : Sh(T) \longrightarrow Sh(S)$ such that (i) F^* is left adjoint to F_*;[26] (ii) F^* is left exact. Thus, let us define a *geometric morphism* $\mathbf{E}_1 \longrightarrow \mathbf{E_2}$ among toposes $\mathbf{E}_1, \mathbf{E}_2$ as a pair of functors $F_* : \mathbf{E}_1 \longrightarrow \mathbf{E}_2$ and $F^* : \mathbf{E}_2 \longrightarrow \mathbf{E}_1$ such that F^* is left exact left adjoint to F_*.

Example 3. This definition gives what we are looking for in the Kripkean case. Let $f : \mathfrak{G} \longrightarrow \mathfrak{F}$ be an order-preserving maps among preordered sets (again the generalization to the case in which $\mathfrak{F}, \mathfrak{G}$ are categories and f is a functor, is straightforward). Such an f induces a functor $F^* : \mathbf{Set}^{\mathfrak{F}^{\mathbf{op}}} \longrightarrow \mathbf{Set}^{\mathfrak{G}^{\mathbf{op}}}$, just by 'taking composition with f'. It is well-known (from the theory of Kan extensions [82]) that F^* has both a right adjoint F_* and a left adjoint $F_!$, hence the pair (F_*, F^*) defines a geometric morphism $\mathbf{Set}^{\mathfrak{G}^{\mathbf{op}}} \longrightarrow \mathbf{Set}^{\mathfrak{F}^{\mathbf{op}}}$. For Kripke semantics, the relevant special case is the case in which $\mathfrak{G}$ is the discrete poset

[25] This idea seems to be due to F. W. Lawvere and was developed in a series of papers by G. E. Reyes and other people [103], [77], [104], [84] (we substantially follow [84] in our exposition). Topos-theoretic semantics *always validates* **S4** *axioms* (see Lemma 48(i)), hence it is unsuitable for weaker systems; in contrast to all the other semantics that are introduced in this chapter, there is no evident way of generalizing the mechanism of topos-theoretic semantics so that it can be adapted to weaker normal systems.

[26] Adjointness means that there is a natural bijection (called transposition) among the hom-sets $Hom(F^*(X), Y) \simeq Hom(X, F_*(Y))$, for every object X in the domain category of F^* and for every object Y in the domain category of F_*.

$(W,=)$ formed by the set of possible words of $\mathfrak{F} = (W, \leq)$. In this case, if $f : (W,=) \longrightarrow \mathfrak{F}$ is the identity map, $F^* : \mathbf{Set}^{\mathfrak{F}^{\mathbf{op}}} \longrightarrow \mathbf{Set}^{(W,=)}$ is the functor associating with the presheaf D, the same D seen as the collection of sets $\{D_w \mid w \in W\}$ indexed by the possible worlds (otherwise said, the maps D_{vw} are forgotten). Subobjects of $F^*(D)$ in the topos $\mathbf{Set}^{(W,=)}$ are consequently what is needed in order to interpret predicates in ordinary modal Kripke semantics.

How to recover modal operators from a geometric morphism $(F_*, F^*) : \mathbf{E}_1 \longrightarrow \mathbf{E}_2$ in the general case? This is done as follows: take an object D from $\mathbf{E}_2$ and a subobject $A \hookrightarrow F^*(D)$. We apply F_* (which preserves monos, being a right adjoint) and get first $F_*(A) \hookrightarrow F_*(F^*(D))$. Now consider the unity $\eta_D : D \longrightarrow F_*(F^*(D))$ of the adjunction (this is the transpose of the identity map on $F^*(D)$) and take the pullback

$$\begin{tikzcd}
\flat(A) \arrow[r, tail] \arrow[d] & D \arrow[d, "\eta_D"] \\
F_*(A) \arrow[r, tail] & F_*(F^*(D))
\end{tikzcd}$$

Applying F^* again (this functor preserves monos, as it is left exact) we finally get a subobject $F^*(\flat(A)) \hookrightarrow F^*(D)$, which we call $\Box A$. Thus we defined operators

$$\flat : Sub(F^*(D)) \longrightarrow Sub(D) \quad \text{and} \quad \Box : Sub(F^*(D)) \longrightarrow Sub(F^*(D)),$$

whose relevant properties are summarized in the following lemma (we omit proofs, that can be easily obtained by unravelling the definitions):

LEMMA 48.

(i) *For $A, B \in Sub(F^*(D))$, we have*

$$\Box A \leq A, \qquad \Box A = \Box\Box A,$$
$$\Box id_{F^*(D)} = id_{F^*(D)}, \qquad \Box(A \wedge B) = \Box A \wedge \Box B,$$

that is, $Sub(F^*(D))$ is an (intuitionistic) interior algebra.

(ii) *For every $h : D' \longrightarrow D$ in $\mathbf{E}_2$ and for every $A \in Sub(F^*(D))$, we have*

$$\Box(F^*(h))^{-1}(A) = (F^*(h))^{-1}(\Box A),$$

that is, $(F^*(h))^{-1}$ is an interior algebra morphism.

(iii) *$\flat$ is the right adjoint to the operator $Sub(D) \longrightarrow Sub(F^*(D))$ taking $A \hookrightarrow D$ to $F^*(A) \hookrightarrow F^*(D)$. This means that we have*

$$F^*(B) \leq A \Rightarrow B \leq \flat(A), \qquad F^*(\flat(A)) \leq A,$$

for all $B \in Sub(D), A \in Sub(F^*(D))$.

Conditions (i)-(ii) are the needed ingredients for the proof of next theorem, whereas condition (iii) makes easier the calculation of the $\Box$-operator in the relevant examples.

THEOREM 49. *Let* $(F^*, F_*) : \mathbf{E}_1 \longrightarrow \mathbf{E}_2$ *be a geometric morphism. Assume also that* $\mathbf{E}_1$ *is a Boolean topos.*[27] *Then the functor* $Sub \circ F^* : \mathbf{E}_2 \longrightarrow \mathbf{Int}^{op}$ *gives a modal hyperdoctrine over* $\mathbf{E}_2$*.*

Proof. Immediate by Lemmas 47 and 48(i)-(ii). ❑

Thus we can define a *topos-theoretic model* of $\mathcal{L}$ as a hyperdoctrinal model of $\mathcal{L}$ into a hyperdoctrine of the kind mentioned in Theorem 49.

Example 3 (continued). In the Kripke framework of Example 3, we can recover, from the definition of a topos-theoretic model, the standard Kripke forcing conditions for first-order modal logic in the following way. Given a presheaf D and a subobject $A \subseteq F^*(D)$ (that is, a collection of subsets $\{A_w \subseteq D_w \mid w \in W\}$), we do not need to know the complicated construction of F_* in order to compute $\flat(A) \subseteq D$: Lemma 48(iii) is sufficient for that. In fact, the adjointness conditions uniquely determine $\flat(A)$ (and hence also the collection of subsets $F^*(\flat A) = \Box A$) as the subpresheaf $\flat(A)_w = \{a \in D_w \mid \forall v\ (v \leq w \Rightarrow D_{vw}(a) \in A_v)\}$. Now, given a topos-theoretic model $\mathfrak{M}$ in the present Kripkean framework, for an n-formula $\phi : n$ and for an n-tuple $\underline{a} \in D^n_w$, write $\underline{a} \models^{\mathfrak{M}}_w \phi$ for $\underline{a} \in ([\![\phi]\!]^{\mathfrak{M}})_w$. Definition 43(iv) now reads[28]

$$\underline{a} \models^{\mathfrak{M}}_w \Box\psi \quad \text{iff} \quad \forall v\ (v \leq w \Rightarrow D_{vw}(\underline{a}) \models^{\mathfrak{M}}_v \psi)$$

(where $D_{vw}(\underline{a})$ means the componentwise application of the function D_{vw} to the tuple $\underline{a}$). Similarly, Definition 43(i)-(ii)-(iii) gives the standard forcing conditions for atomic formulas, for $\rightarrow$ and for $\forall$, respectively.

Example 4. If we allow $\mathfrak{F}$ to be a category in Example 3, we get full *presheaf semantics*, i.e., the semantics used in [52], [50] in order to prove some of the incompleteness results mentioned in Section 8. Forcing conditions for truth of modal formulas in full presheaf semantics (where presheaves are taken on a category) are derived in complete analogy to the Kripkean case of Example 3.[29] For powerful completeness results with respect to this semantics, see the final remark of Subsection 9.4.

Example 5. In a completely analogous way, forcing conditions can be derived in the etale case, thus establishing a suitable *topological semantics* for first-order modal logic. In fact, let S be a topological space and let $|S|$ be the discretization of S (points are the same as for S, but now every subset is open). The identity map $f : |S| \longrightarrow S$ is continuous and hence it induces a geometric morphism $(F_*, F^*) : Sh(|S|) \longrightarrow Sh(S)$. The 'inverse image part' F^* of this morphism associates with the etale space $e : D \longrightarrow S$ the discrete space $|e| : |D| \longrightarrow |S|$. Using Lemma 48(iii), the operator $\flat$ is easily seen to take a subset to its interior; notice also that (according to the characterization of products in the topos $Sh(S)$) D^n is now the fibered product of D with itself n-times.[30] Hence, given $p \in S$,

[27] This assumption is needed because we are studying (for simplicity) **S4**-systems on a classical basis; for modal systems on an intuitionistic basis this restriction is obviously dropped.

[28] Notice that here the n-tuple $\underline{a}$ plays the role of a *finitary* assignment to the variables $x_1, \ldots, x_n$.

[29] If functional frames are seen as presheaves, we get precisely the truth forcing conditions of Section 8 for functional models.

[30] This means that D^n is the subspace of the n-th cartesian power of D formed by the tuples $(a_1, \ldots, a_n)$ living on the same fiber (i.e., such that $e(a_1) = \cdots = e(a_n)$); the topology on D^n is the relativization of the product topology.

$a_1, \ldots, a_n \in e^{-1}(p)$, if we write $(a_1, \ldots, a_n) \models_p^{\mathfrak{M}} \phi$ for $(a_1, \ldots, a_n) \in [\![\phi]\!]^{\mathfrak{M}}$, we get from Definition 43(iv) the following topological forcing condition:

$$(T) \quad (a_1, \ldots, a_n) \models_p^{\mathfrak{M}} \Box\psi \quad \text{iff} \quad \begin{array}{l} \exists \text{ neighborhoods } J, I_1, \ldots, I_n \text{ of } p, \\ a_1, \ldots, a_n, \text{ respectively, s.t. } \forall q \in J, \\ \forall b_1, \ldots, b_n \in (I_1 \times \cdots \times I_n) \cap e^{-1}(q) \\ \text{we have that } (b_1, \ldots, b_n) \models_q^{\mathfrak{M}} \psi. \end{array}$$

When the topology in S is *preordered* (i.e., when there is a preorder relation on S such that open subsets are just the upward closed subsets), it is not difficult to see that we get again the Kripke frames with equality of Example 3 as a special case.

Validity of **QS4** with respect to topos-theoretic semantics follows from the general validity Theorem 45. Completeness of **QS4** can be proved as well: this however already follows from completeness with respect to Kripke frames with equality (a direct proof, based on the elegant Joyal construction for presheaf completeness of intuitionistic logic, is given in [84]).

10.2 The Need for the Continuity Axiom

We now briefly sketch some further semantic investigations into mathematically motivated models, raising new problems, whose solution requires a better understanding of the types mechanism (mainly in connection to substitution).

A geometric morphism $(F_*, F^*) : \mathbf{E}_1 \longrightarrow \mathbf{E_2}$ is called *essential* in case F^* has a further left adjoint $F_! : \mathbf{E}_1 \longrightarrow \mathbf{E_2}$ (as we saw in Example 3 from Subsection 10.1, this is always the case in Kripke-like frameworks). For essential geometric morphisms, we can define diamond operators $\Diamond_p : Sub(F^*(D)) \longrightarrow Sub(F^*(D))$ by a mechanism similar to the mechanism we used for the $\Box$-operators of Lemma 48. Given a subobject $A \hookrightarrow F^*(D)$, we apply $F_!$, compose with the counity of the adjointness

$$F_!(A) \longrightarrow F_!(F^*(D)) \longrightarrow D$$

and then take epi/mono factorization (which is available in any topos); in this way we get a subobject of D, which we turn into a subobject $\Diamond_p(S)$ of $F^*(D)$ by applying F^* once again. This operator $\Diamond_p : Sub(F^*(D)) \longrightarrow Sub(F^*(D))$ is not interdefinable (via negation) with the $\Box$-operator introduced in Subsection 10.1, rather it is left adjoint to it, meaning that the pair of operators $(\Diamond_p, \Box)$ jointly satisfy the axioms for tense logic (that is, $\Diamond_p$ is a 'past possibility' operator, whereas $\Box$ is a 'future necessity' operator). There is one point that goes wrong here, however: we fail to get a 'tense hyperdoctrine', because the statement of Lemma 48(ii) for $\Diamond_p$ is not true, we only have:

$$(C\Diamond_p) \qquad \Diamond_p(F^*(h))^{-1}(A) \leq (F^*(h))^{-1}(\Diamond_p A).$$

As a consequence, the proof of the instantiation Lemma 44 for the calculus of Table 1 extended with the tense operators does not work. In fact, this extended calculus *is not sound*: remember that it derives the Barcan formula and the necessity of the difference, which are easily seen to be invalid (already in the case of Kripke semantics). As we shall see in Table 2 of next subsection, the semantic failure of such logical principles is tightly related (in fact, it is equivalent to) the failure of the converse of $(C\Diamond_p)$.

We come across a very similar problem if we try to extend topological semantics beyond the etale spaces case [56], [51]. Fix a topological space S. A bundle over S (or, simply, a *bundle*, leaving S as understood) is a topological space D endowed with a continuous map $d : D \longrightarrow S$; a map among bundles $d : D \longrightarrow S$ and $d' : D' \longrightarrow S$ is a continuous map $f : D \longrightarrow D'$ such that $d' \circ f = d$. Let $\mathbf{Top}/S$ be the category of bundles and related maps; this category has products (which are fibered products over S). Moreover, for every bundle D, the powerset $\mathcal{P}(D)$ of D carries an interior algebra structure. Thus, we can come back to the hyperdoctrinal point of view and use Definitions 41, 42, 43 to introduce bundle models. Equivalently, we may replace Definition 43 by the corresponding forcing conditions: for instance, (T) is the forcing condition for $\Box$.[31]

Once again, however, the trouble with bundles is the instantiation Lemma 44. In fact, the notion of a modal hyperdoctrine should be modified [55], [56][32] in order to adapt it to bundles: the powerset functor fails to give a modal hyperdoctrine over $\mathbf{Top}/S$ (in the sense of Definition 40), because if $f : D \longrightarrow D'$ is a continuous function, the inverse image function $\mathcal{P}(f) := f^{-1} : \mathcal{P}(D)' \longrightarrow \mathcal{P}(D)$ is not an interior algebras morphism, we only have

$$(C\Box) \qquad\qquad f^{-1}\Box(A) \subseteq \Box f^{-1}A$$

for every $A \subseteq D'$ (here $\Box$ obviously denotes the topological interior operator). Notice that condition $(C\Box)$ is very similar to condition $(C\Diamond_p)$: the former expresses the continuity definition with respect to interior, whereas the latter expresses 'continuity with respect to a kind of closure'. The calculus of Table 1 is not sound with respect to bundle models:[33] there is no surprise in that, *such calculus wrongly assumes* (through Definition 39(d)) *the converse of* $(C\Box)$ *to hold, i.e., it assumes that all continuous functions are open.* Notice that, on the contrary, continuous maps among etale spaces *are* open: this is why we did not meet any trouble in Example 5 from Subsection 10.1.

In next section, we shall get an axiomatization of bundle models. Since, when all involved topologies are preordered, bundle models reduce to counterpart models and since the latter are sufficient for completeness, we prefer to directly skip to counterpart models.

11 COUNTERPART SEMANTICS

The previous subsection's analysis of the interplay between substitution and modal operators in mathematically motivated models (topological bundles, essential geometric morphisms of toposes) suggests the revision of some basic syntactic definitions from Subsection 9.1: in this way, a *continuity condition* can be easily formulated. Continuity turns out to be *the only axiom schema needed in order to axiomatize counterpart semantics.* We shall devote the present final section to the illustration of this (surprisingly) very simple axiomatization taken from [55].

[31] Bundle models should not be confused with the models over Kripke bundles of [111] (such Kripke bundles define a semantics which is intermediate between Kripke frames with equality and presheaf semantics [121]).

[32] The modification is simple: in Definition 40, just replace **Int** by the category having as objects interior algebras and as arrows the Boolean morphisms f such that $f(\Box a) \leq \Box f(a)$.

[33] For instance, the calculus of Table 1 derives the necessity of identity, which holds (when S is the singleton space) precisely for trivial discrete spaces.

Before philosophically motivating, introducing and discussing counterpart semantics, we prefer to immediately make the needed modifications at the syntactic level. In order to express the continuity axiom, we need to treat substitution carefully: in fact, the statement of the continuity axiom is that only one half of Definition 39(d) holds, the other half being an openness requirement which is not valid (the definition of a continuous map in topology says that inverse image of the interior is *contained* in the interior of inverse image). To get the desired effect, we treat modalized formulas as atomic formulas and change Definition 38(iv) as follows:

(iv') if $\phi : k$ is a k-formula and if $t_1 : n, \ldots, t_k : n$ are n-terms, then $(\Box\phi)(t_1, \ldots, t_k) : n$ is an n-formula.

We shall abbreviate $(\Box\phi)(x_1, \ldots, x_n) : n$ by $\Box\phi : n$. Next, we modify Definition 39(d) by:

(d') if $\underline{v} : m$ is an n-tuple of m-terms and $(\Box\phi)(t_1, \ldots, t_k) : n$ is an n-formula, we let the m-formula $(\Box\phi)(t_1, \ldots, t_k)[\underline{v}] : m$ be equal to $(\Box\phi)(t_1[\underline{v}], \ldots, t_k[\underline{v}]) : m$.

The 'counterpart' modal calculus **CS4** has again the rules and the axiom schemata of Table 1 (to be interpreted according to the new definition of formula and substitution) and, in addition, the following *continuity* axiom schemata:

$$(Cont) \qquad (\Box\phi)[t_1, \ldots, t_k] \to \Box(\phi[t_1, \ldots, t_k]) : n$$

(notice that $(\Box\phi)[t_1, \ldots, t_k]$ is precisely $(\Box\phi)(t_1, \ldots, t_k)$ by the above definitions and conventions).

11.1 Counterpart Models

The origins of counterpart semantics come from philosophical considerations: counterpart semantics is a way of overcoming transworld identification problems when evaluating *de re* statements in possible worlds semantics:

> The counterpart relation is our substitute for identity between things in different worlds. Where some would say that you are in several worlds, in which you have somewhat different properties and somewhat different things happen to you, I prefer to say that you are in the actual world and no other, but you have counterparts in several other worlds ([79], p. 114).

A large philosophical debate (see for instance [64], [42]) has pointed out both the merits and the difficulties of the counterpart-theoretic point of view in the semantics of quantified modal logic. We shall mainly concentrate here on *axiomatization* issues: these turn out to be useful for clarifying aspects of the counterpart doctrine that are commonly considered rather obscure.

Counterpart theory is introduced in [79] by axiomatizing the intuition behind the intended notion of a counterpart. Such intuition is provided by the concept of similarity: informally, a (living in w) is a counterpart of b (living in v) iff 'a resembles to b more closely than anything else living in w'. For the axiomatization of the notion of a counterpart, a suitable first-order theory I is introduced ([79], Section I). A translation of first-order modal language into the extensional language of I is then considered ([79], Section II):

such translation gives implicitly — as happens with standard translation in the Kripkean case — the inductive forcing conditions for counterpart semantics.[34] A counterpart relation is finally joined to a customary accessibility relation (in order to model systems whose propositional basis is not **S5**) and the translation from modal language into the counterpart extensional language is modified accordingly ([79], Section V).

The axioms of I express rather light constraints on the relation 'being a counterpart of': this is taken to be an almost generic binary relation among individuals. In particular, the counterpart relation needs not be symmetric nor transitive, individuals may have one, many, or no counterparts at all in any other world; however individuals live in a unique assigned world and are their own unique counterpart in the world they live in ([79], p.114).

Models of I can consequently be represented as triples $d : D \longrightarrow W$, where W is the set of possible worlds, D is the set of individuals and the function d specifies the world $d(a)$ a given individual $a \in D$ lives in. Both W and D are endowed with binary relations: these are the counterpart relation R_D for D and the accessibility relation R_W for W. The function d must preserve such relation: this means that, whenever b is counterpart of a, then the world $d(b)$ where b lives in should be accessible from the world $d(a)$ where a lives in. Formally we have that

(8) $\quad aR_Db \;\Rightarrow\; d(a)R_Wd(b)$

holds for all $a, b \in D$. Although Lewis does not make assumption (8) in Section V of [79], this assumption is implicit in the translation instructions he gives from the modal language to the extensional language.[35] We shall call *Lewis triples* the triples $d : (D, R_D) \longrightarrow (W, R_W)$ satisfying (8).

Since we want to make a close comparison with the topological bundles of Subsection 10.2, we assume that both D and W are preodered sets: this means that both the accessibility relation R_W and the counterpart relation R_D are assumed to be reflexive and transitive. We point out that we do that *just for enlightening comparisons with topological bundle semantics to be immediate.* In fact, dropping reflexivity and transitivity for both the counterpart and the accessibility relation, would simply result in treating **K**-based systems: this is quite easily done in our framework, because once **S4** axioms are removed from the syntax and reflexivity-transitivity requirements are removed from the semantics, *soundness and completeness results of Subsection 11.2 extend trivially.*

Lewis' requirement that every individual a living in a world w has itself as counterpart in w (together with reflexivity of the accessibility relation) is precisely what is needed in order to make axiom **T** valid: for this reason, this requirement is included in our setting, but should be dropped for **K**-based systems. Finally, Lewis requirement that a is the only counterpart of a in the world a lives in, is a non-modally definable condition which does not affect soundness and completeness of our systems (as will be evident from the completeness proof of Subsection 11.2).

[34] Other translations (different from Lewis' original one) have been proposed by G. Forbes and M. Ramachandran: see the recent paper [28] for an essential account of them and for the relevant pointers to the literature.

[35] In other words, the translation of a modal sentence is not influenced by this extra assumption: quantifiers are relativized to individuals living in the current world w and, when the translation of a modalized formula requires taking into consideration another world v, then v must be accessible from w and the translation instruction takes care of replacing current free variables ranging over individuals living in w by variables ranging over counterparts of them living all in v (see (T2i*)-(T2j*) in [79], p. 125).

Thus we restrict our considerations to reflexive-transitive Lewis triples: these are the triples $d : (D, \leq) \longrightarrow (W, \leq)$, where $(W, \leq)$ and $(D, \leq)$ are preordered sets and d is an order-preserving map. *This is nothing but a special case of the notion of a topological bundle from Subsection 10.2*: more precisely, it is the special case arising when topologies are preordered.[36]

Given a reflexive-transitive Lewis triple $d : (D, \leq) \longrightarrow (W, \leq)$ and a world $w \in W$, we can associate with it the fiber over w, namely the set $D_w = \{a \in D \mid d(a) = w\}$; whenever $v \leq w$, we can also consider the relation $D_{vw} = \{(a, b) \mid a \in D_v, b \in D_w$ and $a \leq b\}$, obtained from the restriction of the counterpart relation to $D_v \times D_w$. Now the collection of sets $\{D_w \mid w \in W\}$ and the collection of relations $\{D_{vw} \mid v \leq w\}$ form a $(W, \leq)$-relational domain, in the sense of the definition below. Relational domains and reflexive-transitive Lewis triples are equivalent formalisms (there are precise and easy technical results guaranteeing that),[37] so that we prefer to move to the relational domain formalism.

We have finally arrived at the relevant formal definitions from [55], [56], [51]. Given a preordered set $\mathfrak{F} = (W, \leq)$, by an *$\mathfrak{F}$-relational domain* D, we mean a collection of sets $\{D_w \mid w \in W\}$, endowed for every pair $v \leq w \in W$ with a relation $D_{vw} \subseteq D_v \times D_w$. Such 'transition' relations are assumed to satisfy the following requirements for all $v \leq w \leq z \in W$, for all $a \in D_v, b \in D_w, c \in D_z$:

$$(L) \qquad\qquad aDa, \qquad aDb \;\&\; bDc \;\Rightarrow aDc$$

(where we write aDb for $(a, b) \in D_{vw}$, etc.). Whenever aDb holds (for $v \leq w, a \in D_v, b \in D_w$) we say that b is a *w-counterpart* (or simply a counterpart) of a.

The following list of further definitions/notational conventions will complete our counterpart domain settings. Let an $\mathfrak{F}$-relational domain D be given; then given tuples $\underline{a} = (a_1, \ldots, a_n) \in D_v^n$, $\underline{b} = (b_1, \ldots, b_n) \in D_w^n$ (with $v \leq w$), the notation $\underline{a}D\underline{b}$ means that a_iDb_i holds for all $i = 1, \ldots, n$. We also use the notation $\underline{a}_i$ to mean the i-th component of the tuple $\underline{a}$ (i.e., if $\underline{a} = (a_1, \ldots, a_n)$, then $\underline{a}_i$ stands for a_i).

A *$\mathfrak{F}$-relational map* $f : D \longrightarrow D'$ among $\mathfrak{F}$-relational domains is a collection of functions $\{f_v : D_v \longrightarrow D'_v \mid v \in W\}$ satisfying the requirement $aDb \;\Rightarrow f_v(a)D'f_w(b)$ (for every $v \leq w, a \in D_v, b \in D_w$). The n-th cartesian power of an $\mathfrak{F}$-relational domain D is the relational domain D^n so specified: $(D^n)_w = (D_w)^n$ and $\underline{a}D^n\underline{b}$ holds (for $v \leq w, \underline{a} \in D_v^n, \underline{b} \in D_w^n$) iff $\underline{a}_iD\underline{b}_i$ holds for every i.[38] For $n = 0$, the singleton $\mathfrak{F}$-relational domain D^0 is so described: D_w^0 contains for every w just the empty tuple $*$ from D_w and we have $*D^0*$ for all $v \leq w \in W$. A sub-relational domain $S \subseteq D$ of an $\mathfrak{F}$-relational domain D is a collection of subsets $S = \{S_w \subseteq D_w \mid w \in W\}$. The following pair of definitions is the expected one:

---

[36] Recall that a topology is said to be preordered iff there is a preorder relation such that the open sets coincide with the upward closed subsets. Notice also that a topology is preordered iff open sets are closed under arbitrary (not just finite) intersections.

[37] We mention precise connections for the interested reader: let **Preord** be the category of preordered sets and let $\mathfrak{F}$ be a preorder. Then the category of counterpart frames $\mathbf{Rel}^{\mathfrak{F}}$ over $\mathfrak{F}$ is equivalent [56], [89] to the category of reflexive-transitive Lewis triples over $\mathfrak{F}$, which is nothing but the slice category $\mathbf{Preord}/\mathfrak{F}$; the latter is embedded in $\mathbf{Top}/\mathfrak{F}$ (both the equivalence and the embedding extend to the modal hyperdoctrinal level).

[38] Thus D^n is the n-th cartesian power of D in the category $\mathbf{Rel}^{\mathfrak{F}}$ [55],[56],[89] of $\mathfrak{F}$-relational domains and $\mathfrak{F}$-relational maps. Similarly, sub-relational domains defined below correspond to regular subobjects in that category.

DEFINITION 50. Let $\mathcal{L}$ be a language and let $\mathfrak{F}$ be a frame; an $\mathfrak{F}$-counterpart model (or, simply an $\mathfrak{F}$-model) $\mathfrak{M}$ consists of the following data:

- an $\mathfrak{F}$-relational domain D (the domain of $\mathfrak{M}$);
- an interpretation $\mathcal{I}$ mapping every function symbol f to an $\mathfrak{F}$-relational map $\mathcal{I}(f) : D^n \longrightarrow D$ and every predicate symbol P to a sub-relational domain $\mathcal{I}(P) \subseteq D^n$ (here n is clearly the arity of f, P).

It is assumed that $\mathcal{I}(\bot) \subseteq D^0$ is the empty sub-relational domain and that $\mathcal{I}(=)_w = \{(a, a) \mid a \in D_w\}$.

DEFINITION 51. Given an $\mathfrak{F}$-model $\mathfrak{M} = (D, \mathcal{I})$ and an n-term $t : n$, the $\mathfrak{F}$-relational map $[\![t]\!]^{\mathfrak{M}} : D^n \longrightarrow D$ is so defined by induction (for all $w \in W$, $\underline{a} \in D^n_w$):

- if $t = x_i$ $(i = 1, \ldots, n)$, then $[\![t]\!]^{\mathfrak{M}}_w(\underline{a}) := \underline{a}_i$;
- if $t = f(t_1, \ldots, t_k)$, then $[\![t]\!]^{\mathfrak{M}}_w(\underline{a}) := \mathcal{I}(f)_w([\![t_1]\!]^{\mathfrak{M}}_w(\underline{a}), \ldots, [\![t_k]\!]^{\mathfrak{M}}_w(\underline{a}))$.

We must now define forcing conditions: this is done in complete analogy with Lewis translation instructions (T2i)-(T2j) from [79] (or, better, as we also have an accessibility relation, with Lewis translation instructions (T2i*)-(T2j*) from Section V of [79]). Notice that: (i) we use model-theoretic forcing instead of a pure syntactic translation into the extensional language of I; (ii) we have typed languages, so our model-theoretic forcing uses finitary assignments; (iii) we modified above the standard definition of a formula, so our truth clause for formulas whose main connective is a modal operator is a combination of the truth clause for $\Box$ and of the truth clause for atomic formulas.

DEFINITION 52. Given an $\mathfrak{F}$-model $\mathfrak{M} = (D, \mathcal{I})$, an n-formula $\phi : n$, a world $w \in W$ and a tuple $\underline{a} \in D^n_w$, the forcing relation $\underline{a} \models^{\mathfrak{M}}_w \phi$ is so defined, by induction:

$$
\begin{array}{lll}
\underline{a} \models^{\mathfrak{M}}_w P(t_1, \ldots, t_k) & \text{iff} & ([\![t_1]\!]^{\mathfrak{M}}_w(\underline{a}), \ldots, [\![t_k]\!]^{\mathfrak{M}}_w(\underline{a})) \in \mathcal{I}(P)_w; \\
\underline{a} \models^{\mathfrak{M}}_w \psi_1 \to \psi_2 & \text{iff} & (\underline{a} \models^{\mathfrak{M}}_w \psi_1 \ \Rightarrow\ \underline{a} \models^{\mathfrak{M}}_w \psi_2); \\
\underline{a} \models^{\mathfrak{M}}_w \forall x_{n+1}\psi & \text{iff} & \text{for all } a \in D_w,\ (\underline{a}, a) \models^{\mathfrak{M}}_w \psi; \\
\underline{a} \models^{\mathfrak{M}}_w (\Box\psi)(t_1, \ldots, t_k) & \text{iff} & \text{for all } w \le v,\ \underline{b} \in D^k_v \\
 & & ([\![t_1]\!]^{\mathfrak{M}}_w(\underline{a}), \ldots, [\![t_k]\!]^{\mathfrak{M}}_w(\underline{a})) D \underline{b} \ \Rightarrow\ \underline{b} \models^{\mathfrak{M}}_v \psi.
\end{array}
$$

We say that $\phi : n$ is valid in $\mathfrak{M}$ iff $\underline{a} \models^{\mathfrak{M}}_w \phi$ holds for all $w \in W, \underline{a} \in D^n_w$.

We underline that, in case $\phi : n$ is just $\Box\psi : n$, the above forcing condition says that *the tuple $\underline{a}$ satisfies $\Box\psi : n$ in w iff for all $w \le v$, all tuples made of v-counterparts of the $\underline{a}$'s satisfy $\psi : n$ in v.* This is just Lewis' translation instruction written in our notation; moreover it coincides with the topological forcing condition (T) from Section 10, in the case of topologies induced by a preorder relation.

11.2 Soundness and Completeness

For the soundness theorem, we first need a suitable instantiation lemma, which is easily proved by induction:

LEMMA 53. *For all $\phi : k$, $v : k$, $t_1 : n, \ldots, t_k : n$ and for all $\underline{a} \in D^n_w$, we have in any $\mathfrak{F}$-model $\mathfrak{M} = (D, \mathcal{I})$:*

(i) $[\![v[t_1,\ldots,t_k]]\!]_w^{\mathfrak{M}}(\underline{a}) \;=\; [\![v]\!]_w^{\mathfrak{M}}([\![t_1]\!]_w^{\mathfrak{M}}(\underline{a}),\ldots,[\![t_k]\!]_w^{\mathfrak{M}}(\underline{a}))$;

(ii) $\underline{a} \models_w^{\mathfrak{M}} \phi[t_1,\ldots,t_k]$ iff $([\![t_1]\!]_w^{\mathfrak{M}}(\underline{a}),\ldots,[\![t_k]\!]_w^{\mathfrak{M}}(\underline{a})) \models_w^{\mathfrak{M}} \phi$.

THEOREM 54. *(Validity). If $\phi : n$ is provable in* **CS4***, then it is valid in every $\mathfrak{F}$-model $\mathfrak{M}$.*

Proof. Rule (*Inst*) is valid by Lemma 53, whereas **S4**-propositional tautologies are valid by conditions (L). Validity of (MP), (Nec), ($\forall$-Ex), ($\forall$-In), ($Refl$) and ($Repl$) are trivial: using the instantiation Lemma 53, we have e.g. for the case of ($\forall$-Ex) (let $\underline{a} = (a_1,\ldots,a_{n+1})$), $\underline{a} \models_w^{\mathfrak{M}} (\forall x_{n+1}\,\psi)[x_1,\ldots,x_n]$ iff $([\![x_1]\!]_w^{\mathfrak{M}}(\underline{a}),\ldots,[\![x_n]\!]_w^{\mathfrak{M}}(\underline{a})) \models_w^{\mathfrak{M}} \forall x_{n+1}\,\psi$ iff $(a_1,\ldots,a_n) \models_w^{\mathfrak{M}} \forall x_{n+1}\,\psi$ and the latter implies $(a_1,\ldots,a_{n+1}) \models_w^{\mathfrak{M}} \psi$, that is $\underline{a} \models_w^{\mathfrak{M}} \psi$. Validity of the continuity schema ($Cont$) follows from the definition of an $\mathfrak{F}$-relational map and Lemma 53 again. ❑

We now sketch in some detail the completeness proof. The first-order (non-modal) language $\mathcal{L}_c$ is obtained by adding to $\mathcal{L}$ a new n-ary predicate symbol $P_{\Box\phi}$ for every n-formula of the kind $\Box\phi : n$ of $\mathcal{L}$. To every modal formula $\psi : m$ of $\mathcal{L}$ we assign a non-modal formula $\psi_c : m$ of $\mathcal{L}_c$ simply by replacing the subformulas of the kind $(\Box\phi)(t_1,\ldots,t_k) : m$ by the atomic formulas $P_{\Box\phi}(t_1,\ldots,t_k) : m$. The classical first-order theory T_c has as proper axioms the formulas $\phi_c : n$ such that $\phi : n$ is provable in **CS4**. Notice that all formulas of $\mathcal{L}_c$ are of the kind $\psi_c : m$ (for suitable $\phi : m$) and that $\psi : m$ turns out to be provable in **CS4** iff $\psi_c : m$ is provable in the classical first-order theory T_c (one direction is trivial from the construction of T_c, for the other side simply observe that T_c has no deductive machinery which is not already available in **CS4**).[39]

We use the letters $w, v, \ldots$ to denote T_c-models (i.e., classical first-order $\mathcal{L}_c$-structures making the universal closures of the proper axioms of T_c true); for a T_c-model w, we use the notation D_w to denote the domain of w, $[\![t]\!]_w$ to denote the interpretation $D_w^n \longrightarrow D_w$ of the term $t : n$ in w, $\underline{a} \models_w \phi_c$ to denote the (finitary assignments) forcing relation in w with respect to classical first-order Tarski semantics.

An *admissible relation* R among T_c-models w, v is a relation $R \subseteq D_w \times D_v$ satisfying the following two requirements, for every $n \geq 0$ and for every $\underline{a} \in D_w^n, \underline{b} \in D_v^n$:

(A1) if $\underline{a}_i R \underline{b}_i$ holds for every $i = 1,\ldots,n$, then $[\![t]\!]_w(\underline{a})\ R\ [\![t]\!]_v(\underline{b})$ holds for every n-term $t : n$;

(A2) if $\underline{a}_i R \underline{b}_i$ holds for every $i = 1,\ldots,n$, then

$$\underline{a} \models_w P_{\Box\phi}(x_1,\ldots,x_n) \;\Rightarrow\; \underline{b} \models_v \phi_c$$

holds for every n-formula $\phi : n$.

Notice that, thanks to the propositional **S4**-axioms, identity relations are admissible and admissible relations compose.

Following model-theoretic terminology, we call *n-type* a set Γ of n-formulas of $\mathcal{L}_c$; an n-type is T_c-consistent iff for no finite conjunction $\psi_c : n$ of formulas from Γ, the formula $\neg\psi_c : n$ is provable in T_c. For a T_c-model w and for an n-tuple $\underline{a} \in D_w^n$, the n-type $\Gamma_{\underline{a}}$ is

[39] For classical first-order logic, we keep for uniformity reasons the same typed framework of Subsection 9.1.

the set of n-formulas $\psi_c : n$ such that $\underline{a} \models_w \psi_c$. An n-type Γ is *realized* in w iff for some $\underline{a} \in D_w^n$ we have $\Gamma \subseteq \Gamma_{\underline{a}}$. It follows from completeness theorem for first-order theories, that a T_c-consistent n-type is always realized in a T_c-model. The following lemma is a crucial step:

LEMMA 55. *Let w, v be T_c-models, $\underline{a} \in D_w^n, \underline{b} \in D_v^n$; if $\{\phi_c : n \mid \underline{a} \models_w P_{\Box\phi}(x_1, \ldots, x_n)\} \subseteq \Gamma_{\underline{b}}$, then there is an admissible relation $D_{wv} \subseteq D_w \times D_v$ such that $\underline{a}_i D_{wv} \underline{b}_i$ holds (for every $i = 1, \ldots, n$).*

Proof. Define D_{wv} as follows: say that $aD_{wv}b$ holds iff there is a term $t : n$ such that $[\![t]\!]_w(\underline{a}) = a$ and $[\![t]\!]_v(\underline{b}) = b$. Condition (A1) holds trivially, whereas for condition (A2) we need the continuity axiom schema. In fact, fix a k-tuple $t_1 : n, \ldots, t_k : n$ of n-terms such that

$$([\![t_1]\!]_w(\underline{a}), \ldots, [\![t_k]\!]_w(\underline{a})) \models_w P_{\Box\phi}(x_1, \ldots, x_k)$$

holds; by the instantiation Lemma 53(ii) (which holds in classical first-order semantics as well), we get $\underline{a} \models_w P_{\Box\phi}(t_1, \ldots, t_k)$. Since $(\Box\phi)[t_1, \ldots, t_k] \to \Box(\phi[t_1, \ldots, t_k]) : n$ is provable in **CS4**, by the definition of T_c we have $\underline{a} \models_w P_{\Box(\phi[t_1,\ldots,t_k])}(x_1, \ldots, x_n)$. By the hypothesis of the lemma, we get $\underline{b} \models_v (\phi[t_1, \ldots, t_k])_c = \phi_c[t_1, \ldots, t_k]$, that is (by the instantiation lemma) $([\![t_1]\!]_v(\underline{b}), \ldots, [\![t_k]\!]_v(\underline{b})) \models_v \phi_c$. ❑

THEOREM 56. *(Completeness).*[55], [51] *If a formula $\phi : n$ is not provable in* **CS4**, *then there are a frame $\mathfrak{F}$ and an $\mathfrak{F}$-model $\mathfrak{M} = (D, \mathcal{I})$, in which $\phi : n$ is not valid.*

Proof. We use the 'subordination frame' technique [67][40] and inductively define a tree $\mathfrak{F} = (W, \leq)$ of T_c-models and of admissible relations as follows. The root of $\mathfrak{F}$ is any T_c-model realizing the T_c-consistent n-type $\{\neg\phi_c : n\}$. Let the node w of $\mathfrak{F}$ be already defined; for every pair $\langle \underline{a}, \Box\psi : m\rangle$ such that $\underline{a} \not\models_w P_{\Box\psi}(x_1, \ldots, x_m)$, we take a T_c-model v, an admissible relation $D_{wv} \subseteq D_w \times D_v$ and a tuple $\underline{b}$ from D_v such that $\underline{b} \not\models_v \psi_c$ and $\underline{a}_i D_{wv} \underline{b}_i$ (for $i = 1, \ldots, n$): this is possible, by Lemma 55, because the m-type

$$\{\psi'_c : m \mid \underline{a} \models_w P_{\Box\psi'_c}(x_1, \ldots, x_m)\} \cup \{\neg\psi_c : m\}$$

is T_c-consistent by propositional modal validities. These v and these D_{wv} are all added to the already defined part of $\mathfrak{F} = (W, \leq)$ in the inductive step of the construction.

Now that $\mathfrak{F}$ has been built, it is clear that the collection of the supports D_w — and of the compositions of the admissible relations D_{wv} introduced during the construction of $\mathfrak{F}$ — gives in the obvious way an $\mathfrak{F}$-relational domain D. Similarly, the collection of the interpretation functions of the various T_c-models $w \in W$ can be glued together to form a global interpretation function $\mathcal{I}$ (notice, however, that (A1) is needed here to show that the global interpretation of a function symbol is an $\mathfrak{F}$-relational map). It remains to prove a standard 'truth-lemma', namely that we have

$$\underline{a} \models_w \psi_c \quad \text{iff} \quad \underline{a} \models_w^{\mathfrak{M}} \psi$$

for all $\psi : m, w \in W, \underline{a} \in D_w^m$. This is trivial, however, by the construction of $\mathfrak{F}$ and by (A2). ❑

[40]If we allow categories (and not just preordered sets) to be frames, there is an obvious 'canonical-model'-like technique that works: just take as $\mathfrak{F}$ the category having T_c-models as objects and admissible relations as arrows.

As pointed out above, Theorem 56 covers also bundle semantics.[41] A past-possibility tense operator $\Diamond_p$ can be added both to the syntax and to the semantics (Theorems 54 and 56 extend trivially): we call the related system $\mathbf{CS4_t}$. More precisely, to get $\mathbf{CS4_t}$, we add for instance to Table 1 the axiom schema $\phi \to \Box\Diamond_p\psi : n$ and the rule $\phi \to \Box\psi : n / \Diamond_p\phi \to \psi : n$ (notice that the continuity principle $\Diamond_p(\phi[\underline{t}]) \to (\Diamond_p\phi)[\underline{t}] : n$ for $\Diamond_p$ follows from the corresponding continuity principle (*Cont*) for $\Box$). The semantic forcing condition for $\Diamond_p$ says that a n-tuple $\underline{a}$ from D_w^n forces $(\Diamond\psi)(t_1, \ldots, t_k) : n$ iff there is a k-tuple $\underline{b}$ that forces $\psi : k$ *of which* $([\![t_1]\!]_w^{\mathfrak{M}}(\underline{a}), \ldots, [\![t_k]\!]_w^{\mathfrak{M}}(\underline{a}))$ is a k-tuple of (respective) w-counterparts.

Natural conditions (like being totally defined, partial functions, etc.) can be imposed on the transition relations D_{vw}: such conditions are modally axiomatizable by suitable axiom schemata in $\mathbf{CS4_t}$. The summary of such extensions [55] of Theorems 54 and 56 is given in Table 2 below:[42] the meaning of that Table is that the semantic condition in the third column is axiomatized by any one of the equivalent axiom schemata written in the corresponding second column (the notation D_{vw}^o means the converse relation of D_{vw}). Notice that the equivalent axiom schemata in the second column sometimes involve properties of substitutions and sometimes they are just well-known standard modal principles (this explains why, if properties of substitutions are built-in in the language through definitions like 39(d), then *there is no way of blocking the derivation of the corresponding modal principles*).

Table 2.

No.	Equivalent Axiom Schemata	Semantic Conditions
1	$z_1 = z_2 \to \Box(z_1 = z_2) : 2$ $\Diamond_p(z_1 = z_2) \to z_1 = z_2 : 2$ $\Box(\phi[\underline{x}, y, y]) \to (\Box\phi)[\underline{x}, y, y] : n{+}1$	all D_{vw} are partial functions
2	$\exists y\Box\phi \to \Box\exists y\phi : n$ $\Diamond_p\exists y\phi \to \exists y\Diamond_p\phi : n$ $\Box(\phi[\underline{x}]) \to (\Box\phi)[\underline{x}] : n{+}1$	all D_{vw} are totally defined relations
3	$z_1 \neq z_2 \to \Box(z_1 \neq z_2) : 2$ $\Diamond_p(z_1 \neq z_2) \to z_1 \neq z_2 : 2$ $(\Diamond_p\phi)[\underline{x}, y, y] \to \Diamond_p(\phi[\underline{x}, y, y]) : n{+}1$	all D_{vw}^o are partial functions
4	$\forall y\Box\phi \to \Box\forall y\phi : n$ $\Diamond_p\forall y\phi \to \forall y\Diamond_p\phi : n$ $(\Diamond_p\phi)[\underline{x}] \to \Diamond_p(\phi[\underline{x}]) : n{+}1$	all D_{vw}^o are totally defined relations

11.3 Conclusions

At the end of a lengthy detour around alternative semantics for predicate modal logics, we met in the present section systems $\mathbf{CS4}$, $\mathbf{CS4_t}$ together with the 'old-style' alternative

[41] For plain topological semantics (i.e., for bundles over the singleton topological space), an extra axiom schema is needed, see [56], [51].

[42] In particular, the axiomatization of the essential geometric morphisms semantics outlined at the beginning of Subsection 10.2 corresponds to lines 1+2 of Table 2. From the axiom schemata of lines 1+2, the openness principle $(\Box\phi)[\underline{t}] \leftrightarrow \Box(\phi[\underline{t}]) : n$ can be derived for $\Box$, but *not* for $\Diamond_p$.

semantics proposed in the sixties by D. Lewis. In fact, although systems **CS4**, $\mathbf{CS4_t}$ were built in [55], [56], [51] in order to axiomatize the mathematical frameworks outlined in Subsection 10.2, we just showed that such systems axiomatize counterpart semantics as well. We feel that this unexpected confluence among mathematically and philosophically motivated research should be taken seriously. We conclude the second part of the chapter by giving some more information on this topic.

- In Definition 52, variables are given only *local* values: this is because Definition 52 uses finitary assignments relative only to the possible world in which a formula is evaluated. This seems to be in accordance with concrete use of free variables as indexicals in linguistics [19] (reference of indexicals is fixed by the pragmatic context in which a sentence containing them is uttered). Moreover, *de re* statements like 'you will eventually spend holidays at the seaside' or 'some actual women will be sooner or later elected as the president of the USA' are correctly evaluated by referring to a future state of affairs in which the individual in question *exists*.[43] This is why, as already pointed out in [79] (p. 124), the converse of the Barcan formula is a *valid* modal principle: if $\exists y \Diamond P(y)$ is true at w, then there is $a \in D_w$ which has a v-counterpart a' enjoying P and this implies that $\Diamond \exists y P(y)$ is true in w as well. The role played by the converse of the Barcan formula in varying domains semantics is played here by the axiom schemata of line 2 of Table 2: such axiom schemata are valid whenever individuals never 'die' in accessible worlds (from the topological point of view, the axiom schemata of line 2 of Table 2 express the special condition that projections from fibered products are open maps).

- Our axiomatization of counterpart semantics seems to clarify some the classical objections that have been raised against it. For instance, Kripke argued in [74] that since the necessity of identity

  (9) $x_1 = x_2 \to \Box(x_1 = x_2) : 2$

  (which is invalid in counterpart semantics) follows from

  (10) $\Box(x_1 = x_1) : 1$

  and from

  (11) $x_1 = x_2 \wedge \Box(x_1 = x_1) \to \Box(x_1 = x_2) : 2$

  then the counterpart theorist is either forced to reject the Leibniz principle of replacement or to reject the evident fact that everything is necessarily equal to itself. However, (11) is *not* an example of the Leibniz principle: the latter principle (which is obtained from the axiom schema (*Repl*) and the rule (*Inst*) of Table 1) can be formulated as:

  (12) $u = v \wedge \phi[\underline{x}, u] \to \phi[\underline{x}, v] : n$

  (where $\phi : n+1$ is an $n+1$-formula and u, v are n-terms). That (11) cannot be confused with the Leibniz principle is clear from the following counterexample

[43] Notice that no existence predicate is used in Lewis' counterpart semantics (but see [23] for an extension in this sense).

(which is a special case of topological bundle semantics from Subsection 10.2): interpret n-ary predicate letters as subsets of $\mathbb{R}^n$, let identity, quantifiers, and Boolean connectives be interpreted as in first-order extensional Tarski semantics and let $\Box$ be interpreted as the interior operator in the product Euclidean topology. It is clear that in this interpretation any correct version (like (12)) of the Leibniz principle holds (trivially, equal points belong to the same subsets). Moreover, the interior of $x_1 = x_1$ contains all points (because the interior of the whole space is the whole space), which means that (10) is valid. Nevertheless, the necessity of the identity (9) is false, because the interior of the diagonal in the plane is empty. Consequently, we must admit that in order to 'derive' (9) we used something quite different from the Leibniz principle (and, as a matter of fact, we used (11) which is easily seen to be invalid).

- Notice that the formula $x_1 = x_2 \wedge \Box R(x_1, x_2) \to \Box R(x_1, x_1) : 2$ is valid, whereas the formula $x_1 = x_2 \wedge \Diamond R(x_1, x_2) \to \Diamond R(x_1, x_1) : 2$ is not. The reason why this happens is that the continuity principle is different for 'interior' and 'closure' (to derive the former formula we need $(\Box R(x_1, x_2))[x_1, x_1] \to \Box(R(x_1, x_2)[x_1, x_1]) : 2$ which is not available for $\Diamond$, because the continuity principle for $\Diamond$ is the converse). This explains why, in order to axiomatize counterpart semantics, we cannot simply use 'generic restrictions' to quantifiers and identity principles that apply to arbitrary intensional contexts.

- In our typed systems, there is a very natural way of formalizing the *de re*/*de dicto* distinctions: we can use $(\Box\phi)[\underline{t}] : n$ and $\Box(\phi[\underline{t}]) : n$, respectively. Constants which are non-rigid designators[44] can consequently be treated either by dropping the continuity principle for them or, in a more uniform way, by taking a suitable many-sorted approach [54] (validity and completeness theorems extend trivially). The notation $(\Box\phi)[\underline{t}] : n$ is very similar to λ-abstraction notation of intensional semantics: in **CS4**-like systems, it can be seen just as a notational variant of λ-abstraction whenever the axiom schema $\Box(\phi[\underline{x}]) \to (\Box\phi)[\underline{x}] : n{+}1$ from line 2 of Table 2 holds.

- Whenever the axiom schemata from line 2 of Table 2 do not hold however (i.e., whenever transition relations are not totally defined), the λ-notation is insufficient if types are omitted: this is because $(a_1, a_2) \models_w^{\mathfrak{M}} \Diamond P(x_1)$ may be false when $a_1 \models_w^{\mathfrak{M}} \Diamond P(x_1)$ holds (a_2 may not have enough counterparts). Hence, the formulas $\Diamond P(x_1) : 2$ and $\Diamond P(x_1) : 1$ should be kept as distinct: the former is relative to contexts in which two free variables (say, two indexicals) have been assigned a value, the latter to contexts in which only one variable has been assigned a value.

- The need for types explains why sometimes people got the wrong impression that basic principles like Aristotle's law fail in Lewis' semantics. What may fail is a formula like $\Box(P(x_1) \to Q(x_2)) \to ((\Box P(x_1))[x_1] \to (\Box Q(x_1))[x_2]) : 2$, which is *not* an example of the Aristotle schema; the latter obviously is $\Box(\phi \to \psi) \to (\Box\phi \to \Box\psi) : n$ and, as such, it can be instantiated only into valid formulas, like e.g. $\Box(P(x_1) \to Q(x_2)) \to (\Box P(x_1) \to \Box Q(x_2)) : 2$.

[44] A non-rigid designator constant c is interpreted as a collection of elements $\{c_w \in D_w \mid w \in W\}$ such that c_v needs not be a v-counterpart of c_w when $w \leq v$ holds. Using the isomorphism of $\mathfrak{F}$-relational domains and preordered bundles over $\mathfrak{F}$, these are exactly arbitrary *non-continuous* functions from the terminal bundle $\mathfrak{F}$ to D.

Additional comments can be found in [54]; still the overall implications of the above systematization of counterpart semantics need to be further explored.

ACKNOWLEDGEMENTS

The first author wishes to thank the participants of a research seminar at Roskilde University for comments on the first part of the chapter. The second author wishes to thank all the people (a partial list includes: S. Artemov, J. van Benthem, G. Corsi, C. Pizzi, V.B. Shehtman, D.P. Skvortsov, F. Wolter, M. Zakharyaschev), who helped him in collecting relevant important information.

1 INTRODUCTION

A logic is called *higher order* if it allows for quantification (and possibly abstraction) over higher order objects, such as functions of individuals, relations between individuals, functions of functions, relations between functions, etc. Higher order logic (often also called *type theory* or the *Theory of Types*) began with Frege, was formalized in Russell [46] and Whitehead and Russell [52] early in the previous century, and received its canonical formulation in Church [14].[1] While classical type theory has since long been overshadowed by set theory as a foundation of mathematics, recent decades have shown remarkable comebacks in the fields of *mechanized reasoning* (see, e.g., Benzmüller et

[1]For a good survey of (non-modal) higher order logic, see van Benthem and Doets [8]; for a textbook development, Andrews [3].

al. [9] and references therein) and *linguistics*. Since the late 1960's philosophers and logicians, for various reasons which we will dwell upon, have started to combine higher order logic with modal operators (Montague [35, 37, 38], Bressan [11], Gallin [22], Fitting [19]). This combination results in *higher order modal logic*, the subject of this chapter.

The chapter will be set up as follows. In the next section we will look at possible motivations behind the idea of combining modality and higher order logic. Then, in Section 3, Richard Montague's system of 'Intensional Logic', by far the most influential of higher order modal logics to date, will be discussed. This logic will be shown to have some limitations. One of these is that, despite its name, the logic is not fully intensional, as it validates the axiom of Extensionality. This leads to a series of well-known problems centering around 'logical omniscience'. Another limitation is that the logic is not Church-Rosser (it matters in which order λ-conversions are carried out). These limitations can be overcome and the remaining sections of the chapter will contain an exposition of a modal type theory that is intensional in two ways: in the sense of being a modal logic and in the sense that Extensionality does not hold. The logic in itself is not strong enough to make the usual rules of λ-conversion derivable, but these rules can consistently be added as an axiomatic extension and in that case the Church-Rosser property will hold (as an alternative, the rules can be hard-wired into the theory, in which case the theory is also Church-Rosser). Section 4 will introduce the basic syntax and semantics of this logic, Section 5 will give a tableau calculus, and Section 6 provides some elementary model theory in the form of a model existence theorem and its usual corollaries, such as generalized completeness. We conclude with a conclusion.

2 MOTIVATION

Why should one want to combine modality with quantification or abstraction over objects of higher type? Possible reasons come from areas as diverse as rational theology, the axiomatization of classical mechanics, the semantics of natural language, and modal logic itself. Let us look at each of these in turn.

2.1 The Ontological Argument

Anselm (1033–1109) proved the existence of God by defining him as "a being than which none greater can be thought" and by arguing that, since that definition can be understood, such a being must "exist in the understanding". But if this being exists in the understanding, one can also think of it as existing in reality and, since real existence is "greater" than mere conceptual existence, the "being than which none greater can be thought" must truly exist. Otherwise one could think of an even greater being that did truly exist. Moreover, by an analogous argument, Anselm comes to the conclusion that it is even *impossible* to think of God as nonexistent. For something that cannot be thought of as nonexisting is greater than something that can be so thought of. It follows that a "being than which none greater can be thought" cannot merely exist contingently, otherwise one could think of an even greater being with necessary existence.

Anselm's original argument was phrased in ordinary Latin and its lack of precision may be deemed a weakness by some, but increasingly more precise variants of the argument have been put forward by Descartes, Leibniz and, more recently, Gödel [24]. Gödel's argument centers around "positive" properties and being a god can be defined as having

every positive property. There are axioms regulating the behaviour of the predicate "positive", stipulating e.g. that exactly one of a property or its complement is positive, that, whenever P is positive and the extension of P necessarily is a subset of that of Q, Q is also positive, that necessary existence is a positive property, etc., etc. The conclusion is identical to that of Anselm's: God necessarily exists (and is unique), but this time premises and argument are spelled out in great detail (some of the premises may be hard to swallow, even for those who are willing to accept the conclusion). The argument combines quantification over properties with the modal notions of necessity and possibility and as a consequence is naturally framed in a higher order modal logic. For a recent evaluation of Gödel's proof, its history, a precise formalization, and extensive discussion of the argument and subsequent literature, see Fitting [19].

2.2 Axiomatization of Classical Mechanics

As a second example of the use of a higher order modal logic, let us briefly mention the proposal in Bressan [11] for a logical foundation of classical mechanics in general and Mach's often criticized definition of *mass* in particular. Mach's definition has a counterfactual character and this is where modality comes in. Suppose we have a particle M, whose mass is to be established. Fix some inertial frame. If a particle M_1 with unit mass and velocity v_1 parallel to M's velocity v were to collide with M at time t, then, if the changes in the velocities of M and M_1 at t would be $\Delta v \neq 0$ and Δv_1 respectively, the mass of M would be $\Delta v_1/\Delta v$. This means that the mass of M *can* be established experimentally, but, as Bressan points out, in an axiomatic foundation of physics it is important that the axioms do not imply that the experiment actually takes place, as many physically possible situations that one wants to be able to describe are in fact incompatible with such an assumption. Thus, Bressan argues, an axiomatization based on a modal logic is required. Bressan's logic is not only modal but also higher order, as it essentially replaces set theory and concepts such as natural number and real number should therefore be definable within the logic (for example, the natural number n is defined as the property of having n elements, $\lambda F.\exists_n x\, Fx$, with $\exists_n$ the obvious abbreviation, in Frege's way).

2.3 The Semantics of Natural Language

A third illustration of the use of higher order modal logic comes from Richard Montague's [36, 37, 38] contributions to the semantics of natural language, work that truly revolutionized the subject.[2] It was Montague's aim to treat the semantics of natural language in a completely precise way and to provide a truth definition for sentences of (say) English very much in accordance with the usual Tarski truth definition for logical languages. One way to achieve this is to directly assign modeltheoretic objects to syntactic expressions. This road was taken in Montague [36], but a way that is easier to go in practice is to translate expressions of English to an interpreted logical language. The interpretation of the logic then indirectly provides a model theory for the fragment of English under consideration. This is done in Montague [37, 38]. The logic used is higher order and modal.

[2]The presentation here is inspired by Montague's work but deviates from it in many minor details.

Why did Montague use a logic that combined modality with higher order quantification and abstraction? It is not difficult to see why one should want a *modal* logic for the treatment of natural language, as the latter abounds with phrases and constructions that have motivated modal logics in the first place (temporal operators, counterfactuals, true modals like *can, might* and *would*, propositional attitude verbs, and so on). But the reason for employing a *higher order* logic may be less clear to logicians not working in linguistics. Although natural language is able to quantify over properties and in general can express things that are not normally expressible with first order means only (think of sentences like *most men have green eyes*, for example), this is not the sole or even the primary reason for using type theory in linguistics. The main reason is that in type theory the availability of lambda-abstraction allows for a *closure of the gap between the syntactic forms of natural language expressions and those of their logical translations.*

Let us illustrate this with the help of the simple example sentence in (1a). Linguists almost universally provide this sentence with a constituent structure along the lines of (1b), i.e. the determiner *every* is thought to form a constituent (a noun phrase) with the noun *elephant* and this resulting constituent then forms another constituent (a sentence) with the verb phrase *danced*. Essentially, therefore, the linguistic analysis of such sentences follows the pre-Fregean pattern of dividing each sentence in a subject (here *every elephant*) and a predicate (*danced*).

(1) a. every elephant danced
b. [[every elephant] danced]
c. $\forall x\,(Ex \to Dx)$
d. $(((\lambda P_1 \lambda P_2.\forall x\,(P_1 x \to P_2 x))E)D)$

The analysis of natural language expressions as consisting of larger and larger clusters of constituents is an important feature of modern linguistic theory, and syntacticians are in the possession of a whole battery of empirical tests to determine constituenthood, but the syntactic form that is given to any sentence is not in general congruent with its usual logical form. The structure in (1b), for example, is fundamentally different from that of the logical sentence (1c), the usual translation of (1a). While the constituents *elephant* and *danced* in (1b) reappear in (1c) as E and D respectively, there are no continuous parts of (1c) corresponding to *every* or *every elephant.* This gap between logical form and linguistic form is what logicians such as Russell and Quine had in mind when they alluded to the *misleading form* of natural language: the 'correct' form of (1a) according to this perspective is (1c); (1b) merely misleads. This point of view could never be shared by the linguistic community, as giving up the standard notion of constituenthood would greatly diminish the predictive power of syntactic theory.

Can the gap be bridged? Here lambdas come to the rescue, for in a higher order logic with lambda abstraction (1c) can alternatively be written as (1d). While (1c) is the β-normal form of (1d), the latter, but not the former, follows the syntactic pattern in (1b). Lambdas allow us to have our cake and eat it. They allow us to maintain the view that the logical form of an expression closely mirrors its syntactic form without having to give up the usual logical analysis.

In fact, with lambdas in hand, it is now possible to think of inductive translation mechanisms sending syntactic forms to logical forms. In the present case one can translate *every* as $\lambda P_1 \lambda P_2.\forall x\,(P_1 x \to P_2 x)$, a term containing two λ-abstractions over predicates, *elephant* can be translated as the predicate constant E and *dances* as D. If

one lets onstituent formation correspond to application, [every elephant] translates as $(\lambda P_1 \lambda P_2.\forall x\,(P_1 x \rightarrow P_2 x))E$, which reduces to $\lambda P_2.\forall x\,(Ex \rightarrow P_2 x)$ (a *generalized quantifier*), and a further step shows that (1b) translates as (1d), or, equivalently, (1c).

But now a difficulty crops up. If [every elephant] translates as $\lambda P_2.\forall x\,(Ex \rightarrow P_2 x)$, how are we going to translate the verb phrase [fed [every elephant]] in (2b), the syntactic analysis of (2a)? The verb *fed* should presumably be translated as some binary relation F between individuals and this is not the kind of object that $\lambda P_2.\forall x\,(Ex \rightarrow P_2 x)$ can apply to (or that can apply to that term).

Montague solved this by complicating the translations of transitive verbs like *fed*. He translated *fed* not simply as F, but as the term $\lambda Q \lambda x.Q(Fx)$[3] (with Q ranging over quantifiers and x over individuals), and if the translations for *a* and *girl* are chosen to be $\lambda P_1 \lambda P_2.\exists x\,(P_1 x \wedge P_2 x)$ and G respectively, the translation in (2c) results, as the reader may care to verify.

(2) a. a girl fed every elephant

b. [[a girl][fed [every elephant]]]

c. $\exists x\,(Gx \wedge \forall y\,(Ey \rightarrow Fxy))$

d. $\forall y\,(Ey \rightarrow \exists x\,(Gx \wedge Fxy))$

Translating an intransitive verb like *fed* as $\lambda Q \lambda x.Q(Fx)$, and not as the simpler and more intuitive binary relation symbol F, seems ad hoc, however. In fact, researchers in the Montague tradition have argued that a combination of giving simple translations with providing systematic ways of obtaining certain translations from others is not only more elegant than Montague's original approach was, but also gives a better fit with the data (Partee and Rooth [44], Hendriks [26, 27]). Discussing the calculi for 'shifting' translations that these authors have proposed would lead us too far afield here. Suffice it to say that from their considerations, in conjunction especially with those of van Benthem [7], the picture emerges that *linear combinators*[4] play an all-important role. The translation of *fed* as $\lambda Q \lambda x.Q(Fx)$, for example, can be thought to result from applying the linear combinator $\lambda R \lambda Q \lambda x.Q(Rx)$ to a basic translation F, while applying the combinator $\lambda R \lambda Q_1 \lambda Q_2.Q_1(\lambda y.Q_2(\lambda x.Rxy))$ to F results in a translation that eventually leads to (2d), another possible translation of the original sentence.[5]

For more information on Montague's approach to the semantics of natural language, see the textbooks Dowty et al. [15] and Gamut [23], the survey in Partee with Hendriks [43], and the chapter on Linguistics by Moss and Tiede in this handbook (Chapter 19). Montague's higher order modal logic **IL** will be described shortly.

---

[3] For the sake of exposition I am disregarding Montague's intensional operators here.

[4] A *combinator* is a closed λ-term built from variables with the help of λ-abstraction and application only. A combinator M is *linear* if each abstractor λX in M binds exactly one X in M.

[5] While linear combinators play an important role in semantic composition, just letting them apply to semantic translations without further ado results in serious overgeneration. Applying the permutation operator $\lambda R \lambda y \lambda x.Rxy$ to F above, for example, would allow the derivation of translations for *a girl fed every elephant* that are normally associated with *an elephant fed every girl*. Partee and Rooth [44] and Hendriks [26, 27] provide calculi in which permutation is not derivable, while de Groote [25] and Muskens [40, 41] base their grammars entirely on linear lambda terms but make sure that any permutation in semantics is mirrored by a permutation in syntax.

2.4 Modal Logics with Propositional Quantifiers

Motives inherent in modal logic itself may also lead to a combination of modality with higher order, or at least second order, quantification. The standard definition of the truth of a formula in a frame at a world is defined with the help of a quantification over valuations and therefore essentially corresponds to universal quantification over sets of possible worlds. More precisely, the frame truth of a formula φ containing proposition letters $p_1, \ldots, p_n$ corresponds to the truth of a formula $\forall P_1 \ldots P_n \varphi'$, where φ' is the standard translation $ST(\varphi)$ of φ; see Chapter 1 by Blackburn and van Benthem in this handbook. This gives *global* second order quantification, with the second order universal quantifiers taking scope over the whole formula, but one may now be inspired to add quantifiers $\forall p$ and $\exists p$ ranging over sets of possible worlds to given modal logics. This was done in Kripke [33] and modal logics with propositional quantifiers have been studied by a variety of authors since, amongst whom are Bull [12], Fine [16], Kaplan [30], Kremer [32, 31], Fitting [18], and ten Cate [13], to name but a few.

Semantically there are two lines of attack here. If one has a frame $\langle W, R\rangle$, the most obvious interpretation of quantifiers $\forall p$ and $\exists p$ in that frame lets them range over the power set $\mathcal{P}(W)$ of the set of possible worlds W. This is called the *second order* (or *primary) interpretation* of propositional quantifiers. If propositional quantifiers are added to a modal logic **L** in this way (where **L** = **S4**, **S5**, etc.), the resulting logic is called **L**π+. The behaviour of the logics thus obtained rather varies. **S5**π+, on the one hand, is decidable (Fine [16], Kaplan [30]), as this logic is embeddable into monadic second order logic. (The embedding essentially is the standard translation, with clauses such as $ST(\Box\varphi) = \forall x ST(\varphi)$ and $ST(\forall p\varphi) = \forall P\, ST(\varphi)$.) Fine and Kaplan also axiomatize **S5**π+. The logics **K**π+, **T**π+, **K4**π+, **B4**π+, **S4.2**π+, and **S4**π+, on the other hand, are recursively isomorphic to full second order logic (this was proved independently by Kripke and Fine; Fine [16] has a weaker result).

In order to obtain nice proof systems for modal logics with propositional quantification, one can also follow the example of Henkin [28], who, in the context of higher order logic, defined a class of models in which higher order quantifiers do not necessarily range over *all* subsets of the relevant domains, but only over designated subsets of them. In the present context such a set-up means that frames $\langle W, R\rangle$ are replaced by triples $\langle W, R, \Pi\rangle$ such that $\Pi \subseteq \mathcal{P}(W)$. Here Π must be closed under boolean operations, including arbitrary unions and intersections and it must be the case that $R[P] \in \Pi$ and $R^{-1}[P] \in \Pi$ whenever $P \in \Pi$ (see e.g. Thomason [50], who considers such structures for tense logics). Propositional quantification is now interpreted as quantification over Π. This is the so-called *first order* (or *secondary*) *interpretation* of propositional quantifiers. The resulting logics are denoted as **S4**π, **S5**π, etc., according to the constraints that are put on accessibility relations R. All these logics are axiomatizable with the help of reasonable axioms.

How does the axiomatization of **S5**π that one gets in this way (basically the usual **S5** axioms and rules + the usual quantification axioms and rules for propositional quantification) compare to the one obtained by Fine and Kaplan? Curiously, an axiomatization of **S5**π+ requires one additional axiom, namely

(3) $\exists p(p \wedge \forall q(q \rightarrow \Box(p \rightarrow q)))$

A little reflection shows that if this formula is evaluated in a world w in a frame $\langle W, R\rangle$ using the primary interpretation, it is true, with $\{w\}$ as a sole witness for p. On the other hand, evaluation with respect to w in a frame $\langle W, R, \Pi\rangle$ may not result in truth, as there

may be no $P \in \Pi$ such that $w \in P$ and $P \subseteq P'$ for all P' such that $w \in P' \in \Pi$. A very similar situation obtains in higher order logic. In the models of Henkin [28] sets may be so sparse that there are not enough of them to distinguish between objects that are in fact not identical. Two distinct objects d_1 and d_2 may have exactly the same properties, and in particular $\{d_1\}$ may fail to exist (Andrews [2]). In a modal context definability of singleton sets $\{w\}$ can be enforced through the introduction of *nominals* (Blackburn et al. [10], Areces and ten Cate, Chapter 14 of this handbook).

3 MONTAGUE'S INTENSIONAL LOGIC

In the previous section we explained some of Montague's ideas with the help of a non-modal logic, but Montague himself actually framed them in **IL** (Intensional Logic), a higher order modal logic that will be discussed in this section. (See also Moss and Tiede's Chapter 19 of this handbook. For a highly interesting alternative to Montague's **IL**, see Zalta [53, 54, 55]). The logic is an extension of Church's [14] theory of types and inherits many, though not all, of the latter's properties.

3.1 Overview of **IL**

In order to set up the logic, one first needs to define a simple type system.

DEFINITION 1. The set of **IL** *types* is the smallest set of strings such that:

(i) e and t are **IL** types;

(ii) If α and β are **IL** types, then $(\alpha\beta)$ is an **IL** type;

(iii) If α is an **IL** type, then $(s\alpha)$ is an **IL** type.

Here the type e is the type of *entities*, while t is the type of *truth-values*. Note that, while s can be used to form complex **IL** types, it is not itself an **IL** type. The intended interpretation of the types defined here is that objects of a type $\alpha\beta$ (also written $\alpha \to \beta$) are functions from objects of type α to objects of type β and that objects of type $s\alpha$ are functions from the set of possible worlds to objects of type α.

The next step is to define the *terms* of **IL**. It will be assumed that each **IL** type α comes with a denumerably infinite set of variables and a countable set of constants. Terms are built up from these as follows.

DEFINITION 2. Define, for each **IL** type α, the set of **IL** terms T_α as follows.

(i) Every constant or variable of any type α is an element of T_α;

(ii) If $A \in T_{\alpha\beta}$ and $B \in T_\alpha$, then $(AB) \in T_\beta$;

(iii) If $A \in T_\beta$ and x is a variable of type α then $(\lambda x.A) \in T_{\alpha\beta}$;

(iv) If $A, B \in T_\alpha$ then $(A \equiv B) \in T_t$;

(v) If $A \in T_\alpha$ then $({}^\wedge A) \in T_{s\alpha}$;

(vi) If $A \in T_{s\alpha}$ then $({}^\vee A) \in T_\alpha$.

So we have application and abstraction, identity, and "cap" and "cup" operators that, as we will see, are very much analogous to application and abstraction. If $A \in T_\alpha$ we will often indicate that fact by writing A_α. Terms of type t are called *formulas* and we often use metavariables φ, ψ, etc. to range over them.

Definition 2 does not seem to provide us with the expressivity that we want, as the common logical operators, including the modal $\Box$ and $\Diamond$ seem to be absent, but in fact such operators are definable from the ones just adopted (Henkin [29], Gallin [22]).

DEFINITION 3. Write

$$\begin{aligned}
\top &\text{ for } (\lambda x_t.x) \equiv (\lambda x_t.x),\\
\bot &\text{ for } (\lambda x_t.x) \equiv (\lambda x_t.\top),\\
\neg\varphi &\text{ for } \bot \equiv \varphi,\\
\varphi \wedge \psi &\text{ for } (\lambda f_{tt}.f\varphi \equiv \psi) \equiv (\lambda f_{tt}.f\top),\\
\forall x_\alpha \varphi &\text{ for } (\lambda x_\alpha.\varphi) \equiv (\lambda x_\alpha.\top), \text{ and}\\
\Box\varphi &\text{ for } {}^\wedge\varphi \equiv {}^\wedge\top.
\end{aligned}$$

Other operators will have their usual definitions.

Whether these abbreviations make sense can be checked as soon as we are in the possession of a semantics for the language. So let us turn to that.

DEFINITION 4. A *(standard) model* for **IL** is a triple $\langle D, W, I\rangle$ such that D and W are non-empty sets and I is a function with the set of all constants as its domain, such that $I(c) \in D_{s\alpha}$ for each constant c of type α, where the sets D_α are defined using the following induction.

$$\begin{aligned}
D_e &= D\\
D_t &= \{0, 1\}\\
D_{\alpha\beta} &= \{F \mid F : D_\alpha \to D_\beta\}\\
D_{s\alpha} &= \{F \mid F : W \to D_\alpha\}.
\end{aligned}$$

The function I is called an *interpretation* function. Intuitively, we interpret D as a domain of possible individuals and W as a set of possible worlds.

In order to interpret terms on models, we additionally need to define an *assignment* to $M = \langle D, W, I\rangle$ as a function a with the set of all variables as its domain, such that $a(x) \in D_\alpha$ if x is of type α. The notation $a[d/x]$ is defined as usual. Terms can now be evaluated on models with the help of a Tarski-style truth definition.

DEFINITION 5. The *value* $\|A\|^{M,w,a}$ of a term A on a model $M = \langle D, W, I\rangle$ in world $w \in W$ under an assignment a to M is defined in the following way:

(i) $\|c\|^{M,w,a} = I(c)(w)$ if c is a constant; $\|x\|^{M,w,a} = a(x)$ if x is a variable;

(ii) $\|AB\|^{M,w,a} = \|A\|^{M,w,a}(\|B\|^{M,w,a})$;

(iii) $\|\lambda x_\beta A\|^{M,w,a}$ = the function F with domain D_β such that $F(d) = \|A\|^{M,w,a[d/x]}$ for all $d \in D_\beta$;

(iv) $\|A \equiv B\|^{M,w,a} = 1$ iff $\|A\|^{M,w,a} = \|B\|^{M,w,a}$;

(v) $\|{}^\wedge A\|^{M,w,a}$ = the function F with domain W such that $F(w') = \|A\|^{M,w',a}$ for all $w' \in W$;

(vi) $\|{}^\vee A\|^{M,w,a} = \|A\|^{M,w,a}(w)$;

Note the special treatment of the non-logical constants in the first clause of this definition: constants of type α are interpreted as functions of type $s\alpha$ by the interpretation function I but these functions are applied to the current world in order to get the actual value, an object which is of type α again. The second and third clauses interpret application and

abstraction in a way that is to be expected. The fourth clause interprets $\equiv$ as identity *relative to a possible world*, i.e. $A \equiv B$ means that A and B have the same extension in the world of evaluation, not necessarily in all possible worlds. The last two clauses interpret the cap and cup operators in a way that is analogous to abstraction and application; cap is abstraction over possible worlds while cup is application to the current world. We leave it to the reader to verify that the abbreviations of definition 3 provide the operators defined there with their usual semantics (with $\Box$ the universal modality).

A formula φ is *true* in a model M in world w under an assignment a if $\|\varphi\|^{M,w,a} = 1$. The notion of standard entailment, or s-entailment for short, is defined accordingly.

DEFINITION 6. Let Γ and Δ be sets of **IL** formulae. We say that Γ *s-entails* Δ, $\Gamma \models_s \Delta$, if, whenever $M = \langle D, W, I\rangle$ is a model, $w \in W$, and a is an assignment to M, $\|\varphi\|^{M,w,a} = 1$ for all $\varphi \in \Gamma$ implies $\|\psi\|^{M,w,a} = 1$ for some $\psi \in \Delta$.

While it is clear from Gödel's incompleteness theorem that the relation $\models_s$ can have no recursive axiomatization, it is possible to define a *generalized* notion of entailment $\models_g$ that can be so axiomatized. For Church's logic this was done in Henkin [28], while Gallin [22] (in general a rich source of information about Montague's logic) generalizes the completeness proof found there to the setting of **IL**. The $\models_g$ notion is obtained with the help of *generalized* (or: *Henkin*) *models*, the main difference between these and standard models being that, while for each α and β it must hold that $D_{\alpha\beta} \subseteq \{F \mid F : D_\alpha \to D_\beta\}$, the $D_{\alpha\beta}$ need not be the *entire* function spaces $\{F \mid F : D_\alpha \to D_\beta\}$. Similarly, it is only required that $D_{s\alpha} \subseteq \{F \mid F : W \to D_\beta\}$. We will not pursue the proof of Henkin (or: generalized) completeness for **IL** here, but refer to Gallin's original work. For a generalized completeness proof for a similar higher order modal logic, see Section 6.

3.2 Limitations of **IL**

Montague's work has been a tremendous boost for natural language semantics but with the advantage of hindsight it is possible to point out some shortcomings of the logic that he used. These limitations will be reviewed here. First, let us ask ourselves the question whether the logic lives up to its name. Is **IL** really an *intensional* logic? If "intensional" merely is another word for "modal" there can be no discussion, but there is an older definition of the concept of intensionality that makes perfect sense in a higher order context and in which sense **IL** is not intensional. Whitehead and Russell's *Principia Mathematica* [52, number *20] is one place where this definition can be found. In this work a distinction between *extensional* and *intensional* functions of functions is made and Whitehead and Russell give as "the mark of an extensional function f" a condition which in their notation reads

(4) $\varphi!x. \equiv_x .\psi!x :\supset_{\varphi,\psi}: f(\varphi!\hat{z}). \equiv .f(\psi!\hat{z})$

but which in the present setting can be written as

(5) $\forall gh(\forall x(gx \equiv hx) \to fg \equiv fh)$

Thus a function of functions f is extensional if, whenever f is applied to a function g, the resulting value fg depends only on the extension of g; a function of functions is intensional if not extensional.[6]

[6]Whitehead and Russell only consider *propositional* functions and as a consequence their f, if it had been typed in our way, would have received a type of the form $(\alpha t)t$ (so that $\equiv$ can be read as $\leftrightarrow$). In

Whitehead and Russell point out that contexts of propositional attitude such as "I believe that p" are examples of functions that are not extensional and hence intensional. However, it is immediately clear that in **IL** all functions of functions are extensional in the sense of (5) and that intensional functions are ruled out. **IL** conforms to the following form of the axiom of Extensionality:

(6) $\forall f \forall gh(\forall x(gx \equiv hx) \to fg \equiv fh)$

For an Intensional Logic this seems below par. The situation is alleviated in a sense by the fact that the following scheme (in which $\varphi\{P := F\}$ denotes the result of substituting the constant F for the variable P in φ) is not generally valid.

(7) $\forall x(Fx \equiv Hx) \to (\varphi\{P := F\} \equiv \varphi\{P := H\})$

For example, one does not have

(8) $\forall x(Fx \equiv Hx) \to (\Box(H \equiv F) \equiv \Box(H \equiv H))$,

as it is easy to construct a model in which H and F are coextensive at some point but not at another. This is desirable, since from the premise that all and only humans are featherless bipeds (to take a truly Russellian example) it should not follow that being a featherless biped necessarily is being human.

But now there is room for a second point of criticism, for how come (6) can be valid while (7) is not? Surely, one can always instantiate g as the constant F, h as H, f as $\lambda P.\, \varphi$ and from

(9) $\forall x(Fx \equiv Hx) \to ((\lambda P.\varphi)F \equiv (\lambda P.\varphi)H)$

get (7) with the help of two β-conversions? The answer is that β-conversion unfortunately is not generally valid in **IL** but is subject to side conditions additional to the usual constraint on substitutability. $(\lambda P.\Box(H \equiv P))F$, for example, is not semantically equivalent to $\Box(H \equiv F)$, as the reader may care to verify.

We will turn to the side conditions on β-conversion shortly, but first, as a third criticism, let us notice that, while the scheme in (7) is not valid, the strengthened version in (10) does hold in all models at any possible world (the proof is by induction on the complexity of φ).

(10) $\Box\forall x(Fx \equiv Hx) \to (\varphi\{P := F\} \equiv \varphi\{P := H\})$

But this is far from desirable. Read "is provable with the help of Zorn's Lemma" for F and "is provable with the help of the Axiom of Choice" for H while choosing "John believes that Zorn's Lemma is P" for φ. It is presumably a necessary fact that everything that is provable with the help of Zorn's Lemma is provable with the help of the Axiom of Choice and vice versa. But from "John believes that Zorn's Lemma is provable from Zorn's Lemma" one cannot conclude "John believes that Zorn's Lemma is provable from the Axiom of Choice". Hence (10) should in fact not be valid. This is what is usually called the problem of logical omniscience but is really a consequence of one variant of the Extensionality principle.

Let us consider the side conditions on β-conversion in **IL**. They will unfortunately lead to a fourth problem. Define a term to be *modally closed* if it is built up from variables and terms of the form $\hat{\ }A$ with the help of application, λ-abstraction and $\equiv$. The following scheme is valid.

IL the scheme in (5) will be valid for f of any type $(\alpha\beta)\gamma$ (with g and h of type $\alpha\beta$ and x of type α).

(11) $(\lambda x_\alpha A_\beta)B_\alpha \equiv A\{x := B\}$, if

(a) B is free for x in A, and

(b) either no free occurrence of x in A lies within the scope of $\hat{}$ or B is modally closed.

This is in fact one of the six axiom schemes that are used to axiomatize generalized consequence in Gallin [22]. But, as was observed by Friedman and Warren [21], the second side condition that needs to be imposed here destroys one of the attractive properties that lambda calculi usually have. For notions of reduction $\twoheadrightarrow$ such as $\twoheadrightarrow_\beta$ or $\twoheadrightarrow_{\beta\eta}$ (see Barendrecht [4] for definitions), one can often establish that whenever $A \twoheadrightarrow A_1$ and $A \twoheadrightarrow A_2$ there is an A_3 such that $A_1 \twoheadrightarrow A_3$ and $A_2 \twoheadrightarrow A_3$, i.e. it is immaterial in which order reductions are made. This so-called *Church-Rosser* property is not retained in **IL** as Friedman and Warren show with the help of (12).

(12) $(\lambda x_\alpha(\lambda y_\alpha.\hat{}y \equiv f_{\alpha(s\alpha)}x)x)c_\alpha$

Here x, y, and f are variables, while c is a constant. One possible reduction leads to

(13) $(\lambda y.\hat{}y \equiv fc)c$,

while another reduction of (12) results in

(14) $(\lambda x.\hat{}x \equiv fx)c$.

Neither of these terms can be reduced any further (as c is not modally closed but the variable that is abstracted over occurs in the scope of $\hat{}$) and hence there is no single term to which both reduce.

Gallin [22] gives a translation of **IL** into a two-sorted variant $\mathbf{TY}_2$ of Church's original logic, which has an extra type s for possible worlds. The translation proceeds by letting $\hat{}$ correspond to λ-abstraction over a fixed variable x_s, while $\check{}$ corresponds to application to x_s (the translation is related to the standard translation of modal logic into first order logic). Constants are translated as the result of application of a constant to the fixed type s variable. This translation clarifies the behaviour of **IL** in many ways. For example, since a term that is not modally closed will translate to a term containing a free occurrence of x_s, the side condition (ii) in (11) in a sense reduces to side condition (i) after all. Since the logic $\mathbf{TY}_2$ is just Church's logic (but two-sorted), it is Church-Rosser, but the difficulty of not being intensional is shared between **IL** and $\mathbf{TY}_2$.

4 A MODAL TYPE THEORY

In the previous section Montague's logic **IL** was described and various criticisms were levelled against it. In this and the next few sections we will propose a logic **MTT** that is compatible with the usual (α), (β) and (η) rules and that is intensional in the sense that two relations can have the same extension yet be different. In order to obtain this logic we must deviate from **IL** in two respects. First, we shall follow Bressan [11] in letting the value of an expression AB in some world w depend not only on (the value of A and) the value of B in w, but possibly on the values of B in other worlds as well. This

immediately solves the problem with β-conversion, as no extra side conditions on that rule will then be necessary.[7]

For the second deviation from **IL**, and indeed from the usual semantics for Church's [14] classical type logic, a class of models will be considered that is a further generalization of the generalized models considered in Henkin [28]. These *intensional models*, as they will be called here, derive from the structures considered in the proofs of cut elimination in Takahashi [49] and Prawitz [45]. The latter also play an important role in Andrews' [1] proof that his (non-extensional) resolution calculus corresponds to the first six axioms of Church [14]. The structures considered by these authors are proof-generated and are defined on the basis of a purely syntactic notion (Schütte's [47] semivaluations), but recently purely semantic, stand-alone, generalizations of such models have been offered in Fitting [19] ('generalized Henkin models') and in Benzmüller et al. [9] ('Σ-models'). Fitting's models involve a non-standard interpretation of abstraction, while the models of Benzmüller et al. have a non-standard form of application, but these complications seem unnecessary, as our intensional models will do without them.

Intensional models will serve two purposes. The first is that they deal with problems of logical omniscience. A second use is technical: the notion of entailment one gets from intensional models is easily axiomatized with the help of a cut free tableau calculus. This second point will be dwelled upon below; for the first point consider the following example. While it is reasonable to assume that sentences (15a) and (15b) determine the same set of possible worlds, it is not reasonable to assume that applying the function "Mary knows that p" to (15a) necessarily results in the same value as applying that function to (15b): (15c) might be true while (15d) is false. Intensional models provide a way to make the necessary distinction. The idea will be that co-entailment, or, more generally, having the same extension in all models, will not imply identity, i.e. the axiom of Extensionality will not hold.

(15) a. The cat is out if the dog is in
b. The dog is out if the cat is in
c. Mary knows that the cat is out if the dog is in
d. Mary knows that the dog is out if the cat is in

4.1 Types and Terms

Unlike **IL**, which is based on hierarchies of *functions*, the logic **MTT** will be based on hierarchies of *relations* (Orey [42], Schütte [47]), as relational models are pleasant to work with. Some definitions therefore must be changed and we shall start with the definition of *types*. Assume that some set $\mathcal{B}$ of *basic types*, among which must be the type s of possible worlds, is given.

DEFINITION 7. The set $\mathcal{T}$ of *types* is the smallest set of strings over the alphabet $\mathcal{B} \cup \{\rangle, \langle\}$ such that (i) $\mathcal{B} \subseteq \mathcal{T}$ and (ii) if $\alpha_1, \ldots, \alpha_n \in \mathcal{T}$ $(n \geq 0)$ then $\langle \alpha_1 \ldots \alpha_n \rangle \in \mathcal{T}$.

Types formed with clause (ii) of this definition will be called *complex*. The complex type $\langle\rangle$, obtained by letting $n = 0$ in (ii), will be the type of *propositions*; this will also be the

[7] See also N. Belnap's foreword to Bressan [11], especially point 11, where this "nonextensional predication" (nonextensional in the modal sense, not in the stronger sense used in this chapter) is called Bressan's cardinal innovation.

type of formulas, which will have sets of possible worlds as their extensions. In general, extensions for terms of type $\langle\alpha_1 \ldots \alpha_n\rangle$ will be $n+1$-ary relations, with one argument place for a possible world (the world where the relation is evaluated) and one for each of the α_i. Note that we have defined types to be certain strings, so that there is a difference between (say) the type s and the type $\langle s\rangle$. The latter is associated with a set of possible worlds in each world, or, equivalently, with the type of binary relations between worlds. Any of these relations can be viewed as an *accessibility* relation.

A *language* will be a countable set of non-logical constants such that each constant has a unique type. If $\mathcal{L}$ is a language, the set of constants from $\mathcal{L}$ having type α is denoted $\mathcal{L}_\alpha$. For each $\alpha \in \mathcal{T}$ we assume the existence of a denumerably infinite set $\mathcal{V}_\alpha$ of variables of type α, such that $\mathcal{V}_\alpha \cap \mathcal{V}_\beta = \varnothing$ if $\alpha \neq \beta$. We let $\mathcal{V} = \bigcup_{\alpha\in\mathcal{T}} \mathcal{V}_\alpha$. In proofs it will occasionally be useful to be able to refer to fixed well-orderings $<_\mathcal{L}$ and $<_\mathcal{V}$ on languages $\mathcal{L}$ and on the set $\mathcal{V}$ respectively, so we will assume that these are in place as well.

The following definition gives terms in all types. Apart from variables and non-logical vocabulary, there will be application and abstraction, and a basis for defining the usual connectives and quantifiers. Moreover, for any term R of type $\langle s\rangle$ there will be a modal operator $\langle R\rangle$ and a term $R^\smile$ intended to denote the converse of R.

DEFINITION 8. Let $\mathcal{L}$ be a language. Define sets $T^\mathcal{L}_\alpha$ of *terms* of $\mathcal{L}$ of type α, for each $\alpha \in \mathcal{T}$, as follows.

(i) $\mathcal{L}_\alpha \subseteq T^\mathcal{L}_\alpha$ and $\mathcal{V}_\alpha \subseteq T^\mathcal{L}_\alpha$ for each $\alpha \in \mathcal{T}$

(ii) If $A \in T^\mathcal{L}_{\langle\beta\alpha_1\ldots\alpha_n\rangle}$ and $B \in T^\mathcal{L}_\beta$, then $(AB) \in T^\mathcal{L}_{\langle\alpha_1\ldots\alpha_n\rangle}$

(iii) If $A \in T^\mathcal{L}_{\langle\alpha_1\ldots\alpha_n\rangle}$ and $x \in \mathcal{V}_\beta$, then $(\lambda x.A) \in T^\mathcal{L}_{\langle\beta\alpha_1\ldots\alpha_n\rangle}$

(iv) $\bot \in T^\mathcal{L}_{\langle\rangle}$

(v) If $\varphi \in T^\mathcal{L}_{\langle\rangle}$ and $\psi \in T^\mathcal{L}_{\langle\rangle}$ then $\varphi \to \psi \in T^\mathcal{L}_{\langle\rangle}$

(vi) If $\varphi \in T^\mathcal{L}_{\langle\rangle}$ and $x \in \mathcal{V}_\alpha$ then $\forall x\varphi \in T^\mathcal{L}_{\langle\rangle}$

(vii) If $R \in T^\mathcal{L}_{\langle s\rangle}$ and $\varphi \in T^\mathcal{L}_{\langle\rangle}$ then $\langle R\rangle\varphi \in T^\mathcal{L}_{\langle\rangle}$

(viii) If $R \in T^\mathcal{L}_{\langle s\rangle}$ then $R^\smile \in T^\mathcal{L}_{\langle s\rangle}$

The operation of taking converses will be useful in applications where the notion arises naturally, such as in temporal logic where, if $<$ is used to denote the relation of temporal precedence, $\langle<\rangle$ will be Prior's future operator F and $\langle<^\smile\rangle$ (or $\langle>\rangle$ after an obvious abbreviation) his past operator P.

We will write $T^\mathcal{L}$ for the set of all terms of the language $\mathcal{L}$, i.e. for the union $\bigcup_{\alpha\in\mathcal{T}} T^\mathcal{L}_\alpha$. If A is a term of type α, we may indicate this by writing A_α and we will use φ, ψ, χ for terms of type $\langle\rangle$, i.e. formulas. The notions *free* and *bound* occurrence of a variable and the notion B *is free for* x *in* A are defined as usual, as are *closed* terms and *sentences*. *Substitutions* are functions σ from variables to terms such that $\sigma(x)$ has the same type as x. If σ is a substitution then the substitution σ' such that $\sigma'(x) = A$ and $\sigma'(y) = \sigma(y)$ for all $y \not\equiv x$ is denoted as $\sigma[x := A]$. If A is a term and σ is a substitution, $A\sigma$, the extension of σ to A, is defined in the usual way. The substitution σ such that $\sigma(x_i) = A_i$ and $\sigma(y) = y$ if $y \notin \{x_1, \ldots, x_n\}$ is written as $\{x_1 := A_1, \ldots, x_n := A_n\}$.

Parentheses in terms will often be dropped on the understanding that association is to the left, i.e. ABC is $((AB)C)$. The operators $\top$, $\neg$, $\wedge$, $\vee$, $\leftrightarrow$ and $\exists$ are obtained as

usual. The following definition gives some other useful operators.

DEFINITION 9. We will write

$$\begin{aligned} =_{\langle\alpha\alpha\rangle} &\text{ for } \lambda x_\alpha \lambda y_\alpha \forall z_{\langle\alpha\rangle}(zx \to zy), \\ [R]\varphi &\text{ for } \neg\langle R\rangle\neg\varphi, \\ \Diamond\varphi &\text{ for } \langle\lambda x_s.\top\rangle\varphi, \\ \Box\varphi &\text{ for } [\lambda x_s.\top]\varphi, \text{ and} \\ \dot{A} &\text{ for } \forall x_{\langle s\rangle}[x]x^\smile A_s. \end{aligned}$$

The first of these abbreviations gives equalities of type $\langle\alpha\alpha\rangle$ for each α. Of course we will usually write $A = B$ instead of $=AB$. The second abbreviation introduces the usual dual to $\langle\cdot\rangle$ and, for example, allows us to write $[<]$ for Prior's G and $[>]$ for his H. The second and third conventions let us write $\Diamond$ and $\Box$ for the *global* possibility and necessity operators, which have the universal relation on worlds as their underlying accessibility relation. The abbreviation $\dot{A}$, lastly, introduces what are called *nominals* (see Blackburn et al. [10] or Areces and ten Cate, Chapter 14 of this handbook, for much more on these). As will become apparent below, $\dot{A}$ will be true in a world w if and only if w is denoted by A.

4.2 Standard Models

Before we introduce the intensional models that will interpret **MTT** terms, let us have a brief look at a class of models that, in order to conform to general usage, will be called *standard* (even though for many practical purposes the intensional models defined below will be preferred).

DEFINITION 10. A *standard collection of domains* is a set $D = \{D_\alpha \mid \alpha \in \mathcal{T}\}$ such that $D_\alpha \neq \varnothing$ if α is basic, $D_\alpha \cap D_\beta = \varnothing$ if $\alpha \neq \beta$ and α and β are basic, while $D_{\langle\alpha_1\ldots\alpha_n\rangle} = \mathcal{P}(D_s \times D_{\alpha_1} \times \cdots \times D_{\alpha_n})$ for each $D_{\langle\alpha_1\ldots\alpha_n\rangle}$. A *standard model* is a pair $\langle D, J\rangle$ such that $D = \{D_\alpha \mid \alpha \in \mathcal{T}\}$ is a standard collection of domains and J is a function with the set of all constants as its domain, such that $J(c) \in D_\alpha$ for each constant c of type α. J is called the *interpretation* function of $\langle D, J\rangle$.

Letting the interpretation function J send constants of type α directly to D_α diverges from the set-up in **IL**, but is in conformity with Church's original logic. It will bring the behaviour of constants in line with that of free variables.

An *assignment* a for a standard collection of domains $D = \{D_\alpha \mid \alpha \in \mathcal{T}\}$ is a function which has the set of variables $\mathcal{V}$ as domain and has the property that $a(x) \in D_\alpha$ if $x \in \mathcal{V}_\alpha$. The usual notational conventions for assignments obtain: If a is an assignment, $x_1, \ldots, x_n$ are pairwise distinct variables, and $d_1, \ldots, d_n$ are objects such that $d_i \in D_\alpha$ if x_i is of type α, then $a[d_1/x_1, \ldots, d_n/x_n]$ is the assignment a' defined by letting $a'(x_i) = d_i$ and $a'(y) = a(y)$, if $y \notin \{x_1, \ldots, x_n\}$.

When working with hierarchies of relations it is often expedient to have a way of interpreting relations as certain functions. The following definition provides one (compare Muskens [39]).

DEFINITION 11. Let R be an n-ary relation ($n > 0$) and let $0 < k \leq n$. Define the *k-th slice function* $F_R^k(d)$ of R by:

$$F_R^k(d) = \{\langle d_1, \ldots, d_{k-1}, d_{k+1}, \ldots, d_n\rangle \mid \langle d_1, \ldots, d_{k-1}, d, d_{k+1}, \ldots, d_n\rangle \in R\}$$

So $F^k_R(d)$ is the $n-1$-ary relation that is obtained from R by fixing its k-th argument place by d. Note that if R is a relation in $\mathcal{P}(D_s \times D_{\alpha_1} \times \cdots \times D_{\alpha_n})$ its first slice function is a function from possible worlds to relations in $\mathcal{P}(D_{\alpha_1} \times \cdots \times D_{\alpha_n})$ and can therefore be identified with what Montague would call a *relation-in-intension*. This motivated the choice of letting $D_{\langle \alpha_1 \dots \alpha_n \rangle}$ equal $\mathcal{P}(D_s \times D_{\alpha_1} \times \cdots \times D_{\alpha_n})$ in definition 10.

The next definition provides terms with values in standard models. Clauses (i) and (iv)–(viii) will probably not surprise the reader, as they are essentially standard; for clauses (ii) and (iii) *second* slice functions provide motivation. For (ii) lets $V(a, AB)$ be equal to the result of applying the second slice function of $V(a, A)$ to $V(a, B)$, while (iii) defines $V(a, \lambda x_\beta.A)$ as the relation whose second slice function is the function F such that, for all $d \in D_\beta$, $F(d) = V(a[d/x], A)$.

DEFINITION 12. The *value* $V_M(a, A)$ of a term A on a standard model $M = \langle D, J \rangle$ under an assignment a to M is defined as follows (we drop subscripts M):

(i) $V(a, c) = J(c)$ if c is a constant; $V(a, x) = a(x)$ if x is a variable;

(ii) $V(a, AB) = \{\langle w, \vec{d} \rangle \mid \langle w, V(a, B), \vec{d} \rangle \in V(a, A)\}$;

(iii) $V(a, \lambda x_\beta.A) = \{\langle w, d, \vec{d} \rangle \mid d \in D_\beta \text{ and } \langle w, \vec{d} \rangle \in V(a[d/x], A)\}$;

(iv) $V(a, \bot) = \varnothing$;

(v) $V(a, \varphi \to \psi) = D_s - (V(a, \varphi) - V(a, \psi))$;

(vi) $V(a, \forall x_\alpha \varphi) = \bigcap_{d \in D_\alpha} V(a[d/x], \varphi)$;

(vii) $V(a, \langle R \rangle \varphi) = \{w \mid \exists w' \in V(a, \varphi) \text{ such that } \langle w, w' \rangle \in V(a, R)\}$;

(viii) $V(a, R^\smile) = \{\langle w, w' \rangle \mid \langle w', w \rangle \in V(a, R)\}$.

4.3 Intensional Models

Intensional models generalize the standard models just given in two ways. The first generalization follows Henkin [28] in not necessarily associating domains $D_{\langle \alpha_1 \dots \alpha_n \rangle}$ with the full powerset $\mathcal{P}(D_s \times D_{\alpha_1} \times \cdots \times D_{\alpha_n})$, but to be contented with some subset of this relational space. When this generalization is made it becomes possible to prove (generalized) completeness for the logic. However, if a tableau system is used it will contain a Cut rule. In order to avoid invoking the latter it seems to be necessary to adopt a second generalization and to move to a class of structures that do not necessarily validate the axiom of Extensionality, which says that two predicates are identical when they can be predicated of the same objects. The strategy of taking out Extensionality, pioneered by Takahashi [49] and Prawitz [45], allows one to prove the completeness of a cut-free system, after which Extensionality can be added to the logic again if that should be desired.

In the present set-up, which is inspired by Fitting [19], we will get rid of Extensionality by distinguishing between the *intension* and the *extension* of a term of complex type. The basic idea will be that any object in a domain D_α can be the intension of some term. Intensions of complex type will not be constructed set-theoretically out of those of a less complex type. Extensions, on the other hand, will be relations over the relevant domains of intensions, with their identity criteria therefore given by set membership. One and the same extension may be determined by two or more different intensions.

Let us see how this can be done. A *collection of domains* will be a set of non-empty sets $\{D_\alpha \mid \alpha \in \mathcal{T}\}$, such that $D_\alpha \cap D_\beta = \varnothing$ if $\alpha \neq \beta$. There are no further constraints

on collections of domains. *Assignments* and the notational conventions pertaining to assignments are defined as before. The set of all assignments for a collection of domains D is denoted $\mathcal{A}_D$. The *intension functions* defined below send terms to almost arbitrary domain elements. There are a few restrictions on these functions but they are rather liberal.

DEFINITION 13. An *intension function* for a collection of domains $D = \{D_\alpha \mid \alpha \in \mathcal{T}\}$ and a language $\mathcal{L}$ is a function I with domain $\mathcal{A}_D \times T^{\mathcal{L}}$ such that

(i) $I(a, A) \in D_\alpha$, if A is of type α

(ii) $I(a, x) = a(x)$, if x is a variable

(iii) $I(a, A) = I(a', A)$, if a and a' agree on all variables free in A

(iv) $I(a, A\{x := B\}) = I(a[I(a, B)/x], A)$, if B is free for x in A

Before we continue with also defining *extension* functions, let us pay some attention to the nitty-gritty and observe that the intension functions just defined behave well when the language is restricted or extended. The following property will be used a couple of times below.

PROPOSITION 14. *(i) Let I be an intension function for D and $\mathcal{L}$ and let $\mathcal{L}' \subseteq \mathcal{L}$. Then the restriction I' of I to $\mathcal{A}_D \times T^{\mathcal{L}'}$ is an intension function for D and $\mathcal{L}'$. (ii) Let I be an intension function for D and $\mathcal{L}$, let $\mathcal{L} \subseteq \mathcal{L}'$ and let f be a function with domain $\mathcal{L}' \backslash \mathcal{L}$ such that $f(c) \in D_\alpha$ if $c \in \mathcal{L}'_\alpha \backslash \mathcal{L}_\alpha$. Then there is an intension function I' for D and $\mathcal{L}'$ such that I and I' agree on $\mathcal{A}_D \times T^{\mathcal{L}}$ and $I'(a, c) = f(c)$ for every $c \in \mathcal{L}' \backslash \mathcal{L}$.*

Proof. (i) is trivial, so let us verify (ii). Let A be an arbitrary term in $T^{\mathcal{L}'}$ and let $c_1, \ldots, c_n$ be the constants occurring in A that are in $\mathcal{L}'$ but not in $\mathcal{L}$ such that $c_i <_{\mathcal{L}'} c_j$ if $i < j$. Let $A^\dagger$ be the result of replacing each c_i in A with the first variable x_i in $<_{\mathcal{V}}$ such that x_i is not free in A, has the type of c_i and is distinct from each of the x_j $(j < i)$. Clearly $A = A^\dagger\{x_1 := c_1, \ldots, x_n := c_n\}$. Let $I'(a, A) = I(a[f(c_1)/x_1, \ldots, f(c_n)/x_n], A^\dagger)$ and check that I' meets the requirements. ❑

The next definition provides the promised extension functions, which send objects of complex type to certain relations. We first give very general constraints; more requirements will follow in definition 17.

DEFINITION 15. An *extension function* for $D = \{D_\alpha \mid \alpha \in \mathcal{T}\}$ is a function E with domain $\cup\{D_\alpha \mid \alpha \text{ is complex}\}$ such that $E(d) \subseteq D_s \times D_{\alpha_1} \times \cdots \times D_{\alpha_n}$ if $d \in D_{\langle \alpha_1 \ldots \alpha_n \rangle}$.

Note that there is no requirement that the restriction of an extension function to any $D_{\langle \alpha_1 \ldots \alpha_n \rangle}$ should be *onto* $\mathcal{P}(D_s \times D_{\alpha_1} \times \cdots \times D_{\alpha_n})$ or that extension functions should be injective. This reflects the two generalizations discussed above. The possible lack of surjectivity is Henkin's generalization and the possible lack of injectivity reflects the move that Prawitz and Takahashi made.

DEFINITION 16. A *generalized frame* for the language $\mathcal{L}$ is a triple $\langle D, I, E \rangle$ such that D is a collection of domains, I is an intension function for D and $\mathcal{L}$, and E is an extension function for D.

We are interested in the extensions $E(I(a, A))$ of terms A. For the sake of readability we will often write $V(a, A)$ for these, letting V denote the composition of E and I. The following definition puts a series of constraints on extension functions that make things start to behave in a desired way.

DEFINITION 17. A generalized frame $\langle D, I, E\rangle$ for $\mathcal{L}$ is a *intensional model* for $\mathcal{L}$ if

(i) $V(a, AB) = \{\langle w, \vec{d}\rangle \mid \langle w, I(a, B), \vec{d}\rangle \in V(a, A)\}$;

(ii) $V(a, \lambda x_\beta.A) = \{\langle w, d, \vec{d}\rangle \mid d \in D_\beta \text{ and } \langle w, \vec{d}\rangle \in V(a[d/x], A)\}$;

(iii) $V(a, \bot) = \varnothing$;

(iv) $V(a, \varphi \to \psi) = D_s - (V(a, \varphi) - V(a, \psi))$;

(v) $V(a, \forall x_\alpha \varphi) = \bigcap_{d \in D_\alpha} V(a[d/x], \varphi)$;

(vi) $V(a, \langle R\rangle\varphi) = \{w \mid \exists w' \in V(a, \varphi) \text{ such that } \langle w, w'\rangle \in V(a, R)\}$;

(vii) $V(a, R^{\smile}) = \{\langle w, w'\rangle \mid \langle w', w\rangle \in V(a, R)\}$.

The clauses here are identical to the relevant ones in definition 12, with one important exception: in the clause for AB the (second slice function of) the value of A is no longer applied to the *extension* of B, but to its *intension*. The idea is that the extension of a predicate A determines and is determined by all the things that A can truthfully be predicated of while the intension of A determines and is determined by all the predicates that hold of A.

Do intensional models exist? One answer is that the standard models defined in the previous section obviously correspond to a subclass of the class of intensional models in which E is the identity function, but one would like to see intensional models that are not standard. For the latter we refer to the construction in the section on elementary model theory below.

Having the notion of intensional model in place we can define what it means for a sentence to be made true by an intensional model in a given world or to be valid in an intensional model.

DEFINITION 18. Let $M = \langle D, I, E\rangle$ be an intensional model for $\mathcal{L}$, let $w \in D_s$ and let φ be a sentence of $\mathcal{L}$. M and w *satisfy* φ (or *make* φ *true*), $M, w \models \varphi$, if $w \in V(a, \varphi)$ for any a. We also say that M satisfies φ if there is some $w \in D_s$ such that $M, w \models \varphi$ and that φ is *satisfiable* if some M satisfies φ. If $M, w \models \varphi$ for all $w \in D_s$ then φ is said to be *valid* in M and we write $M \models \varphi$.

The corresponding notion of entailment is defined as follows.

DEFINITION 19. Let Π and Σ be sets of sentences in $\mathcal{L}$. Π is said to *intensionally entail* or *i-entail* Σ, $\Pi \models_i \Sigma$, if, for every intensional model $M = \langle D, I, E\rangle$ for $\mathcal{L}$ and every $w \in D_s$, if $M, w \models \varphi$ for all $\varphi \in \Pi$ then $M, w \models \varphi$ for some $\varphi \in \Sigma$.

This gives a rather weak logic in comparison with other type logics. In applications it will usually be necessary to strengthen the logic with sets of sentences $\mathcal{S}$ which may typically contain modal axioms, but may also contain classical axioms, such as instantiations of the Extensionality scheme, the Axiom of Descriptions, or axioms regulating λ-conversion. About the latter notion the following proposition lists some useful facts.

PROPOSITION 20. *Let $M = \langle D, I, E\rangle$ be an intensional model, and let a be an assignment for D. Then, for all A and B of appropriate types,*

(i) $V(a, \lambda x.A) = V(a, \lambda y.A\{x := y\})$, *if y is free for x in A;*

(ii) $V(a, (\lambda x.A)B) = V(a, A\{x := B\})$, *if B is free for x in A;*

(iii) $V(a, \lambda x.Ax) = V(a, A)$, *if x is not free in A.*

Proof. Left to the reader. ❑

Table 1. Tableau rules for **MTT**.

These statements show that λ-conversion preserves identity of extension, but that does not imply that intensional identity is also preserved and that V can be replaced uniformly with I in the proposition above. If such intensional identities are wanted, and in most applications one will certainly want to have at least the possibility of α and β conversion in any context, an axiomatic extension of the logic may provide them. See 5.2 below.

5 TABLEAUS FOR MODAL TYPE THEORY

5.1 Tableaus

In this section the proof theory of **MTT** will be given in the form of a tableau system. The calculus will be set up as a form of labeled deduction, with labels storing information about worlds and truth values. Formally, a *labeled sentence* of $\mathcal{L}$ will be a triple $\langle \mathsf{S}, u, \varphi\rangle$ consisting of a *sign* S, which can either be T or F, a constant $u \in \mathcal{L}_s$, and a sentence φ of $\mathcal{L}$. Labeled sentences $\langle \mathsf{S}, u, \varphi\rangle$ will typically be written as $\mathsf{S}u{:}\,\varphi$, where $\mathsf{T}u{:}\,\varphi$ can be read as 'φ is true in world u' and $\mathsf{F}u{:}\,\varphi$ as expressing that φ is false in u.

Tableaus will be defined as certain sets of branches. A *branch* in its turn will be a set of labeled sentences. The notion of *satisfaction* can easily be extended from sentences to labeled sentences and branches, for we can define an intensional model $M = \langle D, I, E\rangle$ to satisfy $\mathsf{T}u{:}\,\varphi$ if $I(a, u) \in V(a, \varphi)$ for some (and hence every) a, while letting M satisfy $\mathsf{F}u{:}\,\varphi$ if $I(a, u) \notin V(a, \varphi)$ for any a. M is said to *satisfy* a branch Γ if it satisfies all $\vartheta \in \Gamma$. If no model M satisfies Γ, Γ is said to be *unsatisfiable*; otherwise Γ is *satisfiable*.

We will use the usual sequent notation for branches, writing Γ, θ for $\Gamma \cup \{\theta\}$, etc. Diverging slightly from the usual set-up of tableaus, tableau rules will be defined as certain relations between branches, not as relations between labeled sentences. The interpretation of these rules (that are given in Table 1) is one of replacement of branches,

$$\frac{\mathsf{T}u\colon \neg\varphi}{\mathsf{F}u\colon \varphi}\,\mathsf{T}\neg \qquad \frac{\mathsf{F}u\colon \neg\varphi}{\mathsf{T}u\colon \varphi}\,\mathsf{F}\neg \qquad \frac{\mathsf{T}u\colon \varphi\wedge\psi}{\mathsf{T}u\colon \varphi,\ \mathsf{T}u\colon \psi}\,\mathsf{T}\wedge \qquad \frac{\mathsf{F}u\colon \varphi\wedge\psi}{\mathsf{F}u\colon \varphi \mid \mathsf{F}u\colon \psi}\,\mathsf{F}\wedge$$

$$\frac{\mathsf{T}u\colon \varphi\vee\psi}{\mathsf{T}u\colon \varphi \mid \mathsf{T}u\colon \psi}\,\mathsf{T}\vee \qquad \frac{\mathsf{F}u\colon \varphi\vee\psi}{\mathsf{F}u\colon \varphi,\ \mathsf{F}u\colon \psi}\,\mathsf{F}\vee \qquad \frac{\mathsf{T}u\colon \exists x\varphi}{\mathsf{T}u\colon \varphi\{x:=c\}}\,\mathsf{T}\exists\ (c \text{ fresh}) \qquad \frac{\mathsf{F}u\colon \exists x\varphi}{\mathsf{F}u\colon \varphi\{x:=A\}}\,\mathsf{F}\exists$$

$$\frac{\mathsf{T}u\colon \varphi\leftrightarrow\psi}{\mathsf{T}u\colon \varphi,\ \mathsf{T}u\colon \psi \mid \mathsf{F}u\colon \varphi,\ \mathsf{F}u\colon \psi}\,\mathsf{T}\leftrightarrow \qquad \frac{\mathsf{F}u\colon \varphi\leftrightarrow\psi}{\mathsf{T}u\colon \varphi,\ \mathsf{F}u\colon \psi \mid \mathsf{F}u\colon \varphi,\ \mathsf{T}u\colon \psi}\,\mathsf{F}\leftrightarrow$$

$$\frac{\mathsf{T}u\colon [R]\varphi}{\mathsf{F}u\colon Ru' \mid \mathsf{T}u'\colon \varphi}\,\mathsf{T}[\cdot] \qquad \frac{\mathsf{F}u\colon [R]\varphi}{\mathsf{T}u\colon Ru', \mathsf{F}u'\colon \varphi}\,\mathsf{F}[\cdot]\ (u' \text{ fresh}) \qquad \frac{\mathsf{T}u'\colon \dot{u}}{\mathsf{T}u'\colon u=u'}\,\mathsf{T}^{\cdot} \qquad \frac{\mathsf{F}u\colon \dot{u}}{}\,\mathsf{F}^{\cdot}$$

$$\frac{\mathsf{T}u\colon \Box\varphi}{\mathsf{T}u'\colon \varphi}\,\mathsf{T}\Box \qquad \frac{\mathsf{F}u\colon \Box\varphi}{\mathsf{F}u'\colon \varphi}\,\mathsf{F}\Box\ (u' \text{ fresh}) \qquad \frac{\mathsf{T}u\colon \Diamond\varphi}{\mathsf{T}u'\colon \varphi}\,\mathsf{T}\Diamond\ (u' \text{ fresh}) \qquad \frac{\mathsf{F}u\colon \Diamond\varphi}{\mathsf{F}u'\colon \varphi}\,\mathsf{F}\Diamond$$

$$\frac{\mathsf{T}u\colon A=B,\ \mathsf{S}u\colon \varphi\{x:=A\}}{\mathsf{S}u\colon \varphi\{x:=B\}}\,\mathrm{LL} \qquad \frac{}{\mathsf{T}u\colon A=A}\,\mathrm{id} \qquad \frac{\mathsf{T}u\colon A=B}{\mathsf{T}u'\colon A=B}\,\mathrm{U}$$

$$\frac{\mathsf{S}u\colon \varphi,\ \mathsf{T}u\colon u=u'}{\mathsf{S}u'\colon \varphi}\,\mathrm{LL}' \qquad \frac{}{\mathsf{T}u\colon \varphi \mid \mathsf{F}u\colon \varphi}\,\mathrm{Cut}$$

Table 2. Derived tableau rules and Cut (abbreviated forms).

for example the interpretation of $\mathsf{T}\!\to$ in Table 1 is that the branch $\Gamma, \mathsf{T}u\colon \varphi \to \psi$ can be replaced by the two branches $\Gamma, \mathsf{F}u\colon \varphi$ and $\Gamma, \mathsf{T}u\colon \psi$ in any tableau. The format also allows the formulation of a *weakening* rule W that allows the removal of signed formulas from a branch.

Compare $\mathsf{T}\!\to$ with a more usual approach where one would have a rule

$$\frac{\mathsf{T}u\colon \varphi\to\psi}{\mathsf{F}u\colon \varphi \mid \mathsf{T}u\colon \psi}\,,$$

meaning that whenever a branch is found to contain $\mathsf{T}u\colon \varphi \to \psi$ it may be split, $\mathsf{F}u\colon \varphi$ may be added to one side and $\mathsf{T}u\colon \psi$ to another. Of course the two approaches very much boil down to the same thing. The present set-up is close to that of a Gentzen calculus for the logic: read T as 'left' and F as 'right' and turn the rules in Table 1 upside down.

A convention that is adopted in Table 1 (and that we shall continue to use) is that wherever the notation $A\{x := B\}$ is used B must be free for x in A. An alternative notation for tableau rules, better suited for inline environments, is $\Gamma/\Gamma_1;\ldots;\Gamma_n$, where / replaces the horizontal line and ; the vertical lines in any rule. The following definition tells how we can expand sets of branches and obtain tableaus.

DEFINITION 21. A set of branches T' is a *one step expansion* of a set of branches T if $T' = (T\backslash\Gamma) \cup \{\Gamma_1,\ldots,\Gamma_n\}$ for some tableau rule $\Gamma/\Gamma_1;\ldots;\Gamma_n$. T' is an *expansion* of T if there is a sequence $T_1,\ldots,T_n$ such that $T_1 = T$, $T_n = T'$ and each T_{k+1} is a one step

Name	Modal axiom	Corresponding R rule
$\mathbf{T}_\forall$	$\Box\forall p([R]p \to p)$	$/\mathsf{T}u{:}\, Ru$
$\mathbf{D}_\forall$	$\Box\forall p([R]p \to \langle R\rangle p)$	$/\mathsf{T}u_1{:}\, Ru_2$ (u_2 fresh)
$\mathbf{4}_\forall$	$\Box\forall p([R]p \to [R][R]p)$	$\mathsf{T}u_1{:}\, Ru_2, \mathsf{T}u_2{:}\, Ru_3/\mathsf{T}u_1{:}\, Ru_3$
$\mathbf{5}_\forall$	$\Box\forall p(\langle R\rangle p \to [R]\langle R\rangle p)$	$\mathsf{T}u_1{:}\, Ru_2, \mathsf{T}u_1{:}\, Ru_3/\mathsf{T}u_2{:}\, Ru_3$

Table 3. Correspondences between modal axioms and certain rules.

expansion of T_k. A set of branches T is a *tableau* if it is an expansion of $\{\Gamma\}$ for some finite branch Γ.

Thus while no finiteness condition was imposed on branches per se, tableaus are stipulated to originate from finite branches. Note that the $\mathsf{T}\bot$ and Ax rules can cause branches to disappear from a tableau while it is being expanded. This can lead to the closure of tableaus as defined in the following definition.

DEFINITION 22. A finite branch Γ *has a closed tableau* if $\varnothing$ is an expansion of $\{\Gamma\}$. If Π and Σ are sets of sentences then $\Pi \vdash \Sigma$ holds if, for some finite $\Pi_0 \subseteq \Pi$, some finite $\Sigma_0 \subseteq \Sigma$ and some $u \in \mathcal{L}_s$ that does not occur in any sentence in $\Pi_0 \cup \Sigma_0$, $\{\mathsf{T}u{:}\,\varphi \mid \varphi \in \Pi_0\} \cup \{\mathsf{F}u{:}\,\varphi \mid \varphi \in \Sigma_0\}$ has a closed tableau.

We employ the usual notational conventions with respect to $\vdash$. A formula φ is called *tableau provable* if $\vdash \varphi$.

For ease of reference Table 2 lists some rules that are derivable from those already given in Table 1. We leave it to the reader to show that these rules are indeed derivable (most cases are entirely trivial, some easy but amusing). Another exercise is to show that $\vdash \exists p(p \wedge \forall q(q \to [R](p \to q)))$. Table 2 also displays the Cut rule, which we will see is admissable. Here we have not bothered to write all the Γs of our official rule presentation and have reverted to the more usual way of presenting tableau rules.

Clearly the rules were chosen in a way that makes it possible to show Soundness to hold.

THEOREM 23 (Soundness). *If Γ has a closed tableau then Γ is unsatisfiable. Hence $\Pi \vdash \Sigma$ implies $\Pi \models_i \Sigma$.*

Proof. For each tableau rule $\Gamma/\Gamma_1; \ldots; \Gamma_n$, if Γ is satisfiable, one of the Γ_i is satisfiable. Verifying this will involve proposition 14 for some cases. By induction, if T is an expansion of $\{\Gamma\}$ then, if Γ is satisfiable, some $\Gamma' \in T$ must be satisfiable. Hence if Γ has a closed tableau, Γ can not be satisfiable. This proves the first statement of the theorem. Suppose $\Pi \vdash \Sigma$. Then for some finite $\Pi_0 \subseteq \Pi$ and $\Sigma_0 \subseteq \Sigma$ and some $u \in \mathcal{L}_s$ that does not occur in $\Pi_0 \cup \Sigma_0$, $\{\mathsf{T}u{:}\,\varphi \mid \varphi \in \Pi_0\} \cup \{\mathsf{F}u{:}\,\varphi \mid \varphi \in \Sigma_0)\}$ has a closed tableau and hence is unsatisfiable. It follows that $\Pi \models_i \Sigma$ ❑

5.2 Axiomatic Extensions

If, in some setting, one wants to restrict attention to a class of models that validate some set of sentences $\mathcal{S}$ then it becomes natural to define $\Pi \models_{\mathcal{S}} \Sigma$ as $\mathcal{S} \cup \Pi \models_i \Sigma$. Similarly, $\Pi \vdash_{\mathcal{S}} \Sigma$ can be defined as $\mathcal{S} \cup \Pi \vdash \Sigma$ and the soundness theorem gives that $\Pi \vdash_{\mathcal{S}} \Sigma$

$$\mathsf{T}u\colon \Box\forall p([R]p \to [R][R]p)$$
$$\mathsf{T}u_1\colon Ru_2$$
$$\mathsf{T}u_2\colon Ru_3$$
$$\mathsf{T}u_1\colon \forall p([R]p \to [R][R]p)$$
$$\mathsf{T}u_1\colon [R]R^{\smile}u_1 \to [R][R]R^{\smile}u_1$$

$$\begin{array}{c|c}
\begin{array}{c}

\begin{array}{c}\mathsf{F}u_2\colon Ru_3\\ \times\end{array}
&
\begin{array}{c}\mathsf{T}u_3\colon R^{\smile}u_1\\ \mathsf{T}u_1\colon Ru_3\end{array}
\end{array}
\end{array}
\end{array}
\end{array}
\end{array}$$

Figure 1. Derivation of $\mathsf{T}u_1\colon Ru_2, \mathsf{T}u_2\colon Ru_3/\mathsf{T}u_1\colon Ru_3$ from $\mathbf{4}_\forall$

implies $\Pi \models_{\mathcal{S}} \Sigma$ (while completeness, yet to be shown to hold, gives the converse). Prime candidates for inclusion in such a theory $\mathcal{S}$ are the usual rules for lambda conversion. These are the universal closures of any instantiation of one of the following schemes.

(α) $\lambda x.A = \lambda y.A\{x := y\}$, if y is free for x in A;

(β) $(\lambda x.A)B = A\{x := B\}$, if B is free for x in A;

(η) $\lambda x.Ax = A$, if x is not free in A.

It is clearly consistent to add these rules to **MTT**, as they are valid in standard models. Once they are added, the derived rules U and LL ensure that

$$\frac{\mathsf{S}u\colon \varphi\{x := A\}}{\mathsf{S}u\colon \varphi\{x := B\}}\,\lambda \qquad \text{if } A =_{\beta\eta} B$$

also becomes a derived rule. Since one can work with the standard notion of reduction $\twoheadrightarrow_{\beta\eta}$ here, it is clear that the resulting logic is Church-Rosser. This will also hold if, for some reason, it is decided that $\mathcal{S}$ should contain (α), but only one of the rules (β) and (η). Note that the (β) rule scheme discussed here should well be distinguished from the rule we have called β-ext, which is much weaker, as it only allows β-conversions in *head* position.

Other obvious candidates for inclusion in a theory $\mathcal{S}$ are the usual modal axioms for modalities $\langle R\rangle$. For instance, one could ensure validity of $\mathbf{T}$ by including the scheme $\Box([R]\varphi \to \varphi)$ (the leading $\Box$ ensures that one gets validity, not just truth of $\mathbf{T}$ in the initial world). Another way to express the same idea, more natural perhaps in the present context, is by quantification over propositions, as in $\Box\forall p([R]p \to p)$, which is called $\mathbf{T}_\forall$ in Table 3, where also quantified analogues of $\mathbf{D}$, $\mathbf{4}$ and $\mathbf{5}$ are found. If such axioms are adopted it is often possible to use derived rules in one's tableaus that closely mirror the usual frame correspondences in modal logic (for the latter see e.g. Chapter 1 of this handbook, by Blackburn and Van Benthem). In fig. 1, for example, is a tableau verifying that $\mathsf{T}u_1\colon Ru_2, \mathsf{T}u_2\colon Ru_3/\mathsf{T}u_1\colon Ru_3$ is a derived rule in the presence of the $\mathbf{4}_\forall$ axiom. On the other hand, if $\mathsf{T}u_1\colon Ru_2, \mathsf{T}u_2\colon Ru_3/\mathsf{T}u_1\colon Ru_3$ should be adopted as an additional rule, $\Box\forall p[R]p \to [R][R]p$ becomes tableau provable, as fig. 2 shows. Table 3 lists some more of

$$
\begin{array}{c}
\mathsf{F}u\colon \Box\forall p([R]p \to [R][R]p)\\
\mathsf{F}u_1\colon \forall p([R]p \to [R][R]p)\\
\mathsf{F}u_1\colon [R]c_{\langle\rangle} \to [R][R]c\\
\mathsf{T}u_1\colon [R]c\\
\mathsf{F}u_1\colon [R][R]c\\
\mathsf{T}u_1\colon Ru_2\\
\mathsf{F}u_2\colon [R]c\\
\mathsf{T}u_2\colon Ru_3\\
\mathsf{F}u_3\colon c\\
\mathsf{T}u_1\colon Ru_3\\
\begin{array}{cc}
\mathsf{F}u_1\colon Ru_3 & \mathsf{T}u_3\colon c\\
\times & \times
\end{array}
\end{array}
$$

Figure 2. Derivation of $\mathbf{4}_\forall$ in the presence of $\mathsf{T}u_1\colon Ru_2, \mathsf{T}u_2\colon Ru_3/\mathsf{T}u_1\colon Ru_3$

these correspondences (use a nominal $\dot{u}_3$ when showing the correctness of the last one) and the reader will have no difficulty providing many more. Note that, with the help of nominals, it is also possible to directly express properties of accessibility relations, even those that are not modally definable in the usual set-up. For example, irreflexivity of R can be expressed as $\Box\forall x_s(\dot{x} \to \neg\langle R\rangle\dot{x})$. See Blackburn et al. [10] for more information on expressing first order relational properties with the help of nominals.

6 ELEMENTARY MODEL THEORY

In this section we will prove some basic modeltheoretic properties of **MTT**: Generalized Completeness, the Generalized Löwenheim-Skolem property, and the admissability of the Cut rule, all via a Model Existence theorem in the way Smullyan [48] did it for first order logic (see also Fitting [17, 19]). None of the techniques employed here is new, but we include full proofs for two reasons. The first of these being that, since our definition of an intensional model deviates from existing notions in the literature and since the devil is always in the details, it is good to have an explicit sanity check on those definitions. The second reason is that readers not already familiar with these kind of proofs may find examples here in a relatively streamlined setting.

Before we tackle the main modeltheoretic properties of **MTT**, some attention must be paid to the notion of *identity* in intensional models, as this relation may not be the identity of the metalanguage.

6.1 Identity and Indiscernability

The decision to let the relations $=_{\langle\alpha\alpha\rangle}$ be abbreviations of $\lambda x_\alpha\lambda y_\alpha\forall z_{\langle\alpha\rangle}(zx \to zy)$, as it was done in definition 9, derives directly from Russell, and via Russell from Leibniz, as the abbreviation equates identity with *indistinguishability*. It is clear that in standard

models identity and indistinguishability coincide, but, as was noted by Andrews [2] for the non-modal case, in nonstandard models it may happen that two objects d_1 and d_2 that are in fact not identical may fail to be distinguished because there simply is no set to keep them apart. This may be thought of as an anomaly and one may be tempted to restrict attention to intensional models that are *normal* in the following sense.

DEFINITION 24. An intensional model $M = \langle D, I, E\rangle$ is *normal* if, for any α, any $d, d' \in D_\alpha$ and arbitrary a, $d = d'$ if $\langle w, d, d'\rangle \in V(a, =)$ for some $w \in D_s$.

In fact restriction to normal models will not buy us any new truths as will be shown shortly. First some facts that will come in handy.

PROPOSITION 25. *Let $M = \langle D, I, E\rangle$ be an intensional model, and let a be an assignment for D. Then, for all A, B and B' of appropriate types,*

(i) $V(a, A = B) = \varnothing$ *or* $V(a, A = B) = D_s$*;*

(ii) $V(a, A = A) = D_s$*;*

(iii) $V(a, A\{x := B\} = A\{x := B'\}) = D_s$ *if* $V(a, B = B') = D_s$*, provided B and B' are free for x in A.*

Proof. (i) Suppose $w \in V(a, A_\alpha = B_\alpha)$, i.e. $w \in V(a, \forall x(xA \to xB))$. Choosing $\lambda y_\alpha.\Box\forall z_{\langle\alpha\rangle}(zA \to zy)$ for x, it is easily shown that $w \in V(a, \Box\forall z(zA \to zB))$. Hence $w' \in V(a, \forall x(xA \to xB))$ for all $w' \in D_s$ and we are done. (ii) Trivial. (iii) Assume that $w \in V(a, B = B'$, i.e. $w \in V(a, \forall y(yB \to yB'))$. Choose $\lambda v.A\{x := B\} = A\{x := v\}$ (with fresh v) for y and derive that $w \in V(a, A\{x := B\} = A\{x := B'\})$. ❑

The following proposition shows that, if desired, one can always 'normalize' models by 'dividing out' the indistinguishability relation. The proof implicitly uses the axiom of choice.

PROPOSITION 26. *Let $M = \langle D, I, E\rangle$ be an intensional model and let $w \in D_s$. There are a normal intensional model $\overline{M} = \langle \overline{D}, \overline{I}, \overline{E}\rangle$ and a $\overline{w} \in \overline{D}_s$ such that, for each sentence φ, $\overline{w}$ satisfies φ in $\overline{M}$ iff w satisfies φ in M.*

Proof. Suppose $M = \langle D, I, E\rangle$. We define the relation $\sim$ between objects of identical type in M's domains as follows. For any α, any $d, d' \in D_\alpha$ and arbitrary a let $d \sim d'$ iff, for some (and therefore every) $w \in D_s$, $\langle w, d, d'\rangle \in V(a, =_{\langle\alpha\alpha\rangle})$. Clearly, $\sim$ is an equivalence relation. Using proposition 25 and definition 13 it is straightforward to show that, for any term A,

$$(16)\quad d \sim d' \Longrightarrow I(a[d/x], A) \sim I(a[d'/x], A)\ .$$

It is also worth noting that, for any w, w' and any φ and a

$$(17)\quad w \sim w' \Longrightarrow (w \in V(a, \varphi) \Longrightarrow w' \in V(a, \varphi))\ .$$

The way to show this is to observe that, if neither x_s nor y_s is free in φ,

$$(18)\quad V(a[w/x], (\lambda y.\varphi)^{\smile}\, x) = D_s \Longleftrightarrow w \in V(a, \varphi)\ ,$$

and to then use the definition of $w \sim w'$.

Define $\overline{d} = \{d' \mid d \sim d'\}$, and let $\overline{D}_\alpha = \{\overline{d} \mid d \in D_\alpha\}$, while $\overline{D} = \{\overline{D}_\alpha \mid \alpha \in \mathcal{T}\}$. Let f be a function such that $f(\overline{d}) \in \overline{d}$, if $\overline{d} \in \overline{D}_\alpha$. For any assignment a for $\overline{D}$, let a°

be the assignment for D defined by $a^\circ(x) = f(a(x))$, for all x. Let $\overline{I}(a, A) = \overline{I(a^\circ, A)}$, for each assignment a for $\overline{D}$ and each term A. Then $\overline{I}$ is an intension function for $\overline{D}$. The first three requirements of definition 13 are easily checked, so let us check the last requirement. Note that

$$\begin{array}{rcl} I(a^\circ, A\{x := B\}) & = & \text{(by definition 13)} \\ I(a^\circ[I(a^\circ, B)/x], A) & \sim & \text{(by (16))} \\ I(a^\circ[f(\overline{I(a^\circ, B)})/x]), A) & = & \text{(by the definition of } \overline{I}) \\ I(a^\circ[f(\overline{I}(a, B))/x]), A) & = & \text{(by the definition of } \circ) \\ I((a[\overline{I}(a, B)/x])^\circ, A)\ . & & \end{array}$$

From this conclude that $\overline{I}(a, A\{x := B\}) = \overline{I}(a[\overline{I}(a, B)/x], A)$.

Define $\overline{E}$ by letting $\overline{E}(\overline{d_\alpha}) = \{\langle \overline{w}, \overline{d_1}, \ldots, \overline{d_n}\rangle \mid \langle w, d_1, \ldots, d_n\rangle \in E(d)\}$, if α is complex. In order to show that this is well-defined assume that $w \sim w'$, $d \sim d'$, and $d_i \sim d'_i$. Then, if $R, x_1, \ldots, x_n$ are distinct variables of appropriate types

$$\begin{array}{rcl} \langle w, d_1, \ldots, d_n\rangle \in E(d) & \Longleftrightarrow & \text{(by def. (17))} \\ w \in V(a[d/R, d_1/x_1, \ldots, d_n/x_n], Rx_1 \ldots x_n) & \Longleftrightarrow & \text{(by (17))} \\ w' \in V(a[d/R, d_1/x_1, \ldots, d_n/x_n], Rx_1 \ldots x_n) & \Longleftrightarrow & \text{(equational reas.)} \\ w' \in V(a[d'/R, d'_1/x_1, \ldots, d'_n/x_n], Rx_1 \ldots x_n) & \Longleftrightarrow & \text{(by def. (17))} \\ \langle w', d'_1, \ldots, d'_n\rangle \in E(d') & & \end{array}$$

so that the definition was legitimate.

Write $\overline{V}(a, A)$ for $\overline{E}(\overline{I}(a, A))$ and observe that

(19) $\langle \overline{w}, \overline{d_1}, \ldots, \overline{d_n}\rangle \in \overline{V}(a, A)$ iff $\langle w, d_1, \ldots, d_n\rangle \in V(a^\circ, A)$

From this it follows by a straightforward induction on term complexity that $\overline{M} = \langle \overline{D}, \overline{I}, \overline{E}\rangle$ is a intensional model. It also follows that $\overline{w}$ satisfies φ in $\overline{M}$ iff w satisfies φ in M and that $\overline{M}$ is normal. ❑

So the notion of identity of the logic may diverge from the notion of identity employed in the metalanguage, but for notions like satisfiability and entailment this does not matter.

6.2 Model Existence

We now come to the Model Existence theorem and its proof. This theorem (Theorem 30 below) roughly says that if a branch Γ does not have a certain kind of property, here called a 'sound unsatisfiability property', it is satisfiable by an intensional model. The proof proceeds in two steps. One step shows that such a branch Γ can be extended to a branch Γ^* that is *downward saturated* in a sense to be defined shortly. The other step shows that downward saturated branches are satisfiable. We will prove the last of these two statements first. Let us start with the definition of a downward saturated branch.

DEFINITION 27. A branch Γ of $\mathcal{L}$ is called *downward saturated* if the following hold:

(a) $\{\mathsf{T}u\colon \varphi,\ \mathsf{F}u\colon \varphi\} \not\subseteq \Gamma$ for any sentence φ and constant u;

(b) $\mathsf{T}u\colon \bot \notin \Gamma$;

(c) $\mathsf{S}u\colon (\lambda x.A)B\vec{C} \in \Gamma \Longrightarrow \mathsf{S}u\colon A\{x := B\}\vec{C} \in \Gamma$, if $\lambda x.A$, B, and the sequence of terms $\vec{C}$ are closed and of appropriate types;

(d) $\mathsf{T}u\colon \varphi \to \psi \in \Gamma \Longrightarrow \mathsf{F}u\colon \varphi \in \Gamma$ or $\mathsf{T}u\colon \psi \in \Gamma$;

(e) $\mathsf{F}u\colon \varphi \to \psi \in \Gamma \Longrightarrow \{\mathsf{T}u\colon \varphi,\ \mathsf{F}u\colon \psi\} \subseteq \Gamma$;

(f) $\mathsf{T}u\colon \forall x_\alpha \varphi \in \Gamma \Longrightarrow \mathsf{T}u\colon \varphi\{x := A\} \in \Gamma$ for all closed A of type α;

(g) $\mathsf{F}u\colon \forall x_\alpha \varphi \in \Gamma \Longrightarrow \mathsf{F}u\colon \varphi\{x := c\} \in \Gamma$ for some $c \in \mathcal{L}_\alpha$

(h) $\mathsf{T}u\colon \langle R\rangle\varphi \in \Gamma \Longrightarrow \{\mathsf{T}u\colon Ru', \mathsf{T}u'\colon \varphi\} \subseteq \Gamma$ for some $u' \in \mathcal{L}_s$;

(i) $\mathsf{F}u\colon \langle R\rangle\varphi \in \Gamma \Longrightarrow \mathsf{F}u\colon Ru' \in \Gamma$ or $\mathsf{F}u'\colon \varphi \in \Gamma$ for all $u' \in \mathcal{L}_s$;

(j) $\mathsf{S}u\colon R^{\smile}u' \in \Gamma \Longrightarrow \mathsf{S}u'\colon Ru \in \Gamma$;

A downward saturated branch Γ of $\mathcal{L}$ is said to be *complete* if $\mathsf{T}u\colon \varphi \in \Gamma$ or $\mathsf{F}u\colon \varphi \in \Gamma$ for each sentence φ of $\mathcal{L}$ and each $u \in \mathcal{L}_s$.

That downward saturated branches are satisfiable is the content of the next lemma. Here an intensional model is constructed using the method employed by Takahashi and Prawitz.

LEMMA 28 (Hintikka Lemma). *If Γ is a downward saturated branch in a language $\mathcal{L}$ such that $\mathcal{L}_\alpha \neq \varnothing$ for each basic type α then Γ is satisfied by a intensional model. If Γ is complete, then Γ is satisfied by a normal countable intensional model.*

Proof. Let Γ be a downward saturated branch in a language $\mathcal{L}$ as indicated. We will find an intensional model satisfying Γ using the Takahashi-Prawitz construction. The following induction on type complexity defines domains D_α as sets of pairs $\langle A, e\rangle$, where A is a closed term of type α and e is called a *possible extension* of A.

(i) If α is basic let $D_\alpha = \{\langle c, c\rangle \mid c \in \mathcal{L}_\alpha\}$;

(ii) If $\alpha = \langle \alpha_1 \dots \alpha_n\rangle$ let $\langle A_\alpha, e\rangle \in D_\alpha$ iff A is closed, $e \subseteq D_s \times D_{\alpha_1} \times \cdots \times D_{\alpha_n}$ and, whenever $\langle B_1, e_1\rangle \in D_{\alpha_1}, \dots, \langle B_n, e_n\rangle \in D_{\alpha_n}$

  (a) If $\mathsf{T}u\colon AB_1 \dots B_n \in \Gamma$ then $\langle\langle u, u\rangle, \langle B_1, e_1\rangle, \dots, \langle B_n, e_n\rangle\rangle \in e$;

  (b) If $\mathsf{F}u\colon AB_1 \dots B_n \in \Gamma$ then $\langle\langle u, u\rangle, \langle B_1, e_1\rangle, \dots, \langle B_n, e_n\rangle\rangle \notin e$.

Each D_α is non-empty. For basic types α this follows from the requirement that $\mathcal{L}_\alpha \neq \varnothing$; for complex types $\langle \alpha_1 \dots \alpha_n\rangle$ consider $\langle \lambda x_{\alpha_1} \dots \lambda x_{\alpha_n}.\bot, \varnothing\rangle$. Since induction on term complexity easily shows that terms have unique types, we also have that $D_\alpha \cap D_\beta = \varnothing$ if $\alpha \neq \beta$. Hence $\{D_\alpha \mid \alpha \in \mathcal{T}\}$ is a collection of domains. It is worth observing that each D_α is a function if Γ is complete. In that case each D_α will be countable.

The set $D = \{D_\alpha \mid \alpha \in \mathcal{T}\}$ will be the collection of domains of the intensional model we are after. We will define a function I which will turn out to be an intension function for D. First some handy notation. If π is an ordered pair, write π^1 and π^2 for the first and second elements of π respectively, so that $\pi = \langle \pi^1, \pi^2\rangle$. If f is a function whose values are ordered pairs, write f^1 and f^2 for the functions with the same domain as f, such that $f^1(z) = (f(z))^1$ and $f^2(z) = (f(z))^2$ for any argument z. Let a be an assignment for D. The substitution $\overleftarrow{a}$ is defined by $\overleftarrow{a}(x) = a^1(x)$ and we let $I^1(a, A) = A\overleftarrow{a}$ for any term A. The second component of I is defined using an induction on term complexity.

(a) $I^2(a, x) = a^2(x)$, if x is a variable;
$I^2(a, c_\alpha) = c$, if α is basic;
$I^2(a, c_\alpha) = \{\langle\langle u, u\rangle, \langle A_1, e_1\rangle, \dots, \langle A_n, e_n\rangle\rangle \mid \langle A_i, e_i\rangle \in D_{\alpha_i}$
$\& \ \mathsf{T}u\colon cA_1 \dots A_n \in \Gamma\}$, if α is complex;

(b) $I^2(a, AB) = \{\langle w, \vec{d}\rangle \mid \langle w, I(a,B), \vec{d}\rangle \in I^2(a,A)\}$;

(c) $I^2(a, \lambda x_\beta.A) = \{\langle w, d, \vec{d}\rangle \mid d \in D_\beta \text{ and } \langle w, \vec{d}\rangle \in I^2(a[d/x], A)\}$;

(d) $I^2(a, \bot) = \varnothing$;

(e) $I^2(a, \varphi \to \psi) = D_s - (I^2(a,\varphi) - I^2(a,\psi))$;

(f) $I^2(a, \forall x_\alpha \varphi) = \bigcap_{d \in D_\alpha} I^2(a[d/x], \varphi)$;

(g) $I^2(a, \langle R\rangle\varphi) = \{w \mid \exists w' \text{ with } \langle w, w'\rangle \in I^2(a,R) \text{ and } w' \in I^2(a,\varphi)\}$;

(h) $I^2(a, R^{\smile}) = \{\langle w, w'\rangle \mid \langle w', w\rangle \in I^2(a,R)\}$.

The definition obviously follows definition 17 save in its first clause. Note that well-definedness does not depend on the question whether I is an intension function for D and $\mathcal{L}$, and indeed the latter is not immediately obvious. We need to check the requirements in definition 13. That $I(a,x) = a(x)$ for any variable x is immediate and that $I(a,A) = I(a',A)$ if a and a' agree on the variables free in A follows by a standard property of substitutions and an easy induction. Suppose that B is free for x in A. Then

$$I^1(a, A\{x := B\}) = A\{x := B\}^{\overleftarrow{a}} = A^{\overleftarrow{a}}[x := B^{\overleftarrow{a}}] =$$
$$A^{\overleftarrow{a}}[x := I^1(a,B)] = A^{\overleftarrow{a[I(a,B)/x]}} = I^1(a[I(a,B)/x], A)\ .$$

That $I^2(a, A\{x := B\}) = I^2(a[I(a,B)/x], A)$ follows by a straightforward induction on the complexity of A which we leave to the reader. It follows that $I(a, A\{x := B\}) = I(a[I(a,B)/x], A)$ if B is free for x in A.

It remains to be shown that $I(a,A) \in D_\alpha$ for any assignment a and term A of type α. This is done by induction on the complexity of A. That $I(a, x_\alpha) \in D_\alpha$ if x is a variable follows from the stipulation that $I(a,x) = a(x)$ and that $I(a, c_\alpha) \in D_\alpha$ if α is basic is immediate. In the remaining cases the type of A is complex. Since it is easily seen by a separate induction that $I^2(a, A_\alpha) \subseteq D_s \times D_{\alpha_1} \times \cdots \times D_{\alpha_n}$ if $\alpha = \langle \alpha_1 \ldots \alpha_n\rangle$, it suffices to prove that, whenever $\alpha = \langle \alpha_1 \ldots \alpha_n\rangle$, and $\langle B_1, e_1\rangle \in D_{\alpha_1}, \ldots, \langle B_n, e_n\rangle \in D_{\alpha_n}$

(a) If $\mathsf{T}u\colon A^{\overleftarrow{a}} B_1 \ldots B_n \in \Gamma$ then $\langle\langle u,u\rangle, \langle B_1, e_1\rangle, \ldots, \langle B_n, e_n\rangle\rangle \in I^2(a,A)$;

(b) If $\mathsf{F}u\colon A^{\overleftarrow{a}} B_1 \ldots B_n \in \Gamma$ then $\langle\langle u,u\rangle, \langle B_1, e_1\rangle, \ldots, \langle B_n, e_n\rangle\rangle \notin I^2(a,A)$.

We will consider some remaining cases of the induction, leaving others to the reader. IH will be short for 'induction hypothesis'.

- $A_\alpha \equiv c$ and $\alpha = \langle \alpha_1 \ldots \alpha_n\rangle$. The requirement follows from the definition of $I^2(a,c)$ and clause (i) of definition 27.

- $A \equiv B_{\langle \beta\alpha_1 \ldots \alpha_n\rangle} C_\beta$. Suppose $\langle B_1, e_1\rangle \in D_{\alpha_1}, \ldots, \langle B_n, e_n\rangle \in D_{\alpha_n}$. From the induction hypothesis it follows that $I(a,C) = \langle C^{\overleftarrow{a}}, I^2(a,C)\rangle \in D_\beta$. Hence

$$\begin{array}{rcl}
\mathsf{T}u\colon (BC)^{\overleftarrow{a}} B_1 \ldots B_n \in \Gamma & \iff & \\
\mathsf{T}u\colon B^{\overleftarrow{a}} C^{\overleftarrow{a}} B_1 \ldots B_n \in \Gamma & \Longrightarrow & \text{(IH)} \\
\langle\langle u,u\rangle, I(a,C), \langle B_1, e_1\rangle, \ldots, \langle B_n, e_n\rangle\rangle \in I^2(a,B) & \iff & \text{(def. of } I\text{)} \\
\langle\langle u,u\rangle, \langle B_1, e_1\rangle, \ldots, \langle B_n, e_n\rangle\rangle \in I^2(a,BC) & &
\end{array}$$

This proves the (a) part of the case; the (b) part is similar.

- $A \equiv (\lambda x_{\alpha_1} C_{\langle \alpha_2 \dots \alpha_n \rangle})$. Again suppose $d_i = \langle B_i, e_i \rangle \in D_{\alpha_i}$, and reason as follows.

$$
\begin{array}{rcl}
\mathsf{F}u\colon (\lambda x.C)\overleftarrow{a}\, B_1 \dots B_n \in \Gamma & \iff & \\
\mathsf{F}u\colon (\lambda x.C\overleftarrow{a}\,[x := x])B_1 \dots B_n \in \Gamma & \Longrightarrow & \text{def. 27, } B_1 \text{ is closed} \\
\mathsf{F}u\colon C\overleftarrow{a}\,[x := B_1]B_2 \dots B_n \in \Gamma & \iff & \\
\mathsf{F}u\colon C\overleftarrow{a[d_1/x]}B_2 \dots B_n \in \Gamma & \Longrightarrow & \text{(IH)} \\
\langle \langle u, u \rangle, d_2, \dots, d_n \rangle \notin I^2(a[d_1/x], C) & \iff & \text{(def. of } I^2) \\
\langle \langle u, u \rangle, d_1, d_2, \dots, d_n \rangle \notin I^2(a, \lambda x.C) & &
\end{array}
$$

  This proves the (b) part, which is similar to the (a) part.

- $A_{\langle\rangle} \equiv \forall x_\beta \varphi$. Let $d \in D_\beta$ be arbitrary. Then $d = \langle B, e \rangle$ for some closed term B. In order to prove the (a) part of the statement we reason as follows.

$$
\begin{array}{rcl}
\mathsf{T}u\colon (\forall x \varphi)\overleftarrow{a} \in \Gamma & \iff & \\
\mathsf{T}u\colon \forall x \varphi\overleftarrow{a}\,[x := x] \in \Gamma & \Longrightarrow & \text{def. 27} \\
\mathsf{T}u\colon \varphi\overleftarrow{a}\,[x := x]\{x := B\} \in \Gamma & \iff & \\
\mathsf{T}u\colon \varphi\overleftarrow{a[d/x]} \in \Gamma & \Longrightarrow & \text{(IH)} \\
\langle u, u \rangle \in I^2(a[d/x], \varphi) & &
\end{array}
$$

  Since d was arbitrary, we conclude that $\langle u, u \rangle \in I^2(a, \forall x \varphi)$. The (b) part is similar.

- The cases $A_{\langle\rangle} \equiv \bot$, $A_{\langle\rangle} \equiv \varphi \to \psi$, $A_{\langle\rangle} \equiv \langle R \rangle \varphi$ and $A_{\langle s \rangle} \equiv R^{\smile}$ are straightforward.

This concludes the proof that I is an intension function for D and $\mathcal{L}$. Now define the function E by letting $E(\langle A, e \rangle) = e$ if $\langle A, e \rangle \in D_\alpha$ for any complex α. Clearly, $E(I(a, A)) = I^2(a, A)$ for any A, E is an extension function for D, and $M = \langle D, I, E \rangle$ is an intensional model for the language $\mathcal{L}$. It is easy to see that M satisfies Γ.

In order to prove the second part of the lemma, assume that Γ is complete. We have already established that M is countable in that case, and proposition 26 gives a normal countable intensional model satisfying Γ. ❑

We now come to the first step sketched in the introduction to this section. The notion of an *unsatisfiability property* (related to the *abstract consistency properties* of Smullyan [48] and Fitting [17]) is defined and it is shown that branches that do not have a 'sound' unsatisfiability property can in fact be extended to a downward saturated branch and hence are satisfiable. The interest in the theorem comes from the fact that many interesting notions can in fact be related to sound unsatisfiability properties as we shall see below.

DEFINITION 29. Let $\mathcal{U}$ be a set of branches in the language $\mathcal{L}$. $\mathcal{U}$ is an *unsatisfiability property* in $\mathcal{L}$ if, for each tableau rule $\Gamma/\Gamma_1; \dots; \Gamma_n$, $\{\Gamma_1, \dots, \Gamma_n\} \subseteq \mathcal{U}$ implies $\Gamma \in \mathcal{U}$.

An unsatisfiability property $\mathcal{U}$ in $\mathcal{L}$ is *sound* if no $\Gamma \in \mathcal{U}$ is satisfied by an intensional model for $\mathcal{L}$.

THEOREM 30 (Model Existence). *Let $\mathcal{L}$ and $\mathcal{C}$ be languages such that each $\mathcal{C}_\alpha$ is denumerably infinite and $\mathcal{L} \cap \mathcal{C} = \varnothing$. Assume that $\mathcal{U}$ is a sound unsatisfiability property in $\mathcal{L} \cup \mathcal{C}$ and that Γ is a branch in the language $\mathcal{L}$. If $\Gamma \notin \mathcal{U}$ then Γ is satisfied by a countable normal intensional model.*

Proof. Let $\mathcal{U}$ and Γ be as described. We construct a downward saturated branch Γ^* such that $\Gamma \subseteq \Gamma^*$. Let $\vartheta_1, \ldots, \vartheta_n, \ldots$ be an enumeration of all labeled sentences in $\mathcal{L} \cup \mathcal{C}$. Write $\#(\vartheta)$ for the index that the labeled sentence ϑ obtains in this enumeration. Let $\Gamma_0 = \Gamma$ and define each Γ_{n+1} by distinguishing the following four cases.

- $\Gamma_{n+1} = \Gamma_n$, if $\Gamma_n \cup \{\vartheta_n\} \in \mathcal{U}$;
- $\Gamma_{n+1} = \Gamma_n \cup \{\vartheta_n\}$, if $\Gamma_n \cup \{\vartheta_n\} \notin \mathcal{U}$ and ϑ_n is not of the form $\mathsf{F}u\colon \forall x\varphi$ or of the form $\mathsf{T}u\colon \langle R\rangle\varphi$;
- $\Gamma_{n+1} = \Gamma_n \cup \{\vartheta_n, \mathsf{F}u\colon \varphi\{x := c\}\}$, where c is the first constant in $\mathcal{C}_\alpha$ which does not occur in $\Gamma_n \cup \{\vartheta_n\}$, if $\Gamma_n \cup \{\vartheta_n\} \notin \mathcal{U}$ and $\vartheta_n \equiv \mathsf{F}u\colon \forall x_\alpha\varphi$;
- $\Gamma_{n+1} = \Gamma_n \cup \{\vartheta_n, \mathsf{T}u\colon Ru', \mathsf{T}u'\colon \varphi\}$, where u' is the first constant in $\mathcal{C}_s$ which does not occur in $\Gamma_n \cup \{\vartheta_n\}$, if $\Gamma_n \cup \{\vartheta_n\} \notin \mathcal{U}$ and $\vartheta_n \equiv \mathsf{T}u\colon \langle R\rangle\varphi$.

This is well-defined since each Γ_n contains only a finite number of constants from $\mathcal{C}$. That $\Gamma_n \notin \mathcal{U}$ for each n follows by a simple induction which uses the definition of an unsatisfiability property and the fact that $\mathsf{F}\forall$ and $\mathsf{T}\langle\cdot\rangle$ are tableau rules. Define $\Gamma^* = \bigcup_n \Gamma_n$. For all finite sets $\{\vartheta_{k_1}, \ldots, \vartheta_{k_n}\}$ and all $k \geq \max\{k_1, \ldots, k_n\}$

(20) $\{\vartheta_{k_1}, \ldots, \vartheta_{k_n}\} \subseteq \Gamma^* \Leftrightarrow \Gamma_k \cup \{\vartheta_{k_1}, \ldots, \vartheta_{k_n}\} \notin \mathcal{U}$

In order to show this, let $k \geq \max\{k_1, \ldots, k_n\}$ and let $\{\vartheta_{k_1}, \ldots, \vartheta_{k_n}\} \subseteq \Gamma^*$. Then there is some ℓ such that $\{\vartheta_{k_1}, \ldots, \vartheta_{k_n}\} \subseteq \Gamma_\ell$. Let $m = \max\{k, \ell\}$. We have that $\Gamma_k \cup \{\vartheta_{k_1}, \ldots, \vartheta_{k_n}\} \subseteq \Gamma_m$. Since $\Gamma_m \notin \mathcal{U}$ and $\mathcal{U}$ is closed under supersets (because of the weakening rule W), it follows that $\Gamma_k \cup \{\vartheta_{k_1}, \ldots, \vartheta_{k_n}\} \notin \mathcal{U}$. For the reverse direction, suppose that $\Gamma_k \cup \{\vartheta_{k_1}, \ldots, \vartheta_{k_n}\} \notin \mathcal{U}$. Then, since $\mathcal{U}$ is closed under supersets, $\Gamma_{k_i} \cup \{\vartheta_{k_i}\} \notin \mathcal{U}$, for each of the k_i. By the construction of Γ^* each $\vartheta_{k_i} \in \Gamma^*$ and $\{\vartheta_{k_1}, \ldots, \vartheta_{k_n}\} \subseteq \Gamma^*$.

Γ^* is a downward saturated branch. The conditions (g) and (h) of definition 27 immediately follow from the construction of Γ^*. For checking the other conditions of definition 27 the equivalence in (20) can be used. Here we check condition (i), which may serve as an example for the other cases. Assume $\mathsf{F}u\colon \langle R\rangle\varphi \in \Gamma^*$ and let u' be a constant of type s. Let k be the maximum of $\#(\mathsf{F}u\colon \langle R\rangle\varphi)$, $\#(\mathsf{F}u\colon Ru')$, and $\#(\mathsf{F}u'\colon \varphi)$. Since, by (20), $\Gamma_k \cup \{\mathsf{F}u\colon \langle R\rangle\varphi\} \notin \mathcal{U}$, it must be the case by definition 29 and the fact that $\mathsf{F}\langle\cdot\rangle$ is a tableau rule that either $\Gamma_k \cup \{\mathsf{F}u\colon Ru'\} \notin \mathcal{U}$ or $\Gamma_k \cup \{\mathsf{F}u'\colon \varphi\} \notin \mathcal{U}$. Using (20) again, we find that either $\mathsf{F}u\colon Ru' \in \Gamma^*$ or $\mathsf{F}u'\colon \varphi \in \Gamma^*$.

We conclude that Γ^* is satisfied by an intensional model M. In order to prove that there is a normal countable intensional model satisfying Γ^* and hence Γ it suffices to show that Γ^* is complete. Let φ be any sentence of $\mathcal{L} \cup \mathcal{C}$ and assume that $\mathsf{T}u\colon \varphi \notin \Gamma^*$ and $\mathsf{F}u\colon \varphi \notin \Gamma^*$. Then, by (20), $\Gamma_k \cup \{\mathsf{T}u\colon \varphi\} \in \mathcal{U}$ and $\Gamma_k \cup \{\mathsf{F}u\colon \varphi\} \in \mathcal{U}$, for sufficiently large k. But M satisfies Γ_k and therefore must either satisfy $\Gamma_k \cup \{\mathsf{T}u\colon \varphi\}$ or $\Gamma_k \cup \{\mathsf{F}u\colon \varphi\}$, contradicting the soundness of $\mathcal{U}$. Thus Γ^* is complete and some normal countable intensional model satisfies Γ^* and Γ. ❑

We can now reap a harvest of corollaries by relating various notions to unsatisfiability properties. In the following Γ will always be a branch in some language $\mathcal{L}$ while Δ ranges over branches in $\mathcal{L} \cup \mathcal{C}$, where $\mathcal{L}$ and $\mathcal{C}$ are as in the formulation of Theorem 30.

COROLLARY 31 (Generalized Compactness). *If each finite* $\Gamma_0 \subseteq \Gamma$ *is satisfiable then* Γ *is satisfiable.*

Proof. $\{\Delta \mid \text{some finite } \Delta_0 \subseteq \Delta \text{ is unsatisfiable}\}$ is a sound unsatisfiability property. ❑

COROLLARY 32 (Generalized Löwenheim–Skolem). *If* Γ *is satisfiable then* Γ *is satisfiable by a countable intensional model.*

Proof. $\{\Delta \mid \Delta \text{ is unsatisfiable}\}$ is a sound unsatisfiability property. ❑

COROLLARY 33 (Generalized Completeness). *If* Γ *is unsatisfiable then* Γ *has a closed tableau.*

Proof. $\{\Delta \mid \Delta \text{ has a closed tableau}\}$ is a sound unsatisfiability property. ❑

COROLLARY 34 (Admissability of Cut). *If* $\Gamma \cup \{\mathsf{T}u{:}\, \varphi\}$ *and* $\Gamma \cup \{\mathsf{F}u{:}\, \varphi\}$ *have closed tableaus then* Γ *has a closed tableau.*

Proof. Use soundness and generalized completeness. ❑

7 CONCLUSION

This chapter has looked at some of the motivations for combining modality with quantification and abstraction over objects of higher order. Montague's logic **IL** was reviewed and was found to have some shortcomings: it is not Church-Rosser and it is not intensional in Whitehead and Russell's original sense. An alternative higher order modal logic **MTT** was then introduced. **MTT** imports many ideas from the higher order logics in Fitting [19], but is based on a simpler notion of model. We have dubbed the generalized models on which **MTT** is based *intensional* models. As was shown above, the usual rules of α, β and η conversion can consistently be added to the logic in which case the logic sports the Church-Rosser property.

The logic is also fully intensional (or "hyperintensional") in the sense that co-entailing expressions need not be identical and we shall use the rest of this conclusion to discuss some points that arise in relation with this. Consider (21–24), where in each case a natural language sentence is accompanied by its **MTT** rendering. (Here *fido*, *fritz* and *mary* are constants of individual type e, *in* is a predicate of type $\langle e \rangle$, and *know* is a relation of type $\langle\langle\rangle e\rangle$.)

(21) a. Fritz is out if Fido is in
b. $\mathit{in}\,\mathit{fido} \rightarrow \neg(\mathit{in}\,\mathit{fritz})$

(22) a. Fido is out if Fritz is in
b. $\mathit{in}\,\mathit{fritz} \rightarrow \neg(\mathit{in}\,\mathit{fido})$

(23) a. Mary knows Fritz is out if Fido is in
b. $\mathit{know}\,(\mathit{in}\,\mathit{fido} \rightarrow \neg(\mathit{in}\,\mathit{fritz}))\;\mathit{mary}$

(24) a. Mary knows Fido is out if Fritz is in
b. $\mathit{know}\,(\mathit{in}\,\mathit{fritz} \rightarrow \neg(\mathit{in}\,\mathit{fido}))\;\mathit{mary}$

Simple tableaus will verify that (21b) and (22b) co-entail, as they should. But (23b) and (24b) do *not* co-entail: Note that $\{\mathsf{T}u\colon(23\text{b}), \mathsf{F}u\colon(24\text{b})\}$ is downward saturated and thus will have an intensional model refuting one direction of the entailment.

It may be protested that there is at least one sense in which Mary knows that Fido is out if Fritz is in if she knows that Fritz is out if Fido is in: While she may have failed to derive the contraposed statement *explicitly*, there is still a sense in which she is *implicitly* committed to it. Such a notion of *implicit knowledge* is also available in **MTT**. Let K be a constant of type $\langle es\rangle$. K can be given the role of an *epistemic alternative relation* by adopting the following meaning postulate.

(25) $\Box\forall x_e\forall w_s(Kxw \leftrightarrow \forall p_{\langle\rangle}(\mathit{know}\,px \rightarrow \Diamond(\dot{w}\wedge p)))$

This says effectively that a world w is an epistemic alternative for a person x if w is in the intersection of the extensions of all propositions that x explicitly knows to hold.[8] A tableau will show that (25) entails (26).

(26) $\forall x_e\forall p_{\langle\rangle}(\mathit{know}\,px \rightarrow [Kx]p)$

Thus it can be deduced that (27), where the modal operator $[K\,\mathit{mary}]$ was used to model Mary's implicit beliefs, follows from (23). In fact *implicit* beliefs are closed under consequence and hence co-entailment.

(27) a. Mary implicitly knows Fido is out if Fritz is in
b. $[K\,\mathit{mary}](\mathit{in}\,\mathit{fritz} \rightarrow \neg(\mathit{in}\,\mathit{fido}))$

The non-equivalence of (23b) and (24b) discussed above illustrates that **MTT** is intensional in Whitehead and Russell's sense of the term. Relations, including zero-place relations, can be co-extensional without being identical. This means that linguistic expressions that are assumed to denote relations are no longer predicted to be intersubstitutable if they have the same extension, not even if they have the same extension in all possible worlds.

This is not unimportant since many expressions in natural language are undoubtedly relational and a nasty foundational problem will no longer be associated with them, but there seems to be a rest category of problems with expressions of *basic* type. Above we have treated *proper names* as having a basic type e, and this leads to the well-known Hesperus–Phosphorus, or Cicero–Tully, kind of problem. If *Hesperus* is translated as $\mathit{hesperus}_e$, *Phosphorus* as $\mathit{phosphorus}_e$, and the identity statement *Hesperus is Phosphorus* as $\mathit{hesperus} = \mathit{phosphorus}$, the consequence will be the false prediction that the two names can be substituted for one another in any context *salva veritate*.

There are two reactions to this. One possible reaction is an adaptation of the logic. One could introduce some domain of individual concepts and allow many-one correspondences between individual concepts and individuals. Such a strategy is followed by Fox and Lappin [20] in a different set-up, but in our case it would lead to a complication of the logic, be it probably a mild one.

The second reaction leaves the logic as is, but adapts the rendering of natural language expressions. If names can be treated as predicates in some way, the intension–extension

[8] Note that the present set-up distinguishes between propositions (the elements of $D_{\langle\rangle}$) and sets of possible worlds. The extension of a proposition will be a set of worlds. Different propositions may determine the same extension.

distinction will come for free for them as well. In fact, the existing literature contains several proposals for treating names as based on predicates and not on individual constants. Russell's description theory of names is an early example and Montague [38] offers another example by essentially treating names as being of the "raised" type $\langle\langle e\rangle\rangle$, not simply of type e. In combination with a treatment of identity as co-extensionality (in all possible worlds) this would avoid the problems if our logic is used. A third proposal that in effect treats names as relations comes from the literature on plurality. Many authors on this subject, starting with Bartsch [5] and Bennett [6] (see Lønning [34] for an overview), have argued that both singular and plural individuals should in fact be treated as sets, with the semantic property of being a singleton corresponding to the grammatical notion of singularity. In the present set-up this effect can be obtained by redefining type e as a complex type $\langle 0\rangle$, where 0 is a new basic type for abstract individuals. Type 0 objects will now correspond one-to-one with the *extensions* of those type e objects that have singleton extensions, i.e. to singular individuals, but there are many intensional models in which $\mathit{hesperus}_e$ and $\mathit{phosphorus}_e$ are co-extensional (with a singleton extension) in all worlds but are not identical. Let $A_e \approx B_e$ be an abbreviation of $\Box\forall x_0(Ax \leftrightarrow Bx)$, i.e. let $A \approx B$ express necessary co-extensionality, and assume that natural language *is* (the "*is* of identity") in fact expresses $\approx$. Then the argument in (28) will be rendered as (29) and will therefore be predicted to be invalid.

$$\text{(28)}\quad \frac{\text{Hesperus is Phosphorus} \qquad \text{Mary knows that Hesperus is Hesperus}}{\text{Mary knows that Hesperus is Phosphorus}}$$

$$\text{(29)}\quad \frac{\mathit{hesperus} \approx \mathit{phosphorus} \qquad \mathit{know}\,(\mathit{hesperus} \approx \mathit{hesperus})\ \mathit{mary}}{\mathit{know}\,(\mathit{hesperus} \approx \mathit{phosphorus})\ \mathit{mary}}$$

Again, the invalidity of the argument depends on the fact that Mary's knowledge was taken to be Mary's *explicit* knowledge. If implicit knowledge is taken, the argument will turn out to be valid, as the reader will have no difficulty to verify.

We conclude that the logic **MTT** is truly intensional, as it will distinguish between the meaning of one relation and another necessarily co-extensive with it. This can be used to avoid many substitution problems in natural language semantics and other areas. If it is moreover accepted that proper names should in fact be treated as constants of complex type, they will also be treated hyperintensionally. For example, letting them be of type $\langle 0\rangle$, a move which may be argued for on independent grounds having to do with the treatment of plurality, will make them start to act as naming individual concepts and substitution problems with them will be avoided.

ACKNOWLEDGEMENTS

I would like to thank Grigori Mints for his valuable comments. The editors I thank for their comments, their patience, and their encouragement.

1 INTRODUCTION

Time has always been with us, though few of us have enough of it. The nature of time itself is a conundrum that we nowadays leave to physicists. But we have always had to find our way through time, plan our activities, and cope with the uncertain future. This can be, indeed, has to be done without a deep scientific knowledge of what makes time tick.

We use language and its rich tense structure to express and reason about events in time. This of course throws up linguistic and philosophical conundrums of its own. With the rise in the 20th century of formal logical languages, it became natural to try to express temporal concepts and arguments in formal terms, and so it was that Arthur Prior from the 1950s came to develop *tense logics.* These were modal logics, with box-modalities H and G for 'always in the past' and 'always in the future', motivated by tenses in natural language. The advent of Kripke semantics in the 1960s gave the enterprise a boost, because a Kripke frame is so naturally seen as a set of time points endowed with an 'earlier-later' relation.

Temporal logic today is a large, busy subject with stakeholders from many disciplines. Philosophers and linguists have continued to make major contributions to it. Since Pnueli's pioneering 1977 paper [147], several branches of computer science and related fields — such as databases, specification and verification, synthesis of programs, temporal planning, temporal knowledge representation — have had a huge influence, and the use of temporal logic in some of these areas has developed to the point of commercial application. There is even some contact with physics, but so far this has been limited.

Temporal logic is in a way a branch of applied modal logic, but modal logicians may be disconcerted by what they find here. Temporal logic has always focused on handling time, it has developed whatever methods it found useful for this end, and not all of them are modal in a narrow sense. Connectives such as Until and Since, again mimicking the natural language constructs, go beyond boxes and diamonds and are of great importance in the subject. Indeed, completely general first-order-definable connectives are used as well. Bearing in mind the evaluation and reference points of natural language, it is natural that many-dimensional evaluation has long been of importance in temporal logic, whereas it only recently attracted great interest in modal logic proper. The focus in temporal logic is on a fairly narrow range of Kripke frames — nearly always irreflexive and transitive, and typically linear orders or trees, though relativistic and circular time are sometimes considered. The natural numbers are the dominant model of linear time, though dense and continuous and indeed arbitrary linear orders have found their way in (and in this chapter we are happy to consider them). Sometimes the pressures of time have led to a style of evaluation of formulas that seems non-modal at first sight (see Section 3.7). A very influential strand of work, started by Kamp in 1968, compares the expressive power of modal and first-order languages on the model (rather than frame) level. Rather than be content with limited but well-behaved modal expressiveness, the thrust of the work created temporal languages as strong as classical first-order logic and even monadic second-order logic. Perhaps because the proofs rely heavily on the assumption that time is linear or even natural number-like, not much similar research in modal logic has been done. Classical logic is not just a benchmark for the expressiveness of 'real' temporal logics: using first-order logic for handling time is itself a respectable tradition. In temporal logic there is an unusual (for modal logic) use of methods from

classical mathematical logic and combinatorial techniques such as automata. Problems such as model-checking (considered in Chapter 17) are all-important in temporal logic but do not appear much in modal logic.

Nonetheless, from Prior's work onwards, modal ideas have been prominent in temporal logic. Its most basic syntax and Kripke semantics are (multi-)modal; one often comes across modal techniques such as canonicity and Sahlqvist's theorem, filtration and non-standard inference rules; and problems of axiomatisation, decidability, and complexity are ubiquitous in modal and temporal logic. Sophisticated results on modal logics above K4 have been transferred to temporal logic. Chapters 2, 3, 4, 9, and 12 are very relevant to temporal logic. In Chapter 17, the reader will find a concentrated discussion of modal and temporal logic in computer science. In the current chapter, we will examine some topics in temporal logic that are considered both in computer science and in other fields. As we have not the space to provide a rigorous development from scratch, the chapter is intended more as a gateway to the subject. It is mostly a survey-style commentary on some important strands, with directions to the literature for those wishing to find out more. Our priority is range rather than depth, but we cannot be comprehensive. A chapter of definitions would be indigestible, so we have tried to include some of the arguments, but space limitations have meant that their level of detail veers wildly from a few words to (occasionally) something approaching a full proof. Readers may of course skip details if they so desire.

We start out in Section 2 with a basic round-up of the semantic options for handling time. In Section 3 we cover some of the logics (syntax and evaluation) that can be used. Bearing in mind the remarks above, it will be no surprise that we do not confine ourselves to modal-style logics: first- and second-order logics, and others, find their way in, and our lack of consideration of mu-calculi is only because chapter 12 is devoted to them. Cn Section 4 we compare the expressivity of classical and modal-style logics. Kamp's famous 1968 expressive completeness theorem makes its appearance here. In Section 5 we discuss temporal reasoning, mainly avoiding automata (see Chapter 17 for them) but covering Hilbert systems, tableaux, resolution, filtration and the finite model property, and other methods.

A word about first-order temporal logic. This is a complex issue. There is a confusing variety of ways to add first-order logic to a temporal system, and undecidability results obtained in the 1960s, accompanied by later expressive incompleteness results, also cast their shade over the development of this part of the subject. But at the time of writing, there is something of a resurgence of interest in it from the database and reasoning communities. We will discuss the rudiments of first-order temporal logic in Sections refchapter11:sec2–3, and also some of the recent results on expressive completeness and decidability in Sections refchapter11:sec4–5. Chapter 9 is also relevant of course.

Temporal logic, then, is a branch of applied logic that brings to bear a gamut of powerful methods from many fields to study time and temporal phenomena. It is not wholly modal, but rests on a modal base — it is a meeting ground for concepts from modal logic, classical first-order logic, and higher-order logic. It has found very successful application in computing, and embodies seminal contributions from philosophy and linguistics as well. We hope our chapter, and other chapters here, will serve as a guide for the reader wishing to discover more about this intensely active field.

2 STRUCTURES

How can we model time? Clearly, such a question can generate much heated debate. Rather than make a futile attempt to settle it, we prefer to take a practical viewpoint, and simply offer the reader a number of options which have been studied in some depth and found useful.

This section is devoted to setting up some of the standard models of time. They will be called *structures.* We will use them as semantics for the various logics of time to be discussed in the next section. For now, we have no specific logic syntax in mind.

However, the future choice of syntax does have an effect here, because the structures we set up must be suitable for evaluating *atomic* formulas of the logics to come. So our treatment will divide into cases, according to the kind of evaluation we envisage. We will begin with the simplest case: models of time suitable for *propositional* temporal logics. This continues in Section 2.2 with cyclical models of time. In Section 2.3, we will consider some options for branching time. Section 2.4 will discuss structures supporting varying granularity of focus. Section 2.5 goes into the options when propositions depend on several time points; this leads naturally into Section 2.6, on temporal intervals. Finally, Section 2.7 considers the options for temporal logics beyond propositional.

2.1 Structures for propositional temporal logic

The simplest and most common form of temporal logic is *propositional temporal logic.* In it, time is viewed as simply a set of points. To facilitate making statements and reasoning about time, additional information is included in the model. We will start off with probably the simplest useful information, which is to state which time points are earlier than, or later than, which. To represent basic facts of interest, there are available a number of *atomic propositions,* or *propositional variables* (or as some say, *propositional atoms*). These are syntactic objects; they are usually written p, q, r, p_0, p_1, etc. Their truth values (true or false) are expected to be given by the model. These truth values will be time-dependent: so each atom will be either true or false at each time point, and the model will specify which. Logical machinery can be erected on top of the atoms in a variety of ways, to permit representation of and reasoning about more complex statements; this is the task of the next section.

Thus, our models or structures will have three parts: a set of time points; information about which time points come before or after which (this much is called a *flow of time*); and information about which atoms are true at which time points (this much is called a *temporal structure*).

Flows of time, and temporal structures

DEFINITION 1. A *flow of time* is a pair $(T, <)$, where T is a non-empty set, and $<$ is an irreflexive and transitive binary relation on T.

The idea is that T is the set of *time points,* and $<$ is the *earlier-later relation* on T. For time points $t, u \in T$, $t < u$ (or equally, $u > t$) will mean intuitively that t is earlier than u, and that u is later than t. This explains the requirements that $<$ be irreflexive — no time point should be in the past or future of itself — and transitive — if t is earlier than u, and u earlier than v, then we expect t to be earlier than v. However, we will

see a few circumstances (such as in Section 2.2) where it is appropriate to modify these requirements.

We can define the notion of two flows of time being isomorphic, or one being a subflow of the other, in the usual way. We also define the time point relations $>$, $\leq$, and $\geq$ in terms of $<$ in the usual way.

Clearly, a flow of time $(T, <)$ can be regarded as a (certain kind of) Kripke frame: the set of possible worlds is T, and the accessibility relation is $<$. This will later lead to modal-style logics for time.

Modelling truth and falsity of the atoms is done in the usual way. We assume a fixed ambient set L of atoms. Let $\wp(T)$ be the set of subsets of any given set T.

DEFINITION 2. A *temporal structure* is a triple $(T, <, h)$, where $(T, <)$ is a flow of time, and $h : L \to \wp(T)$ is a map (called an 'assignment' or 'valuation').

We regard an atom q as being true at a time $t \in T$ if $t \in h(q)$, and false at time t if $t \notin h(q)$. Some authors present valuations in the form $g : T \to \wp(L)$, $g(t)$ being the set of atoms regarded as true at time t. The two methods obviously carry the same information. Clearly, a temporal structure can be regarded as a Kripke structure (see Chapter 1).

Classes of flows of time We will often be interested in various *classes* of flows of time. The class of all flows of time is one such. Another is the class of all linear flows of time:

DEFINITION 3. A flow of time $(T, <)$ is said to be *linear* if given any two distinct time points in it, one is before the other. That is, $(T, <) \models \forall xy(x = y \vee x < y \vee y < x)$.

Linear flows have been very heavily studied, and various classes of linear flows will figure prominently in this chapter (though not to the exclusion of other kinds of flow). Here are some other interesting properties that a linear flow of time may have:

DEFINITION 4. Let $(T, <)$ be a linear flow of time.

1. $(T, <)$ is said to be *discrete* if for each $t \in T$,
   (a) if there is any $u \in T$ with $u > t$, then there is a first such u: one such that there is no $v \in T$ with $t < v < u$, and
   (b) if there is any $u \in T$ with $u < t$, then there is a last such u: one such that there is no $v \in T$ with $u < v < t$.
2. $(T, <)$ is said to be *dense* if for all $t, u \in T$, if $t < u$ then there is $v \in T$ with $t < v < u$. This is in some way the opposite of discrete.
3. $(T, <)$ is said to be *Dedekind complete* if any non-empty subset $S \subseteq T$ that is bounded above — i.e., there is $t \in T$ with $t \geq s$ for all $s \in S$ — has a least upper bound in T: i.e., there is $t \in T$ such that (i) $t \geq s$ for all $s \in S$, and (ii) there is no $t' < t$ with $t' \geq s$ for all $s \in S$. Equivalently, any non-empty $U \subseteq T$ that is bounded below has a greatest lower bound in T. (Any greatest lower bound of U is a least upper bound of $\{t \in T : t \leq u \text{ for all } u \in U\}$, and vice versa.)
4. $(T, <)$ is said to be *continuous* if it is dense and Dedekind complete.

5. $(T, <)$ is said to be *separable* if there is a countable subset $D \subseteq T$ that is *dense in* T*:* for all $t, u \in T$ with $t < u$, there is $v \in D$ with $t < v < u$. (It follows that $(T, <)$ is itself dense.)

The corresponding *classes* of linear flows, such as the dense linear ones, the discrete linear ones, and the continuous linear ones, as well as others such as the class of all finite linear flows, will be important to us. We will later write $\mathcal{L}$ for the class of all linear flows of time, and $\mathcal{D}$ for the class of all Dedekind-complete linear flows.

Non-linear flows such as trees are also much used:

DEFINITION 5. A flow of time $(T, <)$ is said to be a *tree* if for all $t \in T$, the set $\{u \in T : u < t\}$ is linearly ordered by $<$. A *branch* of a tree $(T, <)$ is a maximal linearly-ordered subset of T.

In a tree, the past of any time point is linear. However, its future may not be, so that many branches may pass through (i.e., contain) any given time point. Our models of 'branching time' will be based on trees.

There are also certain specific flows of time that are natural to consider, well studied, and useful in applications. We now list some of them, and make some comments. A general reference for information about linear orders is [171], in which the reader may find more details.

1. The natural numbers, $(\mathbb{N}, <)$, where $\mathbb{N} = \{0, 1, 2, \ldots\}$ and $<$ is the usual order. This is the most commonly used flow of all. It occurs naturally in computing applications, where programs execute instructions at successive moments. Time is viewed as discrete (ticking, so that any non-final moment has a next moment), linear, and with a first moment but no last moment. Of course, these properties alone are insufficient to pin down $\mathbb{N}$: for example, they are also true of the flow of time consisting of a copy of $\mathbb{N}$ followed by a copy of the integers, $\mathbb{Z}$, and indeed, this flow is indistinguishable from $(\mathbb{N}, <)$ by any first-order sentence. One may characterise $(\mathbb{N}, <)$ up to isomorphism in a second-order way as the unique discrete Dedekind-complete linear flow with a first point and no last point.

2. The integers, $(\mathbb{Z}, <)$, where $\mathbb{Z} = \{\ldots, -2, -1, 0, 1, 2, \ldots\}$, and $<$ is the usual order. The discrete Dedekind-complete linear flows of time are precisely the ones that are isomorphic to sub-flows of $(\mathbb{Z}, <)$, and $(\mathbb{Z}, <)$ is up to isomorphism the unique one of these without endpoints.

3. The rationals, $(\mathbb{Q}, <)$, where $\mathbb{Q}$ is the set of all rational numbers and $<$ is the usual order. We can use this flow when we view time as dense; density may correspond more closely than discreteness to our natural intuition about time as we move through it. Density may also be useful in modelling distributed computing applications, in which a program may find another acting in between its own execution steps. By Cantor's theorem, $(\mathbb{Q}, <)$ is up to isomorphism the unique countable linear dense flow of time without endpoints.

   We may wish to impose a 'real-world' constraint on valuations into $(\mathbb{Q}, <)$. If atoms represent basic states of a system, we may decide that only finitely many changes in state may occur, either in any bounded interval, or at all. So we may restrict to temporal structures $(\mathbb{Q}, <, h)$ in which each atom may change its value only finitely often in any bounded interval, or at all.

4. The reals, $(\mathbb{R}, <)$ where $\mathbb{R}$ is the set of all real numbers, and $<$ is the usual ordering. Here we have not only density, but continuity and separability too. In fact, $(\mathbb{R}, <)$ is up to isomorphism the unique continuous separable linear flow of time without endpoints. The reals are one of the most interesting and expressive linear flows; most other common linear flows can be 'encoded' in them.

   Various restrictions on atoms can be considered in the context of $(\mathbb{R}, <)$. Bounded or finite variability is again a possibility. Another is to require that the values of assignments are 'simple' in some way. For example, we might restrict to temporal structures $(\mathbb{R}, <, h)$ with assignments $h : L \to \wp(\mathbb{R})$ such that for each $q \in L$, $h(q)$ is F_σ (a countable union of closed sets), or Borel (in the countably complete Boolean subalgebra of $(\wp(\mathbb{R}), \cup, \setminus, \emptyset, \mathbb{R})$ generated by the closed sets). See [33] for applications of this idea to decidability of temporal logics over $(\mathbb{R}, <)$.

5. The binary tree $\mathcal{T} = ({}^{<\omega}2, <)$. For ordinals α, β, we write ${}^{\beta}\alpha$ for the set of all maps $f : \beta \to \alpha$. We write ${}^{<\beta}\alpha$ for $\bigcup_{\gamma<\beta} {}^{\gamma}\alpha$. So ${}^{<\omega}2$ is the set of all maps from a natural number n into 2. (We treat natural numbers n as ordinals, so that $n = \{0, 1, \ldots, n-1\}$ and $2 = \{0, 1\}$.) We can regard such a map as a sequence of 0s and 1s of length n, so that ${}^{<\omega}2$ can be viewed as the set of all finite sequences of 0s and 1s. The ordering $<$ on $\mathcal{T}$ is that of proper initial segment: so $t < u$ iff u is a proper extension of t. Clearly, $\mathcal{T}$ is a tree. Each branch of $\mathcal{T}$, ordered by the restriction of $<$, is isomorphic to $(\mathbb{N}, <)$; trees with this property will be called *ω-trees.*

   In this case, we may sometimes wish to restrict to assignments $h : L \to \wp({}^{<\omega}2)$ such that $h(q)$ is finite for all $q \in L$. Topological restrictions can also be made: see, e.g., [85].

6. Relativistic temporal logic has been considered a little in the literature: see, e.g., [71] (reprinted in [73]) and [180]. For $n \geq 2$, we can define n-dimensional space-time $\mathcal{T}^n$ to be $(\mathbb{R}^n, \leq)$. Here, $\mathbb{R}^n$ is the set of all n-tuples of real numbers; the first $n-1$ coordinates are for space and the last is for time. We define $(x_1, \ldots, x_n) \leq (y_1, \ldots, y_n)$ iff $\sum_{i=1}^{n-1}(y_i - x_i)^2 \leq (y_n - x_n)^2$ and $x_n \leq y_n$. This ordering is reflexive (so strictly, we are not dealing with a flow of time), and transitive (exercise). $\mathcal{T}^4$ is the traditional Minkowski space-time.

2.2 Cycles

We have defined flows of time to be transitive. One context in which this assumption seems unjustified is in the occasionally studied case of circular or cyclical time. Interest in this has stemmed from studies of general relativity [70] as well as from philosophical and religious motivations. The intuitive idea here is that there is a sequence, or locally linear arrangement of time which has its start temporally after its end time point. If we follow along the flow of time through such a structure we see the same arrangements of atoms repeated forever (and into the past as well as into the future). Obviously this behaviour can be mimicked by making restrictions on the valuations of atoms on an appropriate transitive linear flow of time so that the same pattern of truth values is repeated periodically. Cyclical time models, however, are instead based on a cyclical arrangement of time points.

A moment's thought makes it clear that it is not straightforward to make a mathematical structure to model this idea. It is certainly inadequate to have a flow of time $(T, <)$ with a transitive relation $<$: each time point would be after every other time point as well as being after itself.

Two solutions to this have been proposed. In [104] we see the idea of a model of time (T, ϕ) based on a ternary between-ness relation ϕ. We say that y lies between x and z and put $\phi(x, y, z)$ iff moving forwards in time from x to y does not pass through z. Appropriate conditions on ϕ are suggested in [104].

In [158] we see instead the usual binary $<$ being used as an irreflexive, anti-symmetric and non-transitive relation with $x < y$ meaning something like that y is a while after x but not so long after, not more than half way round the cycle of time. According to this approach we have the following definition.

DEFINITION 6. A *cyclical* flow of time is $(T, <)$ with $<$ being a binary relation on the set T such that $<$ satisfies the following axioms:

total order:	$\forall xy[(x < y) \vee (x = y) \vee (y < x)]$
anti-symmetry:	$\forall xy \neg[(x < y) \wedge (y < x)]$
future transitivity:	$\forall xyzu[(x < y) \wedge (x < z) \wedge (x < u) \wedge (y < z) \wedge (z < u) \rightarrow (y < u)]$
past transitivity:	$\forall xyzu[(y < x) \wedge (z < x) \wedge (u < x) \wedge (y < z) \wedge (z < u) \rightarrow (y < u)]$
non-transitivity:	$\exists xyz[(x < y) \wedge (y < z) \wedge (z < x)]$

2.3 Branching Time

The term *Branching Time* is sometimes used for general, i.e. transitive and irreflexive but not necessarily linear flows of time.

However, there is a more specific use that is more common both in philosophical and in computing contexts. These are the flows of time $(T, <)$ which are trees according to definition 5 above, i.e. in which $<$ is linear towards the past. The branching towards the future is often used to capture the indeterminacy of the future: openness, choices and chances. The linearity of the past instead captures the fixed, (already) determined nature of that part of time.

We shall use *Branching Time* in this latter sense, i.e. to refer to flows of time which are trees. We will see that there are branching time temporal logics in which formulas are evaluated at points (sometimes called nodes) on such tree structures. Branches are maximally linearly ordered subsets of the the set of time points: see Definition 5. Note, however, that the terms *path*, or *history* are sometimes used instead of 'branch' in the literature. Also, it is sometimes the case that a *branch* may be a linearly ordered set of points maximally towards the future but not necessarily towards the past, i.e. 1) b is linear, 2) if $x \leq y$ for all $x \in b$, then $y \in b$, and 3) for all x, y, z, if $x < y < z$ and $x \in b$ and $z \in b$ then $y \in b$.

In Burgess's [28], a more complex branching time temporal structure is suggested. Burgess notes that in some situations it is useful to pick out certain branches of a tree structure as being legitimate and to ignore others. For example, in a computing application some branches might exhibit a required fairness property in that certain atoms are true an infinite number of times along the branch, while other branches are unfair and thus may not be considered to be able to eventuate. In philosophical applications

some branches may correspond to "intended" or "possible" branches while others may be deemed impossible. As discussed in [165], there are also technical reasons to consider tree structures with a pre-identified set of branches. See also [218, 219].

In order to support such reasoning, certain temporal logics are defined on tree structures with identified sets of branches. In order for all the points of the tree to be non redundant and to be able to play a role in the semantics of such logics, it is useful to suppose that for each point there is one of the identified branches containing that point. We thus have the following definition.

DEFINITION 7. We say that a set B of branches of a tree $(T, <)$ is a *bundle* (on $(T, <)$) iff for all $x \in T$ there is $b \in B$ such that $x \in b$. If B is a bundle on tree $(T, <)$ then we say that $(T, <, B)$ is a *bundled tree (frame)* and, if h is a valuation, then $(T, <, B, h)$ is a *bundled structure.*

Temporal logics can be defined on bundled tree structures. Of course, the bundle only comes in to play in the semantics if the logic allows some sort of quantification over branches. Bundled tree temporal logics will also be appropriate in the case that a bundle B in a bundled tree structure is the set $B(T, <)$ of all branches of the tree $(T, <)$. In that case we say that the bundle is *complete.* Bundled tree temporal logics can thus also be used on plain, not bundled tree structures: just use the complete bundle as a default.

Major variations in branching time temporal logics on tree structures, plain or bundled, arise from differences in the locations of evaluation of formulas. If we consider truth to reside in points then we evaluate formulas at points (or worlds) in tree structures. An eminent tradition, however, requires that truth is evaluated at points on branches in structures, i.e. evaluation is at a 'world' = pair (time, history). We will investigate the differences more fully later when we consider the syntax and semantics of temporal logics which utilise them.

This choice of location of evaluation does, however, give rise to an important but subtle difference in structures. Those structures which use time-branch pairs for evaluation of formulas may also permit valuations of atoms to be sensitive to branch. Thus the atom p may evaluate to "true" on branch b at point x but evaluate to "false" on branch b' at point x.

DEFINITION 8. Suppose that $(T, <)$ is a tree.

A map $h : L \to \wp(T)$ is called a *local* assignment.

A map $h : L \to \wp\{(b, x) \mid x \in b \in B(T, <)\}$ is called a *non-local* assignment.

We use similar definitions for the case of bundled structures.

Local versus non-local assignments were first distinguished by Prior in [150]. In [218], they are discussed in terms of atoms containing (or not) a trace of "futurity". Should the truth of an atom at a time, now say, be dependent on which of the many possible futures actually comes about after now? Structures with a non-local assignment to atoms allow atoms to contain this trace of futurity. An example of Stefan Wölfl (quoted in [219]) is the seemingly atomic statement "the King is dying", the truth of which actually depends on the branch of evaluation.

The evaluation of atoms and/or more general formulas at time-branch pairs suggests an alternative model of time which allows us to keep the more traditional modal logic approach of evaluating formulas at worlds. We can arrange the time-branch pairs in a two-dimensional structure. Such an arrangement was suggested by Kamp and recorded in [189].

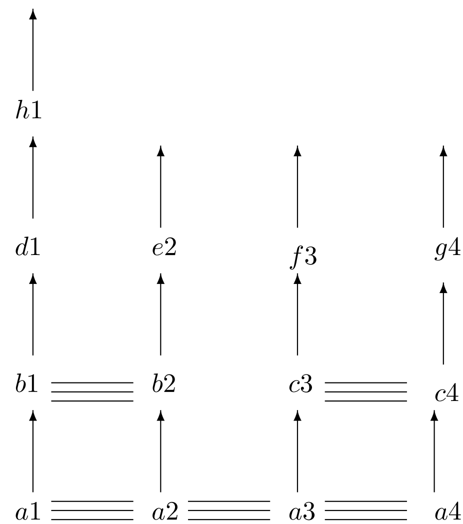

Figure 1. A Kamp Frame

DEFINITION 9. A *Kamp frame* is a triple $(K, <, \equiv)$, where:

1) K is the set of points;
2) $<$ is a union of linear orders on K
   i.e., $\forall xyz(x < y \wedge y < z \to x < z)$,
   $\forall xy\neg(x < y \wedge y < x)$,
   $\forall xyz(x < y \wedge x < z \to (y < z \vee y = z \vee z < y))$
   and $\forall xyz(y < x \wedge z < x \to (y < z \vee y = z \vee z < y))$;
3) $\equiv$ is an equivalence relation such that for all $x, y \in K$:
   if $x \equiv y$ then we do not have $x < y$,
   if $x \equiv y$ and $u < x$ then there is $v < y$ such that $u \equiv v$, and
   if $x \equiv y$ and for all $u > x$ there is $v > y$ with $u \equiv v$ then $x = y$.

A Kamp-structure is a Kamp Frame with a valuation of the atoms which agrees across $\equiv$. Corresponding to each Kamp-structure is a bundled structure: see Figures 1 and 2. The $<$ relation relates worlds (i.e. time-branch pairs) on the same branch while the $\equiv$ relation relates worlds which represent the same time point possibly paired with different branches. See [165] for details.

The special case of ω-trees, i.e. those in which each branch is isomorphic to the natural numbers, is of particular interest in computing. These structures arise as representations of the possible runs starting from a fixed state through a transition system. Let us be more precise.

DEFINITION 10. A *total frame* is a pair (S, R), where:

- S is the non-empty set of *states*
- R is a total binary relation $\subseteq S \times S$
  (i.e. for every $s \in S$, there is some $t \in S$ such that $(s, t) \in R$)

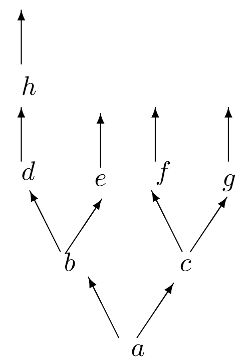

Figure 2. The corresponding tree

DEFINITION 11. A *transition system* is a triple $M = (S, R, g)$ where:
(S, R) is a total frame,
$g : S \to \wp\mathcal{L}$ is a labelling of the states with sets of atoms.

A *fullpath* (or branch or run) in M (or in (S, R)) is an infinite sequence $s_0, s_1, s_2, \ldots$ of states of M such that for each i, $(s_i, s_{i+1}) \in R$. For the fullpath $b = s_0, s_1, s_2, \ldots$, and any $i \geq 0$, we write b_i for the state s_i, $b_{\leq i}$ for the prefix sequence $s_0, s_1, \ldots, s_i$ and $b_{\geq i}$ for the fullpath $s_i, s_{i+1}, s_{i+2}, \ldots$.

The set of all prefixes of fullpaths of a transition system M with a fixed initial state naturally forms a tree: we put $s_0, s_1, \ldots, s_i \leq r_0, r_1, \ldots, r_j$ iff $i \leq j$ and for all $k \leq i$, $s_k = r_k$. The branches of this tree, sometimes called the unwrapping of the transition system, correspond exactly to the fullpaths themselves.

We can easily put an assignment to the atoms on the unwrapping of a transition system. Put $h(p) = \{b_{\leq i} \mid p \in g(b_i)\}$.

For a deeper survey of the range of models used for branching-time semantics, the reader is referred to [218, 219]. *Alternating time* generalises branching time in some ways, and was considered in [9, 78].

2.4 Granularity

For certain applications of temporal reasoning it is important to allow formulas which refer to behaviour occurring across a combination of different layers of time measurements. For example, we might want to say that a property holds during the last week of every month, thus supposing that time is divided somehow into weeks as well as somehow into months. This multi-layered multi-grained aspect of temporal experience is known as *granularity* and several formal structures have been suggested and investigated in order to represent this. One basic suggestion is to use trees in which each particular height of nodes represents a given granularity: a node at that height corresponds to a one unit period of time at that granularity, the nodes at that height are ordered by the earlier-later relation and the children nodes in the tree represent the periods of time at the next finest granularity which comprise that period. For example, a node representing a week may have 7 children representing its days.

For more on granularity, we refer the reader to references such as [55], [137], [17].

2.5 Many-dimensional Evaluation

Some temporal expressions may involve what seems to be two or more dimensions of time. Examples here include formalizations of natural language expressions which rely on multiple points of evaluation (for example see [155, 113]), properties which hold over intervals of time and circumstances where time is being used in several different ways. In such examples there may be a fundamental choice of how to construct a formal temporal model to capture the situation. We might be able to use a standard linear one-dimensional flow of time as defined above, but on which the truth of expressions are evaluated at pairs (or tuples) of time points: we discuss this approach briefly when we consider syntax and evaluation in the next section.

The alternative approach is to model the situation using structures which themselves have a multi-dimensional aspect. We have already considered branching structures which may be regarded, especially in their Kamp-frame incarnation, as two-dimensional. Shortly we will look at interval structures and these are sometimes built from two dimensions of time.

Another important example is in reasoning about databases and database management systems, particularly regarding temporal databases which need to record some timing or date information. In temporal database work, a distinction is sometimes made between *valid time,* that is the date-time when an event or state holds in the world, and *transaction time,* that is when a fact or property is recorded in the database. In reasoning about the correctness of a database system it may be important to have explicit descriptions about relationships between valid and transaction times of various events. See [188], [49] for example. To provide formal semantics for such reasoning, it is useful to consider structures which are a cartesian product of a flow of valid time and a flow of transaction time.

2.6 Intervals

As we will see below, it is possible to reason about linear structures, such as those we have met above, by considering descriptions of the behaviour of atoms across intervals of time. This reasoning is about point-based temporal structures: the atoms are evaluated at points. From these atoms, more complicated expressions can be built which need to be evaluated on intervals of time.

An alternative approach to interval temporal logics is to evaluate propositional atoms on intervals of time. There are natural language motivations for doing this: for example, it is natural to explain the semantics of the proposition "I climbed Everest" with reference to an interval of time. Intervals of time can be posited as the basic ontological entities. An interval temporal structure could be a set of intervals from a linear structure along with an evaluation for the atoms on the intervals.

In general, an interval could be defined to be any convex set of points from a linear structure: i.e. I is an interval of $(T,<)$ iff for all $x < y$ from I, for all z from T, if $x < z < y$ then $z \in I$. Different structures can arise from the choice of $(T,<)$ (e.g., the integers, or the reals) or by only looking at some subset of the set of all intervals, for example the set of closed intervals of the reals.

Allen identified 13 basic relations that may hold between intervals. One interval may precede another with a gap in between, or it may just end where the second one starts,

etc. See [6] for details. An algebra can be defined to capture the relationships between these relations.

The approach of *taking intervals as primitive objects* has also received much attention [192, 87, 196]. A structure is then typically a set I of abstract objects thought of as 'intervals', together with some relations on them, perhaps motivated by some of Allen's 13 relations, and an assignment of atoms to sets of intervals, just as in the point-based approach we assign atoms to sets of time points. For example, van Benthem in [192] takes as primitive relations '$i < j$' and '$i \sqsubseteq j$', and their converses. The intuition is that $i < j$ means that every point in i is earlier than every point in j, and $i \sqsubseteq j$ means that all points in i are in j; but these meanings are only analogies, since i, j are not necessarily intervals but only abstractions of intervals. The 'interval structures' then have the form $(I, <, >, \sqsubseteq, \sqsupseteq, h)$ where $h : L \to \wp(I)$. The elements of I are not necessarily sets of time points, and the interval structure may not even be isomorphic to a set of intervals arising from time points, with relations induced from the point structure. However, it may be of interest to characterise when there is such an isomorphism or to consider similar representation results [119, 7, 196, 31, 20, 76].

2.7 Combining temporal logic with other logics

So far in this section, we have been presenting structures that will serve as semantics for *propositional* logics of time. They have had the form (M, h), where M consists of a set of objects — points, intervals, etc., — representing time, with additional structure such as an earlier-later relation, and h assigns truth values to atoms at time objects in M. Thus, we envisage that the atomic formulas of the associated logics (to be developed in the next section) will be essentially atoms.

We now wish to examine how to handle more complicated atomic formulas. Their meaning will not simply depend on a time object, but also on extra, typically *non-temporal,* information. Since the non-temporal domain will typically have its own associated logic, we are in the area of *combining logics,* or *many-dimensional logics,* to be discussed in detail in Chapter 15. See also [131]. There are applications in computing, philosophy, linguistics, etc., in which these more expressive logics can be useful; they also present intriguing mathematical problems that have been more and more actively studied in the last few years.

Here, we discuss three kinds of structure that offer semantics for combinations of temporal logic with other logics.

1. *Epistemic temporal logic* (see Chapter 18 and [88]) combines temporal logic with a logic of knowledge. To model knowledge, we can use a Kripke frame (W, R). W is the set of possible worlds, and each $w \in W$ is regarded as a state of knowledge. The accessibility relation R is set up to reflect the meaning of $\Box A$ as 'A is known'. To model *temporally-dependent knowledge,* we can use structures that have the form $(T, <, W, R, h)$, where $(T, <)$ is a flow of time, (W, R) is a Kripke frame suitable for representing knowledge, and $h : L \to \wp(T \times W)$ is an assignment: a pair $(t, w) \in h(q)$ is one in which q is regarded as true at time t in state w. Both temporal and epistemic operators can be given meaning in such structures.

2. This approach can be taken further, by adding in a similar way a temporal dimension to an arbitrary Kripke frame. For example, if we use an S5 frame on which

the accessibility relation is global, we obtain essentially parallel identical flows of time, indexed by the worlds of the frame. If we use an equivalence relation that is refined as we move through time, so that any two points equivalent at time t were also equivalent at all earlier times than t, we obtain a special kind of *Kamp frame,* as in definition 9. If we use another flow of time (or another copy of the same flow) then we obtain a structure suitable for two-dimensional temporal logic as described above.

3. One of the most interesting combinations is of temporal logic with classical first-order logic, to obtain *first-order temporal logic.* There are very many options over exactly how to do it: see Chapter 9 and also Garson's excellent survey [68] on first-order modal logic. We confine ourselves here to discussing a single, fairly powerful option, summarised as *constant domains, rigid constants, and flexible functions and predicates.*

   The atomic formulas of our logic will be classical atomic first-order formulas. So we fix a signature (or similarity type, or vocabulary) L, consisting of relation symbols, function symbols, and constants (in many treatments, function symbols and even constants are omitted). A temporal structure will have the form $\mathcal{M} = (T, <, D, (M_t : t \in T))$, where $(T, <)$ is a flow of time, D is a non-empty set (the *domain* of $\mathcal{M}$), and for each $t \in T$, M_t is an L-structure with domain D (so the domain is constant over time). Let us write the interpretation in M_t of a symbol $s \in L$ as s^{M_t}. We require that $c^{M_t} = c^{M_u}$ for each constant $c \in L$ and all $t, u \in T$ (so constants are 'rigid', their meanings not varying over time). There are no restrictions on the interpretations of relation and function symbols; these may vary over time, so are called 'flexible'. For some purposes, for example in databases, we may wish to restrict consideration to models with finite domains.

3 TEMPORAL LOGICAL SYSTEMS

In the preceding section, we set out a variety of temporal structures. Now we have to set up some logical syntax for expressing properties of them. There are many choices here. The most basic choice is whether to adopt an external or internal perspective. Some logical systems, such as first-order logic, make statements about a temporal structure 'from the outside': sentences of these logics are evaluated relative to an entire temporal structure. They are natural for making statements involving 'before' or 'after'. There are other, more modal-style systems in which formulas are evaluated 'internally': e.g., at individual time points. They are more natural for expressing tense constructions like 'tomorrow', 'used to be', and so on. There is an extensive philosophical literature on this point (see, e.g., [149, 150, 151]). The distinction between the two approaches is somewhat artificial, in that each can simulate the other to some extent. But the choice of whether to use first-order logic or extensions of it, or to adopt a more modal-style logic, is still a major decision point.

Modal-style logics of time — commonly referred to as *temporal logics* — have received much attention. Several kinds of temporal logic are available, of varying expressivity, so one may hope to choose the best logic for the problem in hand. Temporal logics are well understood, and compared with first-order-based systems, they are arguably closer to

natural language, and reasoning with them is generally computationally simpler. Various computer implementations of temporal logics exist and have been very successful.

But in fact, it pays to take both the internal and external approaches seriously. There is no real reason not to: each is a legitimate way to handle time. Some situations lend themselves to one, some to the other. A key point is that the availability of both kinds of system allows us to compare them — for example, in expressive power. Roughly, though in some situations they are equally expressive, in general we find that the first-order approach is stronger and more succinct, and this is another reason to consider it. Though the computational complexity of first-order systems is usually higher than for modal-style ones, still there exist powerful computer theorem-provers for first-order logic. First-order logic and its extensions can serve as a benchmark for expressivity of modal-style temporal logics. Moreover, results in first-order logic can be transferred to temporal logic, and potentially vice versa.

We begin this section by exploring some first-order-based systems for time. Afterwards, we set out some 'modal-style' temporal logics. Then we consider extensions of basic temporal logic with various second-order operations. Finally, we examine some logical syntaxes with operations specific to branching time.

3.1 First-order logic

Consider temporal structures of the form $\mathcal{M} = (T, <, h)$, where $(T, <)$ is a flow of time and $h : L \to \wp(T)$ is an assignment, L being the underlying set of atoms. The natural first-order logic appropriate for such structures has signature

$$L^\star = \{<\} \cup \{Q : q \in L\},$$

where $<$ is a binary relation symbol, and for each atom $q \in L$, Q is a unary relation symbol. We may regard $\mathcal{M}$ naturally as an L-structure $\mathcal{M}^\star$, defined as follows. The domain of $\mathcal{M}^\star$ is T. '$<$' is interpreted as the given earlier-later relation $<$ on T. Finally, for each relation symbol Q $(q \in L)$, we set $\mathcal{M}^\star \models Q(t)$ iff $t \in h(q)$, for all $t \in T$. We may now write whatever first-order L-formulas we wish, and evaluate them in $\mathcal{M}^\star$. For example, $\forall x \exists y (y > x)$ is true in $\mathcal{M}^\star$ just when the flow of time $(T, <)$ has no last moment. If the flow of time is $(\mathbb{N}, <)$, we can express that an atom q is true infinitely often, by $\forall x \exists y (y > x \wedge Q(y))$.

3.2 Monadic second-order logic

Second-order formulas can also be useful. *Monadic second-order logic* has a prominent role in the logic of time, as we shall see. In this logic, we can quantify over both individual time points and sets of time points (i.e., unary relations on time), but not over binary and higher-order relations. The syntax of monadic second-order logic is as follows. We have a set $\mathcal{V}_1$ of first-order variables, which will be written $x, y, \ldots$, and a set $\mathcal{V}_2$ of second-order variables, written $X, Y, \ldots$. Both these sets are generally taken to be countably infinite. The atomic formulas of our system are $x = y$, $x < y$, $Q(x)$ for each $q \in L$, and $X(x)$; and if φ, ψ are monadic second-order formulas, then so are $\neg\varphi$, $\varphi \wedge \psi$, $\exists x \varphi$, and $\exists X \varphi$ — all for each $x, y \in \mathcal{V}_1$ and $X \in \mathcal{V}_2$. Evaluation of formulas takes place in a temporal structure $\mathcal{M} = (T, <, h)$ with respect to assignments $\nu_1 : \mathcal{V}_1 \to T$ and $\nu_2 : \mathcal{V}_2 \to \wp(T)$. We define $\mathcal{M}, \nu_1, \nu_2 \models \varphi$ by induction on φ:

- $\mathcal{M}, \nu_1, \nu_2 \models x = y$ iff $\nu_1(x) = \nu_1(y)$,
- $\mathcal{M}, \nu_1, \nu_2 \models x < y$ iff $\nu_1(x) < \nu_1(y)$,
- $\mathcal{M}, \nu_1, \nu_2 \models Q(x)$ iff $\nu_1(x) \in h(q)$,
- $\mathcal{M}, \nu_1, \nu_2 \models X(x)$ iff $\nu_1(x) \in \nu_2(X)$,
- $\mathcal{M}, \nu_1, \nu_2 \models \neg\varphi$ iff $\mathcal{M}, \nu_1, \nu_2 \not\models \varphi$,
- $\mathcal{M}, \nu_1, \nu_2 \models \varphi \wedge \psi$ iff $\mathcal{M}, \nu_1, \nu_2 \models \varphi$ and $\mathcal{M}, \nu_1, \nu_2 \models \psi$,
- $\mathcal{M}, \nu_1, \nu_2 \models \exists x\varphi$ iff $\mathcal{M}, \nu_1', \nu_2 \models \varphi$ for some $\nu_1' : \mathcal{V}_1 \to T$ with $\nu_1'(y) = \nu_1(y)$ for all $y \in \mathcal{V}_1 \setminus \{x\}$,
- $\mathcal{M}, \nu_1, \nu_2 \models \exists X\varphi$ iff $\mathcal{M}, \nu_1, \nu_2' \models \varphi$ for some $\nu_2' : \mathcal{V}_2 \to \wp(T)$ with $\nu_2'(Y) = \nu_2(Y)$ for all $Y \in \mathcal{V}_2 \setminus \{X\}$.

This is a very expressive logic. For example, over the natural numbers $(\mathbb{N}, <)$, we can express that an atom q, represented by the unary relation symbol Q as usual, is true only at even numbers:

$$\exists X(X(0) \wedge \forall xy[x < y \wedge \neg\exists z(x < z < y) \to (X(x) \leftrightarrow \neg X(y))] \wedge \forall x(Q(x) \to X(x))).$$

This cannot be expressed in first-order logic.

3.3 *Temporalised first-order logic*

When we are dealing with a combination of time with first-order logic, a *two-sorted first-order* approach can be used. Recall from Section 2.7 that in this setting, L is an ordinary first-order signature, and structures have the form $\mathcal{M} = (T, <, D, (M_t : t \in T))$, where $(T, <)$ is a flow of time and each M_t ($t \in T$) is an L-structure with domain D. Constants are interpreted rigidly (each constant has the same interpretation in each M_t).

To handle this in two-sorted first-order logic, we use sorts $\mathbf{d}$, $\mathbf{t}$ (standing for 'domain' and 'time', respectively). We introduce an $(n+1)$-ary relation symbol $R^\star$ of sort $\mathbf{t} \times \mathbf{d}^n$, for each n-ary relation symbol $R \in L$. (The notation $\mathbf{t} \times \mathbf{d}^n$ means that the first argument of $R^\star$ is of sort $\mathbf{t}$ and the last n arguments are of sort $\mathbf{d}$.) That is, we make our relation symbols time-dependent. The same process is undertaken for function symbols in L. Each constant symbol of L is rigid in $\mathcal{M}$, so we simply make a copy of it, of sort $\mathbf{d}$. We let $L^\star$ be a new signature consisting of all these symbols. $L^\star$ also has a binary relation symbol $<$ of sort $\mathbf{t} \times \mathbf{t}$.

We now define a two-sorted $L^\star$-structure $\mathcal{M}^\star$ from $\mathcal{M}$. The domain of $\mathcal{M}^\star$ is the disjoint union of two sets, D (sort $\mathbf{d}$) and T (sort $\mathbf{t}$). For n-ary $R \in L$, $a_1, \ldots, a_n \in D$, and $t \in T$, we define $\mathcal{M}^\star \models R^\star(t, a_1, \ldots, a_n)$ iff $M_t \models R(a_1, \ldots, a_n)$. For an n-ary function symbol $f \in L$, $a_1, \ldots, a_n, b \in D$, and $t \in T$, we let $\mathcal{M}^\star \models f^\star(t, a_1, \ldots, a_n) = b$ iff $M_t \models f(a_1, \ldots, a_n) = b$. We let $c^{\mathcal{M}^\star} = c^{M_t} \in D$, for each constant $c \in L$ and any $t \in T$; this is well-defined since constants are rigid in $\mathcal{M}$. And $<$ is interpreted in $\mathcal{M}^\star$ as the earlier-later relation $<$ from $(T, <)$. Now we can readily write two-sorted $L^\star$-formulas to describe the original $\mathcal{M}$, via $\mathcal{M}^\star$. For example, if L contains unary relation symbols dog and day to pick out the dogs and days in an L-structure $\mathcal{M}$, then the $\mathcal{L}^\star$-sentence $\forall t, x(\mathsf{dog}^\star(t, x) \to \exists t\ \mathsf{day}^\star(t, x))$ is true in $\mathcal{M}^\star$ just in case every dog has his day.

3.4 Temporal Logics

Let us now examine the 'modal-style' temporal logics.

The simplest is just the propositional modal logic K4 which has a modal diamond $\Diamond$ added recursively to the formulas of classical propositional logic. The formulas are just then $p \in L$, $\neg\alpha$, $\alpha \wedge \beta$, and $\Diamond\alpha$ where α and β are themselves formulas. The logic can be presented in a semantic way by evaluating these formulas on structures $(T, <, h)$ in which $(T, <)$ is a transitive irreflexive flow of time.

To be absolutely clear in this first case we present the full semantics. Formulas are evaluated at points of time $t \in T$ in such structures $\mathcal{T} = (T, <, h)$. We write $\mathcal{T}, t \models \alpha$ to represent α being true at time point t in the structure. This is defined formally recursively as follows:

$\mathcal{T}, t \models p$ iff $t \in h(p)$,
$\mathcal{T}, t \models \neg\alpha$ iff $\mathcal{T}, t \not\models \alpha$,
$\mathcal{T}, t \models \alpha \wedge \beta$ iff $\mathcal{T}, t \models \alpha$ and $\mathcal{T}, t \models \beta$,
$\mathcal{T}, t \models \Diamond\alpha$ iff there exists $s \in T$ such that $t < s$ and $\mathcal{T}, s \models \alpha$.

K4 is a traditional modal logic. The simplest seriously temporal logic incorporates a modal diamond directed towards the past as well as one directed towards the future. This is one of the temporal logics invented by the "father" of temporal logic, Arthur Prior. In order to present this clearly we switch to his original notation of using F for the future diamond and P for the past diamond. The syntax is obtained by adding both the following two clauses to the standard ones for classical propositional logic: if α is a formula of the logic then so are $F\alpha$ and $P\alpha$. The logic can be given semantics on any temporal structure. The additional semantic clauses are:

$\mathcal{T}, t \models F\alpha$ iff there exists $s \in T$ such that $t < s$ and $\mathcal{T}, s \models \alpha$ (as above in K4)
$\mathcal{T}, t \models P\alpha$ iff there exists $s \in T$ such that $s < t$ and $\mathcal{T}, s \models \alpha$

The dual, modal box, versions of F and P are traditionally known as G and H. $G\alpha$ is true at a time point in a structure if and only if α is going to be true at all points in the future of that point. G can be introduced as a temporal connective in its own right, like F or P, or it can be just regarded as an abbreviation: $G\alpha \equiv \neg F \neg \alpha$. Likewise for H, "has always been true".

Temporal languages with some combination of these connectives F, P, G and H can be given semantics over the class of all temporal structures (i.e. flows of time with assignments to the atoms). Equally, they can be given semantics on smaller classes of structures, even on the set of structures with a given fixed flow of time. Making such restrictions generally gives rise to different temporal logics in the sense of the set of valid formulas of the logic. Take Prior's propositional language with F and P. The formula $Fp \wedge Fq \rightarrow (F(p \wedge Fq) \vee F(q \wedge Fp) \vee F(p \wedge q))$ is not valid: there are structures in which there are points at which this formula is false. If however, we restrict attention to structures over linear flows of time then this formula is valid. We discuss validity and related issues in a later section.

We have used the term "temporal connective" loosely above. It is time to make this a little more precise. By a temporal connective we will mean a tuple consisting of a symbol, its arity and a semantic clause. For example we have seen the 1-ary connective F with its future directed clause. Below we will see how to present the semantic clause in a standard way. This will allow temporal logics to be constructed by choosing a base logic, say classical propositional or predicate logic, choosing a set of connectives, and choosing a class of structures on which the semantics is evaluated. Such flexibility is a

very powerful feature of temporal logics: the right logic can be put together for a specific application.

Before doing this let us mention a few variations on Prior's original temporal connectives. When these connectives are used for computing applications and when the flow of time is taken to be the natural numbers then we often see a variant of F, commonly written as $\Diamond$, which has a reflexive semantics. We might use the symbol $F_{\leq}$ for this "non-strict" version of F. The semantic clause is:

$\mathcal{T}, t \models F_{\leq}\alpha$ iff there exists $s \in T$ such that $t \leq s$ and $\mathcal{T}, s \models \alpha$.

There are similar non-strict versions of P, G and H. Note too, that in general there is no reason for them only to be seen in the context of natural numbers time.

Also in the context of natural numbers time, and especially in combination with non-strict F, it is common to see a connective written as X, T, or $\bigcirc$, and meaning 'tomorrow' or 'next-time'. The semantics could be presented for general flows as

$\mathcal{T}, t \models X\alpha$ iff there exists $s \in T$ such that $t < s$ and $\mathcal{T}, s \models \alpha$ and there is no u with $t < u < s$,

but for natural numbers flows only, we can be more straightforward and define

$(\mathbb{N}, <, h), n \models X\alpha$ iff $(\mathbb{N}, < h), n+1 \models \alpha$.

A yesterday or last-time connective can also be given but there is a subtlety: what to do at the start of time? In fact, there end up being two yesterday connectives, a weak yesterday W and a strong yesterday Y:

$(\mathbb{N}, <, h), n \models W\alpha$ iff $n = 0$ or $(\mathbb{N}, < h), n-1 \models \alpha$, and

$(\mathbb{N}, <, h), n \models Y\alpha$ iff $n > 0$ and $(\mathbb{N}, < h), n-1 \models \alpha$.

These are in fact duals of each other: $W\alpha \equiv \neg Y \neg \alpha$. Tomorrow is self-dual.

Arbitrary temporal connectives with first-order tables. For an n-ary connective $\#$, there will be a *table* $\tau_{\#}(t, P_1, \ldots, P_n)$ for $\#$ being a formula of the first-order logic $L^{\star}$ (introduced in Section 3.1 above), written using variables including t, and the 1-ary relation symbols $P_1, \ldots, P_n$. The table gives the semantics of $\#$ in the following sense. Suppose that $\#$ is one of the temporal connectives in a temporal language so that the formulas include $\#(\alpha_1, \ldots, \alpha_n)$ whenever $\alpha_1, \ldots, \alpha_n$ are formulas. Suppose that $\mathcal{T} = (T, <, h)$ is a temporal structure. As usual we define truth of all formulas at all time points in $\mathcal{T}$ by induction on the construction of the formulas. The semantic clause for $\#(\alpha_1, \ldots, \alpha_n)$ is used when we have defined the truth of the α_i at every time point. First, let $S_i = \{b \in T \mid \mathcal{T}, b \models \alpha_i\}$. Then the semantic clause tells us that for any $a \in T$, $\mathcal{T}, a \models \#(\alpha_1, \ldots, \alpha_n)$ iff $\mathcal{T}^{\star} \models \tau_{\#}(a, S_1, \ldots, S_n)$ (where we use the semantics for $L^{\star}$ over $\mathcal{T}^{\star}$ defined in Section 3.1 above).

Some tables of connectives we have already met include:

Fp	$\exists s(t < s \wedge P(s))$
$F_{\leq}p$	$\exists s(t \leq s \wedge P(s))$
Pp	$\exists s(s < t \wedge P(s))$
Gp	$\forall s(t < s \rightarrow P(s))$
Hp	$\forall s(s < t \rightarrow P(s))$
Xp	$\exists s(t < s \wedge P(s) \wedge \neg \exists u(t < u < s))$
Yp	$\exists s(s < t \wedge P(s) \wedge \neg \exists u(s < u < t))$

In more philosophical temporal logic work, and especially that motivated by trying to give formal semantics to natural language tense constructs, a connective capturing the idea of "until" is often seen as $U(\alpha, \beta)$. Its table is:

$U(p, q)$ $\exists s\big((t < s) \wedge P(s) \wedge \forall u[((t < u) \wedge (u < s)) \rightarrow Q(u)]\big)$

This is read as "until p, q", meaning that until p holds we have q holding: q holds at all time points after now until some time at which p holds. There is a mirror image "since" connective. Its table is:

$S(p,q) \quad \exists s\big((s<t)\wedge P(s)\wedge\forall u[((s<u)\wedge(u<t))\rightarrow Q(u)]\big)$

In many computing applications an "until" connective is also seen. This is commonly written $\alpha U\beta$ and read as 'α holds until β does'. The semantics is:

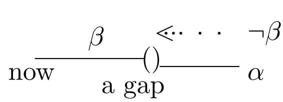
$pUq \quad \exists s\big((t\leq s)\wedge Q(s)\wedge\forall u[((t\leq u)\wedge(u<s))\rightarrow P(u)]\big)$

Thus, pUq is not the same as $U(q,p)$! The "philosophical" until is sometimes called the strict one (as $U(p,q)$ does not hold just because p holds now) while the "computing" until is called the non-strict one: qUp holds if p holds now. We will sometimes write $U_<$ for the former and $U_\leq$ for the latter: otherwise, they will be distinguished by the context. A mirror image $S_\geq$ of the S (or "$S_>$") above can be defined similarly.

For the most basic computing applications of temporal logic the much favoured language is the (propositional) temporal logic with the next-time X connective and the non-strict U connective. This language and/or its logic over the natural numbers flow of time is often called PLTL or PTL and it was introduced in the papers [147] and [66] which first proposed using temporal logics for reasoning about programs. It is easy to see that this logic is equally as expressive as the logic with just strict until over the natural numbers.

The language with X, $U_\leq$, Y, and $S_\geq$, sometimes called TL, was recommended for computing applications in [124] as the past-time connectives allow more natural expression of certain properties of interest to computer scientists. However, it is not hard to use the *separation* results mentioned in Section 4.6 to show that the past-time connectives are not really necessary in order to express any properties of a natural numbers-flowed structure (as far as evaluating properties at the zero time is concerned).

Expressivity concerns also led to the introduction of certain more complicated connectives for use with dense, in particular non-Dedekind-complete, flows of time. Such flows of time may have "gaps" or Dedekind cuts: that is, the flow can be partitioned into two non-empty sets A and B, say, with every time in A before every time in B, but A does not have a last time and B does not have a first time. These connectives are the *Stavi connectives* U' and S' which were mentioned in [66] as having to be added to (strict) 'until' and 'since' to achieve expressive completeness over general linear time. $U'(\alpha,\beta)$ holds if β is true from now until a gap in time after which β is arbitrarily soon false but after which α is true for a while: $U'(\alpha,\beta)$ is as pictured



S' is defined via the mirror image. Despite involving a gap, U' is in fact a first-order connective. Here is the first-order table for U':

$$
\begin{aligned}
&U'(p_1,p_2)\equiv\\
&\quad\exists s\Big(t<s\wedge\exists u(t<u<s\wedge\neg P_2(u))\wedge\exists u[t<u<s\wedge\forall v(t<v<u\rightarrow P_2(v))]\\
&\qquad\quad\wedge\forall u\big(t<u<s\rightarrow\big[\exists v(u<v\wedge\forall w(t<w<v\rightarrow P_2(w)))\big]\\
&\qquad\qquad\qquad\qquad\vee\big[\forall v(u<v<s\rightarrow P_1(v))\wedge\exists v(t<v<u\wedge\neg P_2(v))\big]\big)\Big)
\end{aligned}
$$

Roughly, this says that there is some $s>t$ which is on the other (future) side of the gap, so that any u between t and s is either before the gap (first disjunct) or after the gap

(second disjunct). Also, p_2 is false before s and true for a while after t. Of course, S' has the mirror image table.

Note that if $(T, <)$ is Dedekind complete then any formula of the form $U'(\alpha, \beta)$ or $S'(\alpha, \beta)$ is everywhere false.

3.5 Extensions of temporal logic

Now we very briefly mention a few miscellaneous extensions to temporal logics.

1. *Hybrid logic.*

   It has long been an undertaking for temporal logicians to invent more expressive languages and one temptation is to import some of non-modal first-order logic's abilities to reason explicitly about the states, i.e. the time points. Examples include Prior's "third grade tense logics" [150], the universal quantifier in [26], the "holds" predicate for intervals in [7] and more recent work in [19] and [74]. Temporal logics which allow some sort of naming of points within formulas are called *hybrid* logics, and these are discussed fully in Chapter 14. Having names for time points is particularly helpful for temporal reasoning tasks and systems of temporal inference can be designed to exploit this.

2. *Metric temporal logic.*

   In many applications of complex systems, timing or metric considerations are important. Reasoning about the behaviour of safety critical systems [144] and multimedia specifications [24] are just two examples. A good account of this so-called real-time logic area appears in [8]. A formula of the logic TPTL [8],

   $$\Box x.(p \to \Diamond y.(q \wedge y \leq x + 1))$$

   for example, can express that every p-state is followed by a q-state in at most one unit of time. Most of the timing work is built on discrete time temporal logics (for example via the timed state sequence formalism of [8]) and indeed any move to a dense order of times usually results in highly undecidable logics [8]. An alternative approach with reasonable complexity and comparable expressiveness is suggested in [164] via coding of "ticks" of a timer into the temporal logic with 'until' and 'since' over real numbers time. Of course, using abbreviations in terms of ticks as above does not allow us to quantify over metric values. However, as pointed out in [8] it is just this facility which makes metric temporal logics undecidable. Some recent work in metric logics includes [91, 125, 23].

3. *Many-dimensional connectives.*

   So far, we have concentrated on temporal logics whose formulas are evaluated at single time points. They are analogous to first-order formulas with one free variable. But first-order formulas can have many free variables, and by the same token it is sometimes useful to consider temporal formulas that are evaluated at k time points, for any fixed finite $k \geq 1$. The first of these points is rather special, and is called the *evaluation point.* The remaining $k - 1$ extra points are analogous to so-called *reference points* in natural language.

For semantics, we use a flow of time as usual, but there is a choice about how to evaluate atoms in it. Allowing an atom's value to depend on k time points leads us to true many-dimensional temporal logic, and to the interval logics discussed below. Such logics are often computationally intractable, and anyway it is often better to treat them as being ordinary one-dimensional evaluation but in a many-dimensional structure (cf. Section 2.5, and also Chapter 15).

Another option is to allow the values of atoms to depend only on the evaluation point, not the reference points. In consequence, a temporal structure remains of the form $\mathcal{T} = (T, <, h)$, where $h : L \to \wp(T)$. To formalise the semantics of an n-ary connective $\#$, we use a table of the form $\tau_{\#}(x_1, \ldots, x_k, P_1, \ldots, P_n)$, where $P_1, \ldots,$ P_n are now k-ary relation symbols. For time points $t_1, \ldots, t_k \in T$, we define $\mathcal{T}, t_1,$ $\ldots, t_k \models \alpha$ by induction on formulas α. For atomic α, we set $\mathcal{T}, t_1, \ldots, t_k \models \alpha$ iff $t_1 \in h(\alpha)$. The booleans are as expected. Finally, if $\alpha_1, \ldots, \alpha_n$ are formulas and inductively we have $S_l = \{(u_1, \ldots, u_k) \in T^k \mid \mathcal{T}, u_1, \ldots, u_k \models \alpha_l\}$ for each $l \leq n$, then as before we put $\mathcal{T}, t_1, \ldots, t_k \models \#(\alpha_1, \ldots, \alpha_n)$ iff $\mathcal{T} \models \tau_{\#}(t_1, \ldots, t_k, S_1, \ldots,$ $S_n)$.

For some examples of this style of logic, see, e.g., [64, chapter 7].

4. *Interval temporal logics.*

There are two different approaches to interval temporal logics.

In the approach of Moszkowski [138] and the Duration calculus [221] the propositional version of the interval temporal logic is defined on point-based linear temporal structures. Atoms are evaluated at points but we build up more complicated formulas which are evaluated on intervals. A variety of interval temporal logics can be defined by considering various linear temporal structures such as the integers, or a finite subset of them, or such as the reals (in Duration calculus). A variety of operators can be defined such as **empty**, $\bigcirc\alpha$ or $\alpha;\beta$. Consider, for example, a linear temporal structure $(\mathbb{N}, <, h)$. Formulas are evaluated at intervals $\sigma = \{t \in T \mid \sigma_- \leq t \leq \sigma_+\}$ of $(T, <)$: $(T, <, h), \sigma \models p$ iff $\sigma_- \in h(p)$; $(T, <, h), \sigma \models \bigcirc\alpha$ iff $(T, <, h), \sigma^+ \models \alpha$ where $\sigma = \{t \in T \mid \sigma_- + 1 \leq t \leq \sigma_+\}$; and $(T, <, h), \sigma \models \alpha;\beta$ iff there is some $z \in \mathbb{N}$ such that $(T, <, h), \{t \in T \mid \sigma_- \leq t \leq z\} \models \alpha$ and $(T, <, h), \{t \in T \mid z \leq t \leq \sigma_+\} \models \beta$. The Duration Calculus also allows some metric information to be specified, such as the length of intervals, and, via the duration operator, the integrated duration of the truth of a proposition during an interval. See [220] for more details on the Duration Calculus.

In the other approach, such as, for example, the interval temporal logics of Halpern and Shoham [87] and Venema [197], intervals themselves are the basic temporal units of structure and atoms are evaluated on intervals. Generally such logics have unary (or 1-place) modal operators corresponding to binary relations between intervals. We have seen in Section 2.6 above that there are 13 standard relations identified between intervals such as the i *precedes* j (i.e. $i < j$) relation. Thus, in [192], we have a modal diamond P (for precedes) with semantics:

$$\mathcal{I}, i \models Pp \text{ iff } \text{ there is an interval } j \text{ s.t. } j < i \text{ and } \mathcal{I}, j \models p.$$

In [197] we see a more powerful interval logic CDT extending this approach with some binary modal connectives inspired by natural language, computation [172]

and relation algebra. The *chop* connective C from this system (corresponding to ; of the Duration Calculus) is defined in terms of the accessibility relation $A(i,j,k)$ true when the following all hold: i and k begin together, i ends where j starts, and j and k end together. The semantics of chop is:

$$\mathcal{I}, k \models pCq \text{ iff there are intervals } i, j \text{ s.t. } A(i,j,k),\ \mathcal{I}, i \models p \text{ and } \mathcal{I}, j \models q.$$

There is a fuller treatment of interval temporal logics in [193]. See also [77].

5. *Combinations of temporal logic and other modal logics.*

There has been much recent interest in combinations of temporal logic and other modal logics. These include temporal-epistemic [48] and spatio-temporal [65] logics as well as logics of parallel time [120]. The simplest appropriate structure (from [189]) is a set W of classical propositional worlds ($h(p) \subseteq W$) endowed with both a temporal ordering $w_1 < w_2$ and an accessibility relation R_b for each box $\Box_b$ of the modal language. A combined language can have formulas including the atoms, and closed under forming $G\alpha$, $H\alpha$ and $\Box_b\alpha$ from any formula α. Letting $\mathcal{M} = (W, <, \{R_b\}, h)$, the semantic clauses are just:

$\mathcal{M}, w \models G\alpha$ iff for all $w' \in W$, if $w < w'$ then $\mathcal{M}, w' \models \alpha$;
$\mathcal{M}, w \models H\alpha$ iff for all $w' \in W$, if $w' < w$ then $\mathcal{M}, w' \models \alpha$;
$\mathcal{M}, w' \models \Box_b\alpha$ iff for all $w' \in W$, if wR_bw' then $\mathcal{M}, w' \models \alpha$.

One common way of constructing such a structure is as the cartesian product of a temporal structure and a modal structure. The reader is referred to Chapter 15 or [65] for details.

The 2-dimensional temporal logics of [130] and [49] are similar: we just have to distinguish temporal connectives operating in one dimension from those of another dimension.

Predicate temporal logic is a combination (of temporal logic with first-order logic) of a different nature. The standard predicate temporal logic with F and P of constant domains, rigid terms and rigid variable assignments is defined as follows.

Recall from Section 2.7 that the atomic formulas of our logic will be classical atomic first-order formulas from a signature L, consisting of relation symbols, function symbols, and constants. Assume that V is our set of (domain) variable symbols, i.e. those standing for elements of the object domain. The set of formulas will include all the atomic formulas and also $\neg\alpha$, $\alpha \wedge \beta$, $\forall x\alpha$, $F\alpha$ and $P\alpha$ for any formulas α and β and any domain variable symbol x.

A temporal structure will have the form $\mathcal{M} = (T, <, D, (M_t : t \in T))$, where $(T, <)$ is a flow of time, D is the domain of $\mathcal{M}$, and for each $t \in T$, M_t is an L-structure with domain D. An assignment to the variable symbols is just a map from V to D (with no dependence on T).

The assignment ν combines with the interpretations for the predicate and function symbols at time a to give us the interpretation $\nu_a(t) \in D$ for any term t at time a. In particular, $\nu_a(x) = \nu(x)$ for $x \in V$, $\nu_a(f(t_1, \ldots, t_n)) = f^{M_a}(\nu_a(t_1), \ldots, \nu_a(t_n))$.

For an assignment ν, we define truth of formulas at times in $\mathcal{M}$ in a straightforward way. The more interesting clauses are:

$\mathcal{M}, \nu, a \models p(t_1, \ldots, t_n)$ iff $(\nu_a(t_1), \ldots, \nu_a(t_n)) \in p^{M_a}$;
$\mathcal{M}, \nu, a \models \forall x \alpha$ iff for all $d \in D$, $\mathcal{M}, \nu[x \rightsquigarrow d], a \models \alpha$;
$\mathcal{M}, \nu, a \models F\alpha$ iff there is $b \in T$ such that $a < b$ and $\mathcal{M}, \nu, b \models \alpha$.
Here $\nu[x \rightsquigarrow d]$ is just the assignment which is the same as ν except that x is mapped to d.

It is worth mentioning the variation, called TLA or the *Temporal Logic of Actions* [121] on a predicate temporal logic over natural numbers time. This has received much attention in connection with reasoning about specifications of programs. The set of allowable formulas is restricted so that they are each *stuttering invariant*. This means that these formulas can not distinguish between behaviours (of a program) which only differ by having the same state (i.e. values of externally observable program variables) repeated consecutively a different number of times.

3.6 Temporal logic with second-order operations

All the temporal logics so far considered involve connectives with essentially first-order definitions. As we will soon see, each formula of such a logic can be translated into first-order logic in a meaning-preserving way. Sometimes, however, first-order expressivity is insufficient. For example, the property that an atom is true at every even number in a temporal structure $(\mathbb{N}, <, h)$ is not expressible with first-order connectives. We have already mentioned monadic second-order logic in the context of time. Now it is the turn of modal-style temporal logics to benefit from second-order operations.

As usual, there are several ways of introducing second-order devices into temporal logic. We consider four options in turn. The first two are generally used over natural numbers time $(\mathbb{N}, <)$, and finite linear flows; the second two can be used with any flow of time.

1. *Regular expressions.* The addition of these to propositional temporal logic was proposed by Wolper [205, 204, 206]. It can be done as follows. A (right-linear) *grammar* is a triple

$$\mathcal{G} = ((a^1, \ldots, a^k), Q, \delta),$$

where $k \geq 1$ is finite, $a^1, \ldots, a^k$ are distinct objects (the *terminals* of $\mathcal{G}$), Q is a finite non-empty set (the *non-terminals* of $\mathcal{G}$), and δ is a finite set of *rules* of the form $u \to av$ and $u \to a$, where $u, v \in Q$ and $a \in \{a^1, \ldots, a^k\}$. We write A for the set $\{a^1, \ldots, a^k\}$; the order of enumeration of A given in $\mathcal{G}$ will be significant below.

Given $\mathcal{G}$ as above, and $v_0 \in Q$, we define sets S_n $(n < \omega)$ and $S(\mathcal{G}, v_0)$. Intuitively, S_n is the set of words over $A \cup Q$ constructible from v_0 by n applications of rules in δ; $S(\mathcal{G}, v_0)$ is the set of finite or infinite words over A constructible from v_0 by $\leq \omega$ applications of the rules. The sets are defined formally by induction as follows. We let $S_0 = \{v_0\}$. Given S_n, we let $S_{n+1} = \{a_1 \ldots a_{n+1}v : \exists u \in Q(a_1 \ldots a_n u \in S_n \wedge u \to a_{n+1}v \in \delta)\}$. Finally, we let $S(\mathcal{G}, v_0) = (A^* \cap \bigcup_{n<\omega} S_n) \cup \{a_1 a_2 \ldots : (\forall n < \omega)(\exists v \in Q) a_1 \ldots a_n v \in S_n\}$. Here A^* denotes the set of finite words over A; the effect of taking the intersection with it is to restrict to words without non-terminals.

As an example, if $\mathcal{G} = ((a,b), \{v\}, \{v \to av,\ v \to b\})$, then

$$\begin{aligned} S_0 &= \{v\}, \\ S_n &= \{\overbrace{aa\ldots a}^{n}v,\ \overbrace{aa\ldots a}^{n-1}b\}, \text{ for } 0 < n < \omega, \\ S(\mathcal{G}, v) &= \{b, ab, aab, aaab, \ldots\} \cup \{aaaaa\ldots\}. \end{aligned}$$

We remark that a grammar can be viewed as a finite-state automaton, with alphabet A, state set Q, and transition table δ. It follows that the sets of the form 'the set of all finite words in $S(\mathcal{G}, v)$', for arbitrary $\mathcal{G}$ and non-terminal v of $\mathcal{G}$, are precisely the regular languages.

Now let $\mathcal{T}$ be any propositional temporal logic suitable for temporal structures $\mathcal{M} = (\mathbb{N}, <, h)$ based on natural numbers time, where $h : L \to \wp(\mathbb{N})$. The extended temporal logic ETL($\mathcal{T}$) is then defined as follows. Its atomic formulas are $\top$, $\bot$, and q for each $q \in L$. More complex formulas are formed in two ways. First, given any n-ary connective $\sharp$ of $\mathcal{T}$, and ETL($\mathcal{T}$)-formulas $\alpha_1, \ldots, \alpha_n$, we can form the ETL($\mathcal{T}$)-formula $\sharp(\alpha_1, \ldots, \alpha_n)$; it is evaluated in $\mathcal{M}$ in the usual way. Second, given any grammar $\mathcal{G} = ((a^1, \ldots, a^k), Q, \delta)$, any $v \in Q$, and ETL($\mathcal{T}$)-formulas α_1, $\ldots, \alpha_k$, we can form the ETL($\mathcal{T}$)-formula $\mathcal{G}_v(\alpha_1, \ldots, \alpha_k)$. Then $\mathcal{M}, t \models \mathcal{G}_v(\alpha_1, \ldots, \alpha_k)$ iff there is a word $a^{i_0}a^{i_1}\ldots$ in $S(\mathcal{G}, v)$ of length $l \le \omega$, say, where $1 \le i_j \le k$ for each $j < l$, such that for all $j < l$ we have $\mathcal{M}, t + j \models \alpha_{i_j}$.

For example, if we take the grammar $\mathcal{G} = ((a,b), \{v\}, \{v \to av,\ v \to b\})$ mentioned above, then $\mathcal{M}, t \models \mathcal{G}_v(\alpha, \beta)$ iff either there is $u \ge t$ such that $\mathcal{M}, u \models \beta$ and $\mathcal{M}, v \models \alpha$ for all v with $t \le v < u$, or else $\mathcal{M}, u \models \alpha$ for all $u \ge t$. Roughly, because the words in $S(\mathcal{G}, v)$ are of the form $aaa\ldots ab$ or $aaa\ldots$, and we associate α with a and β with b, we require the pattern $\alpha\alpha\alpha\ldots\alpha\beta$ or $\alpha\alpha\alpha\ldots$ to begin at t. This is a weak form of the 'non-strict until' considered earlier. It is easily checked that $\mathcal{G}_v(\alpha, \bot)$ expresses a non-strict form of $G\alpha$, and $\neg\mathcal{G}_v(\neg\alpha, \bot)$ expresses the non-strict eventuality $F_{\le}\alpha$. So $\mathcal{G}_v(\alpha, \beta) \wedge \neg\mathcal{G}_v(\neg\beta, \bot)$ expresses the non-strict $\alpha U_{\le}\beta$ seen in Section 3.4.

In fact, all 'future-oriented' connectives examined earlier can be expressed in extended temporal logic. Moreover, the logic is decidable over natural numbers time, with PSPACE-complete validity problem [206].

2. *Gabbay's fixed point operator [61, 64].* This can be added to the propositional temporal syntax with connectives U (Until) and Y (Yesterday), creating a system known as UYF. Its syntax is as follows. The atomic formulas are $\top$, $\bot$, and q for $q \in L$, and if α, β are UYF-formulas then so are $\neg\alpha$, $\alpha \wedge \beta$, $Y\alpha$, $U(\alpha, \beta)$, and $\varphi q\alpha$, for any atom $q \in L$ such that α is *pure past in q* — this means that every occurrence of q in α that is not in the scope of a φq is in the scope of a Y and not in the scope of an U.

   The semantics of $\wedge, \neg, Y, U$ are as before. The semantics of φ is a little harder to define. Suppose that the formula α is pure past in q, and (inductively) that its semantics has been defined. In any temporal structure $(\mathbb{N}, <, h)$, it turns out (by examining the inductively-defined semantics of α) that the truth value of α at any time $t \in \mathbb{N}$ only depends on the values of q at times $0, 1, \ldots, t-1$. This means that we may define sets $S_t^h \subseteq \{0, 1, \ldots, t\}$ (for $t \in \mathbb{N}$) recursively as follows:

(a) $0 \in S_0^h$ iff $(\mathbb{N}, <, h), 0 \models \alpha$,

(b) for $t > 0$, if $u \leq t$ then $u \in S_t^h$ iff $(\mathbb{N}, <, h_t), u \models \alpha$, where h_t is the same as h except that $h_t(q) = S_{t-1}^h$.

Because α is pure past in q, if $0 \leq t \leq u$ then $t \in S_t^h$ iff $t \in S_u^h$. This means that the S_t^h 'converge' to a value $S^h = \{t \in \mathbb{N} : t \in S_t^h\}$. We then let S^h be the set of times at which $\varphi q \alpha$ is true: we define $(\mathbb{N}, <, h), t \models \varphi q \alpha$ iff $t \in S^h$.

Intuitively, what is going on is that we evaluate α at time 0: its value is independent of $h(q)$ since α is pure past in q. Then, we evaluate α at time 1; now the value of q at 0 does matter (though its values at $1, 2, \ldots$ do not), and we let it be the same value that we obtained for α at 0. Then we evaluate α at 2, giving q the same values at $0, 1$ as α had; and so on. For example, $\varphi q \neg Y q$ evaluates to true at 0, then false at 1, true at 2, and so on: it is true at precisely the even times. We can also express $S(\alpha, \beta)$, by $\varphi q Y(\alpha \vee (q \wedge \beta))$.

It turns out that $\varphi q \alpha$ defines a *fixed point* of the operator $\Phi^h : \wp(\mathbb{N}) \to \wp(\mathbb{N})$ given by

$$\Phi^h : S \mapsto \{t \in \mathbb{N} : (\mathbb{N}, <, h_{q \rightsquigarrow S}), t \models \alpha\},$$

$$\text{where} \quad h_{q \rightsquigarrow S}(p) = \begin{cases} h(p), & \text{if } p \in L \setminus \{q\}, \\ S, & \text{if } p = q. \end{cases}$$

This operator is not monotonic, but because of the pure past restriction, it does in fact have a unique fixed point. However, the 'recursive' view of φ is also natural.

The φ operator was introduced in [61], via a logic called USF expressively equivalent to the UYF just defined. [95] and [64, chapter 8] showed that any UYF-formula is equivalent to one with at most two nested φs, and that UYF is decidable with PSPACE-complete validity problem. They also prove that UYF is expressively equivalent to monadic second-order logic over $(\mathbb{N}, <)$ (see Section 3.2). For any monadic second-order formula $\psi(t, Q_1, \ldots, Q_n)$, where $Q_1, \ldots, Q_n$ are (free) unary relation symbols, there is a UYF-formula $\alpha(q_1, \ldots, q_n)$ such that for any $h : L \to \wp(\mathbb{N})$, and any $t \in \mathbb{N}$, we have $(\mathbb{N}, <, h), t \models \alpha$ iff $(\mathbb{N}, <) \models \psi(t, h(q_1), \ldots, h(q_n))$. This is a second-order form of *expressive completeness,* the first-order form of which will be discussed in Section 4.

3. Moving to arbitrary flows of time, we can add the *μ-calculus* to basic temporal logic. Over $(\mathbb{N}, <)$, this provides expressive power equal to monadic second-order logic; but its use is not limited to this flow. We will not consider it in detail here, because chapter 12 is devoted to it.

4. Another option is to include *second-order quantification.* In its simplest form this means adding, to propositional temporal logic, an ability to quantify over propositional atoms. Given a temporal formula α and an atom q, we may admit the formula $\exists q \alpha$ to our logic. In such a formula, q is a 'bound variable'. The $\exists q$ can be interpreted in several ways:

   - $(T, <, h), t \models_a \exists q \alpha$ iff $(T, <, h) \models_a \alpha(r/q)$ for some $r \in L$; here, $\alpha(r/q)$ denotes the result of replacing all free occurrences of q by r throughout α. This semantics reads $\exists q \alpha$ as $\bigvee_{r \in L} \alpha(r/q)$. We quantify over existing or actual values of atoms (hence the 'a').

- $(T, <, h), t \models_2 \exists q\alpha$ iff $(T, <, g) \models_2 \alpha$ for some assignment $g : L \to \wp(T)$ agreeing with h except perhaps on q (that is, $g(r) = h(r)$ for all $r \in L \setminus \{q\}$). This is straightforward monadic second-order quantification (hence the '2').
- More generally, we can specify a set $\mathcal{S} \subseteq \wp(T)$ over which $\exists$ ranges. We then stipulate that $(T, <, h), t \models_{\mathcal{S}} \exists q\alpha$ iff $(T, <, g) \models_{\mathcal{S}} \alpha$ for some assignment $g : L \to \wp(T)$ agreeing with h except perhaps on q and with $g(q) \in \mathcal{S}$. Setting $\mathcal{S} = \text{rng}(h)$ yields $\models_a$, and $\mathcal{S} = \wp(T)$ yields $\models_2$.

These systems are very powerful but computationally rather complex. In [64, chapter 8], an axiomatisation was given for $\models_a$, and $\models_a$ and $\models_2$ were both shown undecidable.

3.7 Branching Time Operations

Most work on branching time temporal logics, by which we mean those being evaluated on tree structures, divides into two schools. The oldest is the philosophical school studying logics of historical necessity in which arbitrary trees are allowed as flows of time. The other is the computing school studying logics of paths through transition systems which we have seen is closely related to logics of temporal structures with flows which are discrete ω-height trees. There are many common issues across the schools but the notation is different so we tackle each in turn.

Historical Necessity

In the philosophical tradition, temporal logics of branching time are often referred to as logics of historical necessity: there are no alternative past histories before any point of time. We present here a standard approach called Ockhamist logic with local assignment to atoms.

Recall that a branch (or *history*) of $(T, <)$ is a maximal linearly $<$-ordered subset of $(T, <)$. Let $\mathbf{B}(T, <)$ be the set of all branches of $(T, <)$.

Fix a countable set L of atoms. *Structures* $\mathcal{T} = (T, <, h)$ will have a tree frame $(T, <)$ and a valuation h for the atoms i.e. for each atom $p \in L$, $h(p) \subseteq T$.

The language HN is generated by the connectives G, H and $\Box$ along with classical $\neg$ and $\wedge$. That is, we define the set of formulas recursively to contain the atoms and for formulas α and β we include $\neg\alpha$, $\alpha \wedge \beta$, $G\alpha$, $H\alpha$ and $\Box\alpha$.

Formulas are evaluated at points on branches in structures. We write $\mathcal{T}, \sigma, x \models \alpha$ when α is true at the point x of the branch σ of the structure $\mathcal{T}$. This is defined recursively as follows. Suppose that we have defined the truth of formulas α and β at all points of all branches of $\mathcal{T}$. Then for all branches σ, for all points x of σ:

$\mathcal{T}, \sigma, x \models p$	iff	$x \in h(p)$, for p atomic;
$\mathcal{T}, \sigma, x \models \neg\alpha$	iff	$\mathcal{T}, \sigma, x \not\models \alpha$;
$\mathcal{T}, \sigma, x \models \alpha \wedge \beta$	iff	both $\mathcal{T}, \sigma, x \models \alpha$ and $\mathcal{T}, \sigma, x \models \beta$;
$\mathcal{T}, \sigma, x \models G\alpha$	iff	for all $y > x$ in σ we have $\mathcal{T}, \sigma, y \models \alpha$;
$\mathcal{T}, \sigma, x \models H\alpha$	iff	for all $y < x$ in σ we have $\mathcal{T}, \sigma, y \models \alpha$;
$\mathcal{T}, \sigma, x \models \Box\alpha$	iff	for every branch π containing x we have $\mathcal{T}, \pi, x \models \alpha$.

As well as the linear time abbreviations we also have $\Diamond\alpha \equiv \neg\Box\neg\alpha$.

We say that α is *valid* in HN iff for all structures $\mathcal{T}$, for all branches σ in $\mathcal{T}$, for all points $x \in \sigma$, we have $\mathcal{T}, \sigma, x \models \alpha$. Let us write $\models \alpha$ in that case.

Variations and extensions on this traditional set-up abound. They include the addition of (strict) until and since operators [217], allowing the truth of propositions to be dependent on branch as well as time point (discussed by Prior in [150] and referred to as non-local assignment in [218] and [165]) and the *bundled* logics of [28] in which the modal quantification over branches is restricted to a given set.

An important class of branching time temporal logics are those termed Peircean branching time logics by Prior. These logics are defined so that truth of all formulas depends only on a time point of evaluation and not on a branch of evaluation. An example includes the sublanguage of the Ockhamist historical necessity logic above in which the branch and temporal modalities are only allowed in the combinations $\Box G$, $\Box F$, $\Box H$, $\Box P$, $\Diamond G$, $\Diamond F$, $\Diamond H$ and $\Diamond P$. See [150, 151, 216] for details.

PCTL, CTL*, CTL and QCTL*

A simple branching time temporal logic for computing applications called CTL for computational tree language was described in [35]. The branching is used to capture indeterminacy, choice or openness to the environment. A much more expressive language, CTL*, also called the full computational tree logic, was provided in [46] and [43] to extend, in expressiveness, both CTL and the linear PTL. We will work with a further extension here. The branching time logic PCTL* [123], [162] extends both CTL* and linear time temporal logic augmented with past-time operators.

The formulas of PCTL* are built from the atomic propositions in L recursively using classical connectives $\neg$ and $\wedge$ as well as the temporal connectives X, S, Y and U and the path quantifier A: if α and β are formulas then so are $X\alpha$, $\alpha S\beta$, $Y\alpha$, $\alpha U\beta$ and $A\alpha$.

Formulas are evaluated in *transition systems* (see definition 11 above). Since ω-height trees are transition systems this is a generalization of working with a tree shaped model of time.

Truth of formulas is evaluated at indexes in fullpaths in transition systems. We write $M, b, i \models \alpha$ iff the formula α is true at the index (time) i of the fullpath b in the transition system $M = (S, R, g)$. This is defined recursively by:

$$
\begin{array}{lll}
M, b, i \models p & \text{iff} & p \in g(b_i), \text{ any } p \in L \\
M, b, i \models \neg\alpha & \text{iff} & M, b, i \not\models \alpha \\
M, b, i \models \alpha \wedge \beta & \text{iff} & M, b, i \models \alpha \text{ and } M, b, i \models \beta \\
M, b, i \models X\alpha & \text{iff} & M, b, i+1 \models \alpha \\
M, b, i \models \alpha U\beta & \text{iff} & \text{there is some } j \geq i \text{ such that } M, b, j \models \beta \\
 & & \text{and for each } k, \text{ if } i \leq k < j \text{ then } M, b, k \models \alpha \\
M, b, i \models Y\alpha & \text{iff} & i > 0 \text{ and } M, b, i-1 \models \alpha \\
M, b, i \models \alpha S\beta & \text{iff} & \text{there is some } j \leq i \text{ such that } M, b, j \models \beta \\
 & & \text{and for each } k, \text{ if } j < k \leq i \text{ then } M, b, k \models \alpha \\
M, b, i \models A\alpha & \text{iff} & M, b', i \models \alpha \text{ for every fullpath } b' \text{ such that } b_{\leq i} = b'_{\leq i}
\end{array}
$$

We say that α is *valid* in PCTL*, and write $\models_P \alpha$, iff for all transition systems M, for all fullpaths b in M, for all indexes i, we have $M, b, i \models \alpha$.

We use the usual past-time linear temporal logic abbreviations plus $E\alpha \equiv \neg A \neg \alpha$.

The formulas of CTL* are just those of PCTL* which do not contain the past operators S or Y. The past before the index i of evaluation is irrelevant for CTL* formulas and so the semantics of CTL* on fullpaths through Kripke structures is usually presented with

no mention of such an index: truth is evaluated from the point of view of the beginning of the fullpath. The semantics of CTL* is defined so that $M, b \models A\alpha$ iff $M, b' \models \alpha$ for any fullpath b' through M starting at the same state as b does.

Note that formulas of CTL* which are boolean combinations of atoms and formulas of the form $A\gamma$ are often called *state formulas.* Their truth depends only on the point of evaluation independent of any fullpath. This is not true in the PCTL* semantics but it is easy to see that for such an α we do have $\models \alpha \leftrightarrow A\alpha$.

The original CTL language actually only consisted of some of the state formulas of CTL*. In fact it contains just boolean combinations of the atoms, and for formulas α and β of CTL, the formulas $EX\alpha$, $E(\alpha U\beta)$, $AX\alpha$ and $A(\alpha U\beta)$. CTL is a Peircean branching time logic.

There also exist branching time temporal logics which extend CTL* via propositional quantification (see for example [57]). The reader should also see Chapter 12 for a full coverage of the μ-calculus which is a popular extension of CTL*.

4 EXPRESSIVE POWER OF INTERNAL AND EXTERNAL PARADIGMS

In the preceding section, we introduced both 'internal' (modal style) and 'external' (first-order style) logics for handling time. Now we wish to compare the two approaches. We will consider their relative expressive power, over various kinds of flow of time, and the complexity of deciding validity for them. Such comparisons probably began with Kamp [112], and they have given rise to a rather rich and interesting field of work. Mainly we will restrict our attention to linear flows of time, but we will mention some results for trees and for arbitrary flows.

The most basic observation is that there is a 'standard' translation of propositional temporal formulas into first-order logic, and we will start with this in Section 4.1. The question then arises of how much of first-order logic is captured by this translation. Section 4.2 introduces the crucial notion of expressive completeness, whereby all first-order properties are expressible by temporal formulas. Expressive completeness is studied in Section 4.3 over all flows of time, and in Section 4.4 over linear flows, where we mention Kamp's famous theorem that Until and Since are expressively complete over Dedekind-complete linear time. Section 4.5 briefly discusses algorithmic issues. In Section 4.6 we discuss separation, an important notion due to Gabbay.

All this is for one-dimensional propositional temporal logic. In the last two sections, we broaden our view. In Section 4.7, we briefly consider expressive completeness for many-dimensional connectives. In recent times, expressive completeness for first-order temporal logic has also received attention, and we end in Section 4.8 by discussing some of this work.

Notation. We will reserve the phrase 'temporal logic' for a modal-style logic. We will use 'first-order style logic' or 'first-order logic' for the other kind. We will generally write temporal formulas as $\alpha, \beta, \ldots$, and classical first-order ones as φ, ψ, etc.

Until the end of Section 4.6, we will restrict our attention to the (one-dimensional) propositional case. Recall that L is our set of atoms, and that $L^\star$ denotes the first-order signature $\{<\} \cup \{Q : q \in L\}$, where the Q are unary relation symbols. For a temporal structure $\mathcal{M} = (T, <, h)$, $\mathcal{M}^\star$ is the $L^\star$-structure obtained from $\mathcal{M}$ in the natural way: see Section 3.1. We will write $\mathcal{L}$ for the class of all linear flows of time, and $\mathcal{D}$ for the

class of all Dedekind-complete linear flows (see definition 4).

4.1 Translating temporal logic into first-order logic

To begin, let us observe that the first-order approach subsumes any temporal logic whose temporal connectives have first-order definitions ('tables').

Suppose we have a set $\mathcal{T}$ of connectives, each $\sharp \in \mathcal{T}$ being defined by a first-order table $\tau_\sharp(t, P_1, \ldots, P_n)$ written with variables in a fixed set $\mathcal{V}$, say. For each $v \in \mathcal{V}$, let $\tau_\sharp(v, P_1, \ldots, P_n)$ denote the result of applying to the variables of $\tau_\sharp(t, P_1, \ldots, P_n)$ a permutation $\pi_\sharp$ of $\mathcal{V}$ that takes t to v. Then we may recursively translate each $\mathcal{T}$-formula $\alpha(q_1, \ldots, q_n)$ into a first-order $L^\star$-formula $\alpha^v(v, Q_1, \ldots, Q_n)$, with free variable v and written with variables in $\mathcal{V}$. The translation is defined by induction, as follows:

1. For an atom q, and $v \in \mathcal{V}$, we set $q^v = Q(v)$.
2. We let $\top^v = \top$ and $\bot^v = \bot$.
3. We define $(\neg\alpha)^v = \neg(\alpha^v)$, and $(\alpha \wedge \beta)^v = \alpha^v \wedge \beta^v$.
4. For each $\sharp \in \mathcal{T}$, we define $(\sharp(\alpha_1, \ldots, \alpha_n))^v$ to be the formula obtained from $\tau_\sharp(v, P_1, \ldots, P_n)$ by simultaneously replacing each atomic subformula $P_i(u)$ of it (where $i \leq n$ and $u \in \mathcal{V}$) by α_i^u.

As an example, consider the set $\mathcal{T}$ of connectives F, U, with tables as defined before, written with variables in $\mathcal{V} = \{t, u, v\}$. Then we could let

$$\begin{aligned}
(Fq)^t &= \exists u(u > t \wedge Q(u)),\\
U(p,q)^u &= \exists v(v > u \wedge Q(v) \wedge \forall t(u < t < v \to P(t))),\\
F\neg U(p,q)^t &= \exists u(u > t \wedge (\neg U(p,q))^u)\\
&= \exists u(u > t \wedge \neg\exists v(v > u \wedge Q(v) \wedge \forall t(u < t < v \to P(t)))).
\end{aligned}$$

The particular $\mathcal{V}$ used is generally unimportant, so long as it is large enough; so we will generally abuse notation slightly by writing $\alpha^\star(t, P_1, \ldots, P_n)$ or just $\alpha^\star(t)$ for the $L^\star$-formula α^t above, for any variable t. $\alpha^\star$ will be called the *standard translation* of α.

It should be clear that the standard translation is meaning-preserving. Formally, for any temporal structure $\mathcal{M} = (T, <, h)$, any $\mathcal{T}$-formula α, and any $a \in T$, we have

$$\mathcal{M}, a \models \alpha \iff \mathcal{M}^\star \models \alpha^\star(a, h(q_1), \ldots, h(q_n)).$$

This shows that first-order logic is at least as expressive as $\mathcal{T}$. Observe that we only need a $\mathcal{V}$ large enough to write the tables of the connectives of $\mathcal{T}$. So for example, the two-variable fragment of first-order logic is enough to express every formula of the temporal logic with F and P, and three variables suffice for U and S.

4.2 Expressive completeness

Clearly, the formulas $\{\alpha^x : \alpha \text{ a } \mathcal{T}\text{-formula}, x \in \mathcal{V}\}$ form, in general, a proper fragment of even the $\mathcal{V}$-variable fragment of first-order logic. For example, the formula $\exists y(y \neq x)$ is not of the form α^x for any α of the temporal logic with connectives F and P. This suggests that temporal logic is weaker than first-order logic; but to see if this is really

true, we have to consider not just equality but *equivalence* of first-order formulas to the translations of temporal ones. Of course, 'equivalence' is relative to the underlying flow(s) of time.

DEFINITION 12. Let $\mathcal{C}$ be a class of flows of time.

1. We say that first-order $L^\star$-formulas φ, ψ are *equivalent over* $\mathcal{C}$ if for every temporal structure $\mathcal{M} = (T, <, h)$ with $(T, <) \in \mathcal{C}$, and every assignment ν of the free variables of φ and ψ to elements of T, we have $\mathcal{M}^\star, \nu \models \varphi \leftrightarrow \psi$. Note that φ, ψ need not have the same free variables. For example, $v = v$ is equivalent to $\top$ over any class $\mathcal{C}$.

2. We say that an $L^\star$-formula $\varphi(t)$ is *equivalent over* $\mathcal{C}$ to a temporal formula α, if $\varphi(t)$ and $\alpha^\star(t)$ are equivalent over $\mathcal{C}$.

3. We will use obvious contractions: two formulas are said to be *equivalent over linear time* if they are equivalent over the class of all linear flows of time, *equivalent over a flow of time* $(T, <)$ if they are equivalent over the class $\{(T, <)\}$, and so on.

Since we are especially curious about whether temporal logic can ever match the power of first-order logic, we make the following definition.

DEFINITION 13. Let $\mathcal{C}$ be a class of flows of time, and $\mathcal{T}$ a temporal logic. We say that $\mathcal{T}$ is *(propositionally) expressively complete over* $\mathcal{C}$ if for every first-order $L^\star$-formula φ with one free variable, there is a $\mathcal{T}$-formula α that is equivalent to φ over $\mathcal{C}$.

This is somewhat analogous to the boolean connectives $\wedge, \neg$ being able to express any boolean function with any finite number of arguments. Since all temporal logics with connectives defined by first-order tables can be expressed in first-order logic, an expressively complete temporal logic would be an attractive proposition: it would be able to express all first-order-definable connectives. (Of course, it may not be able to express connectives defined by second-order tables; but here, we are focusing on the comparison of temporal logic with first-order logic. Aspects of second-order expressive completeness were discussed in Section 3.6.) Note that any temporal logic that is expressively complete over $\mathcal{C}$ remains expressively complete over any subclass of $\mathcal{C}$. Also note that if we are willing to allow infinitely many temporal connectives, we can add one for each $L^\star$-formula, yielding a temporal logic that is trivially expressively complete over any class of flows of time. So we will concentrate on temporal logics with *finitely many connectives.* (Another possibility would be to impose a bound on the number of variables in the defining tables of connectives.) Some natural questions now arise (brief answers are in italics):

1. Is there a temporal logic that is expressively complete over the class of all flows of time? *No: see theorem 14.*

2. If not, then for which classes $\mathcal{C}$ of flows of time does there exist an expressively complete temporal logic? *Examples include the linear and Dedekind-complete linear flows: see, e.g., theorem 15. That $\mathcal{C}$ has finite 'Henkin dimension' is a necessary but not sufficient condition; see Section 4.7.*

3. How can we tell whether a given temporal logic is expressively complete (over a given class $\mathcal{C}$ of flows of time)? *Separation is useful: see theorem 17.*

4. If $\mathcal{T}$ is expressively complete over $\mathcal{C}$, is there an effective procedure to convert an arbitrary first-order formula $\varphi(x, P_1, \ldots, P_n)$ into a $\mathcal{T}$-formula α whose standard translation is equivalent to φ over $\mathcal{C}$? How efficient can such a procedure be? *Sometimes; usually non-elementary. See Section 4.5.*

5. If $\mathcal{T}$ is expressively complete over $\mathcal{C}$, what can we say about the minimal length of a $\mathcal{T}$-formula equivalent over $\mathcal{C}$ to a given first-order formula? This is asking how *succinct* $\mathcal{T}$ is, compared with first-order logic. *Sometimes there is a non-elementary blow-up. See Section 4.5.*

6. If $\mathcal{T}$ is not expressively complete over $\mathcal{C}$, is it decidable whether a given first-order formula is equivalent over $\mathcal{C}$ to the standard translation of some $\mathcal{T}$-formula? With what complexity? *Not known. See Section 4.5(4).*

Quite a lot of work has been done on questions like these. We now proceed to give some more detailed answers than above.

4.3 The class of all flows of time

We have seen that given a set $\mathcal{T}$ of temporal connectives whose tables are written using variables in a set $\mathcal{V}$, any $\mathcal{T}$-formula can be translated to a first-order formula written with variables in $\mathcal{V}$. For finite $\mathcal{T}$, a finite set $\mathcal{V}$ will always suffice. This means that there is a finite bound on the number of variables required to write the standard translation $\alpha^\star$ of any $\mathcal{T}$-formula α. As Gabbay showed in [59], it follows that over any class $\mathcal{C}$ of flows of time on which the expressive power of $L^\star$-formulas with one free variable increases infinitely often as the total number of available variables increases, there can be no expressively complete temporal logic with finitely many temporal connectives. This is so for the class of *all* flows of time — for example, for flows of the form $(T, \emptyset)$, it takes n variables to express that $|T| \geq n$. The answer to our first question is therefore 'no':

THEOREM 14 (Gabbay, [59]). *There is no temporal logic with finitely many connectives (with first-order tables) that is expressively complete over the class of all flows of time.*

In Section 4.7, we will say a little more about the connection of expressive completeness to numbers of variables.

4.4 Linear flows — Kamp's theorem

Quite remarkably, over *linear time* the picture is more positive. Recall that we let $\mathcal{L}$ denote the class of all linear flows of time. The negative argument sketched above for the class of all flows does not apply to $\mathcal{L}$: [148, 106] showed that every first-order $L^\star$-formula $\varphi(t, P_1, \ldots, P_n)$ can be equivalently rewritten over $\mathcal{L}$ using only three variables. This is not in itself sufficient to ensure the existence of an expressively complete temporal logic over it [93]. Nonetheless, Kamp showed that:

THEOREM 15 (Kamp, [112]). *The temporal logic with Until and Since is expressively complete over the class $\mathcal{D}$ of all Dedekind-complete linear flows of time.*

This seminal theorem initiated the whole study of expressive completeness, and it remains one of the most interesting and distinctive results in temporal logic; very few, if any, similar 'modal' results exist. Several alternative proofs of it and stronger results

have appeared; none of them are trivial (at least to most people). Kamp's proof is in [112]. A second proof uses *separation,* to be discussed in Section 4.6 below. A third line of proof, reminiscent of classical quantifier elimination, began in [66]. Expressive completeness of Until and Since over $(\mathbb{N}, <)$ was outlined, together with a statement that two further connectives can be added to Until and Since to create a temporal logic that is expressively complete over $\mathcal{L}$. This second statement was proved by Stavi in an unpublished manuscript; the extra connectives are now called the *Stavi connectives* (see Section 3.4). A game-based account of the method appeared in [63, 64]. The proof for Dedekind complete time is simpler and appeared in [94]; it was later streamlined further by Wilke (unpublished).

4.5 Computational issues

Even when we have an expressively complete temporal logic $\mathcal{T}$ over a class $\mathcal{C}$ of flows of time, still there are the issues of whether there is an effective procedure (algorithm) to obtain a $\mathcal{T}$-formula $\alpha_\varphi(p_1, \ldots, p_n)$ that is $\mathcal{C}$-equivalent to any given first-order formula $\varphi(x, P_1, \ldots, P_n)$, what the algorithm's complexity might be, and what might be the length of α_φ in terms of the length of φ (succinctness). We now make some observations on these questions.

1. If the universal monadic second-order theory of $\mathcal{C}$ is decidable — as, for example, it is for $\mathcal{L}$ and $\mathcal{D}$ [33] — by an algorithm $\mathcal{A}$, say, then there is an algorithm to obtain α_φ. For, given $\varphi(x, P_1, \ldots, P_n)$, we may enumerate all $\mathcal{T}$-formulas $\alpha(p_1, \ldots, p_n)$, check using $\mathcal{A}$ whether
$$\mathcal{C} \models \forall P_1 \ldots P_n \forall x(\alpha^*(x, P_1, \ldots, P_n) \leftrightarrow \varphi(x, P_1, \ldots, P_n)),$$
and print out α if yes. By expressive completeness, this process will terminate.

2. However, even over $\mathcal{C} = \{(\mathbb{N}, <)\}$, and with $\mathcal{T}$ the temporal connectives Until and Since, there is no elementary algorithm to obtain an equivalent $\mathcal{T}$-formula to every first-order formula. (An algorithm is *elementary* if it runs in time bounded by $2^{2^{\cdot^{\cdot^{2^n}}}}$ on all inputs of length n, for some stack of 2s of arbitrary but fixed height.) To see this, we note that the validity problem for $\mathcal{T}$ over $\mathcal{C}$ is PSPACE-complete [184]; in particular, there is a PSPACE algorithm $\mathcal{B}$ to decide it. If there were an elementary algorithm to translate first-order formulas into equivalent $\mathcal{T}$-formulas, we could combine it with $\mathcal{B}$, yielding an elementary decision procedure for the universal monadic second-order theory of $(\mathbb{N}, <)$. This contradicts the result of [134, p. 479], [186] that there is no elementary decision procedure for that logic.

3. This does not rule out the possibility that for every first-order φ there is a relatively short equivalent $\mathcal{T}$-formula α_φ, even if there is no elementary algorithm to construct one. But Etessami and Wilke showed in [47] that there is in general a non-elementary gap between the length of a first-order formula and the length of any equivalent temporal formula, over $(\mathbb{N}, <)$ and with respect to the temporal logic with Until and Since. Succinctness is currently a rather active area; see, e.g., [5, 82].

4. Until and Since are not expressively complete over all linear time. Rabinovich has asked if it is decidable whether an arbitrary first-order $L^\star$-formula $\varphi(t, P_1, \ldots, P_n)$

is equivalent over linear time to a temporal formula written with Until and Since. We are not aware of any answer to this question or any of its obvious variants.

4.6 Separation

Roughly, a temporal logic has the separation property if each of its formulas can be equivalently rewritten as a boolean combination of parts depending only on the past, present, and future. Surprisingly, separation is often equivalent to expressive completeness, and is an important method for proving expressive completeness.

We have seen temporal logics such as the logic with F and P, and that with U and S, suitable for linear time. It is natural to observe that formulas such as Pq and $S(q, \neg S(\neg q, r))$ depend only on the past; $q \to r$ depends only on the present and is not temporal at all; FGq and $U(q \wedge \neg U(\top, q), \neg q)$ depend only on the future; and $F(q \wedge Pr)$ has a mixed dependence on past, present, and future. Let us be more precise.

DEFINITION 16. (Gabbay, [61]) Let $\mathcal{C}$ be a class of flows of time. A formula α of a temporal logic $\mathcal{T}$ is said to be

- *pure past over $\mathcal{C}$,* if for any $(T, <) \in \mathcal{C}$, any $t \in T$, and any assignments $g, h : L \to \wp(T)$, if $u \in g(q) \iff u \in h(q)$ for all $u \in T$ with $u < t$ and all $q \in L$, then $(T, <, g), t \models \alpha$ iff $(T, <, h), t \models \alpha$;
- *pure present over $\mathcal{C}$,* for any $(T, <) \in \mathcal{C}$, any $t \in T$, and any assignments $g, h : L \to \wp(T)$, if $t \in g(q) \iff t \in h(q)$ for all $q \in L$, then $(T, <, g), t \models \alpha$ iff $(T, <, h), t \models \alpha$;
- *pure future over $\mathcal{C}$,* if for any $(T, <) \in \mathcal{C}$, any $t \in T$, and any assignments $g, h : L \to \wp(T)$ if $u \in g(q) \iff u \in h(q)$ for all $u \in T$ with $u > t$ and all $q \in L$, then $(T, <, g), t \models \alpha$ iff $(T, <, h), t \models \alpha$;
- *pure over $\mathcal{C}$,* if it is pure past, pure present, or pure future over $\mathcal{C}$,
- *separated over $\mathcal{C}$,* if it is a boolean combination of formulas that are pure over $\mathcal{C}$.

$\mathcal{T}$ is said to have the *separation property over $\mathcal{C}$* if every $\mathcal{T}$-formula is equivalent over $\mathcal{C}$ to a formula that is separated over $\mathcal{C}$.

So a formula is pure past if its truth value at any time depends only on the values of its atoms in the past. This definition is semantic, and couched in terms of atoms. This leads to some oddities that should perhaps be borne in mind. For example, over linear time, $F\top$ is pure present and pure past, as well as pure future; the formula $P\neg U(\top, \neg q)$ is actually pure past, even though it involves Until, and over dense flows like $(\mathbb{Q}, <)$ and $(\mathbb{R}, <)$, it cannot be equivalently rewritten using only Since. The dependence on the underlying flow of time can also lead to surprises. For instance, the formula $S(q, \bot)$ is pure future over $(\mathbb{Q}, <)$, since it is equivalent to $\bot$ over this flow; but it is not pure future over $(\mathbb{N}, <)$.

Now we can connect separation to expressive completeness. This is surprising because the two conditions seem unrelated.

THEOREM 17 (Gabbay; see [61] and [64, §9.3]). *Let $\mathcal{C}$ be a class of linear flows of time, and $\mathcal{T}$ a temporal logic able to express F and P over $\mathcal{C}$. Then $\mathcal{T}$ is expressively complete over $\mathcal{C}$ iff it has the separation property over $\mathcal{C}$.*

Proof. '$\Rightarrow$' is proved by showing that any first-order formula can be separated. The details are in [64].

For '$\Leftarrow$', assume that $\mathcal{T}$ has the separation property. We show that any first-order formula $\varphi(x, P_1, \ldots, P_n)$, with one free variable, x, and unary predicates $P_1, \ldots, P_n$, is equivalent over $\mathcal{C}$ to some $\mathcal{T}$-formula, by induction on the quantifier depth k of φ.

If k is 0, then φ is a boolean combination of formulas of the form $P_i(x)$, $x = x$, and $x < x$, which can be replaced by p_i, $\top$, and $\bot$, respectively, to obtain the result. Assume the result for k. It suffices to find a $\mathcal{T}$-formula equivalent over $\mathcal{C}$ to $\exists y\varphi(x, y, P_1, \ldots, P_n)$, where φ has quantifier depth k. We can suppose that x and y do not occur bound in φ.

Our strategy is first to remove the particular variable x from $\exists y\varphi$. The atomic subformulas of $\exists y\varphi$ involving x are of the form $P_i(x)$, $x = x$, $x < x$, $z = x$, $z < x$, and $z > x$, where z is some variable other than x. We can replace $x = x$ by $\top$ and $x < x$ by $\bot$. Next, we try to remove the occurrences of x in subformulas $P_i(x)$. For each $S \subseteq \{1, 2, \ldots, n\}$, let φ^S be the result of replacing each atomic subformula $P_i(x)$ of φ by $\top$ if $i \in S$, and by $\bot$ if $i \notin S$. φ^S still has the same quantifier depth, k, but has no occurrences of any $P_i(x)$. (It may of course involve $P_i(z)$ for variables z other than x.) Then $\exists y\varphi$ is equivalent to

$$\bigwedge_{S\subseteq\{1,\ldots,n\}} \Big(\bigwedge_{i\in S} P_i(x) \wedge \bigwedge_{j\notin S} \neg P_j(x) \rightarrow \exists y\varphi^S(x, y, P_1, \ldots, P_n)\Big).$$

The formulas $P_i(x)$ are equivalent to p_i, of course. So it is enough if we can express the formulas $\exists y\varphi^S(x, y, P_1, \ldots, P_n)$ as $\mathcal{T}$-formulas.

Let ψ be one of the formulas φ^S. All occurrences of x in atomic subformulas of ψ are of the form $x = z$, $x > z$, and $x < z$. To remove even these, temporarily introduce new atoms $r_=$, $r_<$, $r_>$, with corresponding unary predicates $R_=$, etc. Replace each atomic subformula $x = z$ in ψ by $R_=(z)$. Similarly, replace $z > x$ by $R_>(z)$, and $z < x$ by $R_<(z)$. We obtain a new formula $\psi'(y, P_1, \ldots, P_n, R_<, R_=, R_>)$, of quantifier depth k, in which x does not occur at all. *If we agree to interpret $R_=$ as $\{x\}$, $R_<$ as $\{t : t < x\}$, and $R_>$ as $\{t : t > x\}$, then $\exists y\psi(x, y, P_1, \ldots, P_n)$ is equivalent to $\exists y\psi'(y, P_1, \ldots, P_n, R_<, R_=, R_>)$.*

Now we know by the inductive hypothesis that $\psi'(y, P_1, \ldots, P_n, R_<, R_=, R_>)$ is equivalent over $\mathcal{C}$ to some $\mathcal{T}$-formula $\alpha(p_1, \ldots, p_n, r_<, r_=, r_>)$. So, as the flows in $\mathcal{C}$ are linear, $\exists y\psi'$ is equivalent over $\mathcal{C}$ to $\beta = \alpha \vee F\alpha \vee P\alpha$. Thus, *under our agreement,* the formula $\exists y\psi(x, y, P_1, \ldots, P_n)$ is equivalent over $\mathcal{C}$ to $\beta(p_1, \ldots, p_n, r_<, r_=, r_>)$.

Finally, we remove the r. *Separate β.* We obtain a boolean combination $\gamma(p_1, \ldots, p_n, r_<, r_=, r_>)$ of pure $\mathcal{T}$-formulas that is equivalent over $\mathcal{C}$ to β. Consider a pure past formula $\delta(p_1, \ldots, p_n, r_<, r_=, r_>)$ from this boolean combination. As δ is pure past, it only 'needs to know' the values of the atoms at points $t < x$ when we evaluate it at a point x. Its truth value is independent of their values at points $t \geq x$. So let us replace $r_=$ and $r_>$ in δ by $\bot$, as under our agreement, these atoms are equivalent to $\bot$ at all $t < x$. Replace $r_<$ by $\top$ — these are also equivalent before x. We obtain $\delta^*(p_1, \ldots, p_n) \stackrel{\text{def}}{=} \delta(p_1, \ldots, p_n, \top, \bot, \bot)$. Then *subject to our agreement,* the truth values of δ^* and δ at x are the same. We conduct a similar replacement campaign for each pure formula δ in γ. If δ is pure present, $r_=$ is replaced by $\top$, and the others by $\bot$. For pure future δ, $r_>$ is replaced by $\top$ instead. The result is a boolean combination $\gamma^*(p_1, \ldots, p_n)$, which, subject to our agreement, is equivalent to $\exists y\psi(x, y, P_1, \ldots, P_n)$.

But the agreement concerned atoms that do not appear in γ^* or ψ. So it is irrelevant. Thus, without any restriction on assignments to atoms, γ^* is equivalent over $\mathcal{C}$ to $\exists y\psi(x, y, P_1, \ldots, P_n)$. This completes the proof. ❑

THEOREM 18 (Gabbay; see [61] and [64, 10.2.9]). *The temporal logic with Until and Since has the separation property over* $(\mathbb{N}, <)$ *(i.e., over the class* $\{(\mathbb{N}, <)\}$*).*

THEOREM 19 (Gabbay, Reynolds; see [64, §10.3–11]). *The temporal logic with Until and Since has the separation property over* $(\mathbb{R}, <)$. *The temporal logic with Until, Since, and the Stavi connectives has the separation property over the class* $\mathcal{L}$ *of all linear flows of time.*

Hence, Until and Since are expressively complete over $(\mathbb{N}, <)$ and $(\mathbb{R}, <)$, and Until, Since, and the Stavi connectives are expressively complete over all linear flows. The proofs of theorems 18 and 19 are direct, showing that each formula can be separated. They are tough and tougher, respectively. Nonetheless, they are effective, and so, whilst not quite providing an algorithm to determine if a set of connectives is expressively complete, they do suggest a potential way of telling in practice whether a given set of connectives is expressively complete — in Gabbay's words, *try to separate and see where you get stuck!* The process may suggest additional connectives that are more nearly expressively complete. For example, in the temporal logic with F and P, an attempt to find a separated formula equivalent over linear time to $F(q \wedge Hr)$ shows the need for Until. This formula cannot be separated using only F and P, but it is equivalent to $Hr \wedge r \wedge U(r, q)$, which is separated over linear time.

Suppose we have a $\mathcal{T}$ able to express F and P and with the separation property over a class $\mathcal{C} \subseteq \mathcal{L}$. The proofs of the above theorems can provide an effective way of constructing, for any temporal formula α, a separated (over $\mathcal{C}$) $\mathcal{T}$-formula that is equivalent to α over $\mathcal{C}$. However, there are some outstanding open questions:

1. What is the optimal complexity of algorithms that, given a $\mathcal{T}$-formula α, output a separated formula equivalent to α over $\mathcal{C}$?

   The chief concrete instances of this problem are for U, S over $(\mathbb{N}, <)$ and over Dedekind complete time, and for U, S, and the Stavi connectives over linear time. It is known that all such algorithms require at least exponential time; it is likely that there is no elementary algorithm even for $(\mathbb{N}, <)$.

2. What can one say about the length of a shortest separated $\mathcal{T}$-formula equivalent (over $\mathcal{C}$) to a given $\mathcal{T}$-formula?

   Results in [122] imply that over $(\mathbb{N}, <)$, separation causes at least an exponential blow-up in length for some formulas.

We end this section by mentioning some separation and expressive completeness results for non-linear time. For ω-trees with a bounded number of immediate successors of each node, or similar such restrictions, see [10, 11, 12, 13, 106, 175]. For the language XPath over trees with a left-right ordering, see [128]. [136] shows that the expressive power of the branching time logic CTL* coincides with that of the class of bisimulation invariant properties expressible in so-called monadic path logic: monadic second order logic in which set quantification is restricted to paths. In order to prove this result, the authors first prove a composition theorem for trees. This approach is adapted from the proof in [86] that CTL* coincides with the whole of monadic path logic over the class of full binary trees.

4.7 Many-dimensional temporal logic

We can generalise the notion of standard translation (Section 4.1) in the obvious way to the many-dimensional temporal logics discussed in Section 3.5(3). For a set $\mathcal{T}$ of k-dimensional temporal connectives, the standard translation $\alpha^\star$ of a $\mathcal{T}$-formula α is an $L^\star$-formula with (in general) k free variables. For a class $\mathcal{C}$ of flows of time, $\mathcal{T}$ is said to be *(propositionally) expressively complete over* $\mathcal{C}$ if every $L^\star$-formula with k free variables is equivalent over $\mathcal{C}$ to (the standard translation of) a $\mathcal{T}$-formula. We briefly consider now what can be said about this notion. We will say more in the first-order case, in Section 4.8.

How does many-dimensional expressive completeness relate to the one-dimensional expressive completeness discussed above? Suppose we have a class $\mathcal{C}$ of flows of time. If $\mathcal{T}$ is a set of k-dimensional temporal connectives that is propositionally expressively complete over $\mathcal{C}$, we can very easily construct a finite set of $(k+1)$-dimensional connectives that are also expressively complete over $\mathcal{C}$. [64, theorem 13.3.4] has details of this 'dimension-boosting' technique.

On the other hand, there are classes of flows of time for which there is a finite expressively complete set of 2-dimensional temporal connectives but no finite expressively complete one-dimensional set. An example based on circular time is given in [64, theorem 13.7.12].

There are some partial characterisations of when many-dimensional expressive completeness can be expected. A class $\mathcal{C}$ of flows of time is said to have the *k-variable property* if every $L^\star$-formula φ with at most k free variables is equivalent over $\mathcal{C}$ to a formula written with k variables altogether. For example, the class $\mathcal{L}$ of linear flows has the 3-variable property [106, 148]. It was shown in [64, theorem 13.6.7] that if $\mathcal{C}$ has the k-variable property then there is a finite expressively complete set of k-dimensional temporal connectives for $\mathcal{C}$, and if $k \geq 3$, there is even a finite expressively complete set of $(k-1)$-dimensional connectives. (The k-variable property does not imply one-dimensional expressive completeness, because the circular-time example just mentioned has the 3-variable property.)

The related notion of 'Henkin dimension' was considered in [59, 93, 99]. A class $\mathcal{C}$ of flows of time has *Henkin dimension at most k* if every $L^\star$-formula can be equivalently rewritten over $\mathcal{C}$ to use at most k bound variables. In [64, theorem 13.2.4], it is shown that $\mathcal{C}$ having finite Henkin dimension is a necessary condition for there to exist a finite expressively complete set of finite-dimensional temporal connectives for $\mathcal{C}$. For a rather weaker notion of expressive completeness, it is necessary and sufficient.

Obtaining expressively complete connectives over a class of flows of time with the k-variable property or finite Henkin dimension is relatively straightforward. The connectives are many-dimensional and the dimensions can mimic the variables in first-order formulas, of which a bounded number are needed. So their expressive completeness may not be so surprising. Obtaining expressively complete *one-dimensional* connectives is a very different matter. Many-dimensional expressive completeness can be useful as a step on the road to proving expressive completeness for one-dimensional connectives (e.g., [175]), but one-dimensional results such as Kamp's theorem 15 are generally far more profound and difficult than many-dimensional ones, and have very different proofs.

So far, we have taken our temporal structures to have the form $(T, <, h)$, where $h : L \to \wp(T)$. In particular, the values of atoms depend on only a single time point. For k-dimensional temporal connectives, we can generalise our semantics and allow atoms to

depend on k time points: so $h : L \to \wp(T^k)$. This is what we called 'true' many-dimensional temporal logic in Section 3.5(3). If we do this, expressive completeness is no longer available. Venema showed in [198] that there is no finite set of 2-dimensional temporal connectives that is expressively complete over linear flows of time. His example uses a single atom, say q; for each $n \geq 1$, he defines a temporal structure $\mathcal{M}_n = (\mathbb{Q}, <, h_n)$ in which $h_n(q)$ is an equivalence relation with n classes, each of which is dense in $(\mathbb{Q}, <)$. We know that given any finite set $\mathcal{T}$ of 2-dimensional temporal connectives, there is finite n such that the standard translation of every $\mathcal{T}$-formula can be written with n variables. But an Ehrenfeucht–Fraïssé game argument shows that no n-variable first-order sentence can distinguish between $\mathcal{M}_n$ and $\mathcal{M}_{n+1}$. The argument generalises easily to higher dimensions.

4.8 First-order temporal logic

The study of expressive completeness in the setting of first-order temporal logic probably began with Kamp's [113], and the field is currently quite active. The picture is not as nice as in the propositional case: there are a few positive results, but also strong negative ones.

Fix a first-order relational signature L. (We assume for simplicity that L is relational, with no function symbols or constants; but our methods are quite general.) Recall from Section 2.7 that first-order temporal structures are of the form $\mathcal{M} = (T, <, D, (M_t : t \in T))$, where $(T, <)$ is a flow of time, and for some first-order signature L, each M_t is an L-structure with domain D.

We have seen two ways to describe these structures in logic. The first is to use a *temporal logic.* When we mention a set $\mathcal{T}$ of temporal connectives here, it will be implicit that the connectives in $\mathcal{T}$ all have the same finite dimension (perhaps greater than 1) and have first-order tables, but there is no implicit assumption that $\mathcal{T}$ is finite. Given a set $\mathcal{T}$ of connectives, we know how to form a first-order temporal logic $\mathcal{T}(L)$. For example, if $\mathcal{T}$ contains the unary one-dimensional connective F ('sometime in the future'), and L contains unary relation symbols dog and day, then

$$\alpha = \forall x(\mathsf{dog}(x) \to F\,\mathsf{day}(x))$$

('every dog will have his day') is a $\mathcal{T}(L)$-formula.

The second way is to use a *two-sorted first-order logic* over the $L^\star$-structure $\mathcal{M}^\star$ obtained from $\mathcal{M}$ as in Section 3.3. Recall that the two sorts are $\mathbf{t}$ (for time) and $\mathbf{d}$ (for the first-order domain). The domain of $\mathcal{M}^\star$ is the disjoint union of T (sort $\mathbf{t}$) and D (sort $\mathbf{d}$). $L^\star$ is obtained from L by adding an extra, $\mathbf{t}$-sorted coordinate to each relation symbol in L — so, for example, if $R \in L$ is an n-ary relation symbol, then we include in $L^\star$ a relation symbol $R^\star$ of sort $\mathbf{t} \times \mathbf{d}^n$. For $a \in T$ and $d_1, \ldots, d_n \in D$, we let $\mathcal{M}^\star \models R^\star(a, d_1, \ldots, d_n)$ iff $M_a \models R(d_1, \ldots, d_n)$. For $\mathcal{T}, L$ as above, an example of an $L^\star$-formula is

$$\varphi = \forall x(\mathsf{dog}^\star(t, x) \to \exists u(u > t \wedge \mathsf{day}^\star(u, x))).$$

We wish to compare the expressive power of these two approaches. To help distinguish them, we will write $\mathcal{T}(L)$-formulas as $\alpha, \beta, \ldots$, and $L^\star$-formulas as $\varphi, \psi, \ldots$. We write $\mathbf{d}$-variables as $x, y, z, x_1, \ldots, x_n$, etc, and $\mathbf{t}$-variables as $t, u, v, t_1, \ldots, t_m$, etc. We will use a, b, etc., for time elements, and d, e, etc., for domain elements.

Standard translation

Let us first observe that, analogously to the propositional case, each $\mathcal{T}(L)$-formula has a *standard translation* into two-sorted first-order logic. It can be defined as follows. Suppose that $\mathcal{T}$ consists of k-dimensional connectives $\sharp$ with first-order tables $\tau_\sharp(t_1,\ldots,t_k,P_1,\ldots,P_n)$, where $\sharp$ is n-ary and $P_1,\ldots,P_n$ are k-ary relation symbols . We regard all symbols in $\tau_\sharp$ as of sort $\mathbf{t}$. We can suppose that in each atomic subformula $P_i(u_1,\ldots,u_k)$ of $\tau_\sharp$, the variables $u_1,\ldots,u_k$ are distinct. As earlier, for any distinct $\mathbf{t}$-variables $u_1,\ldots,u_k$, $\tau_\sharp(u_1,\ldots,u_k,P_1,\ldots,P_n)$ denotes the result of permuting the variables in $\tau_\sharp(t_1,\ldots,t_k,P_1,\ldots,P_n)$ by a permutation taking $t_1,\ldots,t_k$ to $u_1,\ldots,u_k$, respectively. Then for any $\mathcal{T}(L)$-formula α and distinct $\mathbf{t}$-variables $t_1,\ldots,t_k$, we define the $L^\star$-formula $\alpha^{t_1,\ldots,t_k}$ by induction on α as follows:

$$\begin{aligned}
R(x_1,\ldots,x_m)^{t_1,\ldots,t_k} &= R^\star(t_1,x_1,\ldots,x_m), \text{ for each } m\text{-ary relation symbol } R\in L,\\
(x=y)^{t_1,\ldots,t_k} &= (x=y),\\
\top^{t_1,\ldots,t_k} &= \top, \text{ and similarly for } \bot,\\
(\alpha\wedge\beta)^{t_1,\ldots,t_k} &= \alpha^{t_1,\ldots,t_k}\wedge\beta^{t_1,\ldots,t_k},\\
(\neg\alpha)^{t_1,\ldots,t_k} &= \neg(\alpha^{t_1,\ldots,t_k}),\\
(\exists x\alpha)^{t_1,\ldots,t_k} &= \exists x(\alpha^{t_1,\ldots,t_k}).
\end{aligned}$$

Finally, for each n-ary connective $\sharp$ of $\mathcal{T}$, $\sharp(\alpha_1,\ldots,\alpha_n)^{t_1,\ldots,t_k}$ is defined to be the result of replacing each atomic subformula $P_i(u_1,\ldots,u_k)$ in $\tau_\sharp(t_1,\ldots,t_k,P_1,\ldots,P_n)$ by $\alpha_i^{u_1,\ldots,u_k}$. As before, we generally write $\alpha^{t_1,\ldots,t_k}$ simply as $\alpha^\star(t_1,\ldots,t_k,x_1,\ldots,x_m)$, and refer to $\alpha^\star$ as the *standard translation* of α. For example, the standard translation of α (above) is φ.

It should be clear that for any temporal structure $\mathcal{M}=(T,<,D,(M_t:t\in T))$, any $d_1,\ldots,d_m\in D$, any $a_1,\ldots,a_k\in T$, and any $\mathcal{T}$-formula $\alpha(x_1,\ldots,x_m)$, we have

$$\mathcal{M},a_1,\ldots,a_k\models\alpha(d_1,\ldots,d_m) \iff \mathcal{M}^\star\models\alpha^\star(a_1,\ldots,a_k,d_1,\ldots,d_m).$$

So the standard translation faithfully represents the meaning of the original temporal formula. It is therefore reasonable to generalise definition 12 to first-order temporal logic, as follows.

DEFINITION 20. Let $\mathcal{C}$ be a class of flows of time, and let $(T,<)$ be a flow of time.

1. We say that two-sorted first-order $L^\star$-formulas φ,ψ are *equivalent over* $\mathcal{C}$ if for every temporal structure $\mathcal{M}=(T,<,D,(M_t:t\in T))$ with $(T,<)\in\mathcal{C}$, and every sort-respecting assignment ν of the free variables of φ and ψ to elements of $T\cup D$, we have $\mathcal{M}^\star,\nu\models\varphi\leftrightarrow\psi$. Note as before that φ,ψ need not have the same free variables.

2. Let $\mathcal{T}$ be a set of k-dimensional temporal connectives, and let $(t_1,\ldots,t_k)$ be a sequence of distinct $\mathbf{t}$-variables. We say that a two-sorted $L^\star$-formula $\varphi(t_1,\ldots,t_k,x_1,\ldots,x_n)$ is *equivalent over* $\mathcal{C}$ to a first-order $\mathcal{T}(L)$-formula $\alpha(x_1,\ldots,x_n)$ if $\varphi(t_1,\ldots,t_k,x_1,\ldots,x_n)$ and $\alpha^\star(t_1,\ldots,t_k,x_1,\ldots,x_n)$, the standard translation of α, are equivalent over $\mathcal{C}$. (This definition implicitly depends on the choice of $t_1,\ldots,t_k$.)

3. For short, two formulas are said to be *equivalent over* $(T, <)$ if they are equivalent over the class $\{(T, <)\}$, *equivalent over linear time* if they are equivalent over the class of all linear flows of time, etc.

Standard translations have a restricted syntactic form. This will be important in the analysis to come. Formally:

DEFINITION 21. For an integer $k \geq 1$, let $L_k^\star$ be the fragment of $L^\star$ consisting of all formulas φ such that any subformula of φ of the form $\exists x \psi$, for any $\mathbf{d}$-variable x, has at most k free $\mathbf{t}$-variables.

LEMMA 22. *For any set $\mathcal{T}$ of k-dimensional temporal connectives, the standard translation of any $\mathcal{T}(L)$-formula is in $L_k^\star$.*

Proof. This is proved easily from the definitions by induction on $\mathcal{T}(L)$-formulas, and is essentially because $\mathcal{T}(L)$-formulas are evaluated at k time points. We leave the details to the reader. ❑

Summary of results

There is a positive result in the first-order setting: $L_1^\star$ is exactly as expressive as one-dimensional first-order temporal logic. See theorem 23.

But in the main, the results are negative. Obviously, $L_1^\star \subseteq L_2^\star \subseteq \cdots$, and $\bigcup_{n \geq 1} L_n^\star = L^\star$. It turns out that $L^\star$ is more expressive than any of the fragments $L_k^\star$ ($k = 1, 2, \ldots$). It follows from this and lemma 22 that even using many-dimensional temporal connectives, we cannot hope for full expressive completeness, even though we have it for one-dimensional connectives (Kamp's theorem 15) in the propositional case. Below we will go into this in more detail.

Expressive completeness for $L_1^\star$

[100, 18] showed that in situations where we have *propositional* expressive completeness, we can derive expressive completeness with respect to $L_1^\star$-formulas. This is one of the few first-order expressive completeness results.

THEOREM 23. *Let $\mathcal{T}$ consist of Until and Since only, and let L be any relational first-order signature.*

1. *Every $\mathcal{T}(L)$-formula is equivalent to some $L_1^\star$-formula over the class of all flows of time.*

2. *For every $L_1^\star$-formula $\varphi(t, x_1, \ldots, x_n)$ with one free $\mathbf{t}$-variable, there is a formula $\delta(x_1, \ldots, x_n)$ of $\mathcal{T}(L)$ that is equivalent to φ over the class of all Dedekind-complete linear flows of time.*

Proof. Part (1) is immediate from lemma 22. The proof of part (2) is by induction on the number of quantifiers $\exists x$ (for any $\mathbf{d}$-variable x) in φ. Let Ψ be the (possibly empty) set of all $L_1^\star$-formulas with at most one free $\mathbf{t}$-variable and with fewer $\mathbf{d}$-quantifiers than φ, and inductively assume the result for all formulas in Ψ. Then φ is built from

1. atomic formulas of the form $u < v$, $u = v$, where u, v have sort $\mathbf{t}$ as usual,

2. atomic $L^\star$-formulas of the form $y = z$ and $P^\star(u, y_1, \ldots, y_k)$,

3. formulas of the form $\exists x\psi(u, x, y_1, \ldots, y_m)$ for $\psi \in \Psi$,

using only the boolean operations and quantifiers over **t**-variables. Each formula in (2) has at most one free **t**-variable, so is of the form $\alpha(u, y_1, \ldots, y_k)$ for some **t**-variable u (where $y_1, \ldots, y_k$ are **d**-variables). Our strategy is to treat the formulas in (2) and (3) as unary relation symbols over the flow of time. Then φ turns into a first-order formula to which we can apply Kamp's theorem. What remains can be dealt with by hand/by the induction hypothesis.

Replace each type (2) subformula $\alpha(u, y_1, \ldots, y_k)$ of φ by $Q_\alpha(u)$, where Q_α is a new unary relation symbol. Similarly, for each ψ as in (3), introduce a unary relation symbol Q_ψ, and replace the subformula $\exists x\psi(u, x, y_1, \ldots, y_m)$ of φ by $Q_\psi(u)$. In this way, we obtain a first-order formula $\varphi'(t)$ involving only time variables, unary relation symbols, equality, and $<$. By Kamp's theorem (theorem 15 above), there is a *propositional US*-formula β, whose atoms are q_α, q_ψ for α, ψ as above, and whose standard translation β^t is equivalent to $\varphi'(t)$ over Dedekind complete time.

By the inductive hypothesis, for each formula $\psi(u, x, y_1, \ldots, y_m) \in \Psi$, there is a $\mathcal{T}(L)$-formula $\gamma_\psi(x, y_1, \ldots, y_m)$ whose standard translation $\gamma_\psi^\star(u, x, y_1, \ldots, y_m)$ is equivalent to ψ over Dedekind complete time. Hence, $(\exists x\gamma_\psi)^\star(u, y_1, \ldots, y_m)$ is equivalent to $(\exists x\psi)(u, y_1, \ldots, y_m)$. Replace the atoms q_ψ in β by $\exists x\gamma_\psi(x, y_1, \ldots, y_m)$, for each such ψ, and similarly replace the atoms q_α in β by $\alpha(y_1, \ldots, y_k)$, for each $\alpha(y_1, \ldots, y_k)$ as in (2). We obtain a $\mathcal{T}(L)$-formula $\delta(x_1, \ldots, x_n)$ which is easily seen to be equivalent to φ over Dedekind complete time. ❑

We proved this result for the connectives Until and Since, but the approach is more general. For example, in part (2) we could capture all linear time by adding the Stavi connectives. We do not know whether there are generalisations to $L_k^\star$ for $k > 1$. The issues of separation and complexity and succinctness of translations in first-order temporal logic remain largely unexplored, though one may expect that the lower bounds for propositional temporal logic will be inherited by the first-order case.

Expressive incompleteness

Without the restriction to $L_1^\star$, the picture is not so rosy. Let us first lay down what we would like.

DEFINITION 24. Let $\mathcal{C}$ be a class of flows of time, L a signature, and $\mathcal{T}$ a set of k-dimensional temporal connectives. We say that $\mathcal{T}(L)$ is *first-order expressively complete over* $\mathcal{C}$ if for every two-sorted first-order $L^\star$-formula $\varphi(t_1, \ldots, t_k, x_1, \ldots, x_n)$, there is a $\mathcal{T}(L)$-formula $\alpha(x_1, \ldots, x_n)$ that is equivalent to φ over $\mathcal{C}$.

It has long been known that connectives that are expressively complete in the propositional case can fail to be so in first-order temporal logic. For example, let L consist of a unary relation symbol Q, and let $\mathcal{T}$ consist of the one-dimensional connectives Until and Since. We know by theorem 15 that $\mathcal{T}$ is propositionally expressively complete over $(\mathbb{N}, <)$ and over the class of finite linear flows. But consider the $L^\star$-sentence

$$\chi \;=\; \exists uv(u \neq v \wedge \forall x(Q^\star(u, x) \leftrightarrow Q^\star(v, x))).$$

This says that the temporal structure contains two identical first-order structures. A somewhat analogous English statement is that all those who get married on some day get divorced on some (other) day too. Now χ is not in $L_1^\star$; and since the standard translation of any $\mathcal{T}(L)$-formula is in $L_1^\star$, we might suspect that χ is not expressible in $\mathcal{T}(L)$. Indeed, it turns out that χ is not equivalent to any $\mathcal{T}(L)$-formula over the flow of time $(\mathbb{Q}, <)$ (proved by Kamp in [113]), nor over $(\mathbb{N}, <)$ or the class of all finite linear flows [4, 3]. So:

THEOREM 25 ([113, 4, 3]). *The connectives Until and Since are not first-order expressively complete over any of* $(\mathbb{Q}, <)$, $(\mathbb{N}, <)$, *or the class of all finite linear flows of time.*

The context of [4, 3] is temporal databases, and other workers in this area have recently been active in temporal expressiveness. We now describe three of their results.

First, [191] showed that there is no finite set of one-dimensional temporal connectives that is expressively complete over temporal structures with dense linear flow of time. The proof was again model-theoretic.

Second, [18] showed that (slightly non-standard versions of) Until and Since cannot express χ (above) in temporal structures with linear flow of time. Whilst this result is implied by that of [113], the proof is novel. It can be summarised as follows. Suppose for contradiction that we had an $L_1^\star$-formula χ_1 equivalent to χ over linear time. Although χ does not involve $<$, χ_1 might: it might use the linear order in some devious way to express χ. But because χ does not involve $<$, the truth value of χ and hence χ_1 in any temporal structure $\mathcal{M}$ with linear flow of time is invariant under replacing the order on the $\mathbf{t}$-sort of $\mathcal{M}$ by any other linear order. So χ_1 may use a linear order, but it doesn't care which order it's given. We can say that χ_1 is 'order-independent over linear time'.

Now it can be checked that $L_1^\star$ has the Craig interpolation property. Using this and order-independence and the fact that being a linear order is first-order definable, we can replace χ_1 by another $L_1^\star$-formula χ_1' in which $<$ does not occur. χ_1' is still equivalent to χ over linear time. But the absence of $<$ makes it relatively easy to exhibit two temporal structures with linear flows of time that differ on χ, but agree on all $L_1^\star$-formulas without $<$ and at most as complex as χ_1'. Hence they agree on χ_1', which is impossible since χ_1' is equivalent to χ over linear time. So over temporal structures with linear flow of time, χ is not expressible in $L_1^\star$, and by theorem 23(1), not expressible by Until and Since.

To use Craig interpolation to remove $<$ from χ_1, it was assumed that χ_1 is equivalent to χ over the class of all linear flows of time. The argument does not appear to work for non-first-order definable classes, such as $\{(\mathbb{N}, <)\}$. It does not exclude that there is some $L_1^\star$-sentence that is not order-independent over a wide range of temporal structures but still is equivalent to χ over $(\mathbb{N}, <)$. ([4, 3] and theorem 23 show that there isn't!)

Third, Toman in [190] again used Craig interpolation to show — roughly — that over linear time, there is no finite expressively complete set of k-dimensional connectives for any finite k. He did this by showing that the $L_k^\star$ $(k = 1, 2, \ldots)$ are not eventually constant in terms of expressive power. Since the standard translations of temporal formulas always lie in some $L_k^\star$, no first-order temporal logic with first-order-definable connectives of any fixed finite dimension can be first-order expressively complete over such a class. As far as we know, it is an open question whether there is a set of temporal connectives of some finite dimension that is first-order expressively complete over non-first-order definable classes such as $(\mathbb{N}, <)$ and the class of all finite linear flows of time.

5 TEMPORAL REASONING

There are several reasoning tasks needed for the applications of temporal logic. The most fundamental of these tasks is deciding which formulas of a logic are valid, or at least enumerating the valid ones, i.e. the formulas which hold at every time point in every structure. Being able to decide validity also allows us (in the obvious way) to decide whether one formula is a logical consequence of any given finite set of formulas. Other important reasoning tasks, which we will not examine in this chapter, include model checking (but see Chapter 17), execution of temporal formulas and synthesis of models from formulas.

Many of the techniques for deciding or enumerating validity in temporal logics are extensions of methods developed for classical logics, or perhaps other modal logics but there are also novel techniques. We shall examine some ten or so different techniques. An algorithm which decides the validity of each formula of a given logic is known as a *decision procedure* for the logic, (an encoded version of) a formula is fed as input to the algorithm and it eventually halts with a (correct) "yes" or "no" answer, indicating whether the formula is valid or not. An algorithm which produces in succession each valid formula of a given logic (as output), and outputs no other formulas, is known as a semi-decision procedure for the logic.

Some techniques are quite general and can be modified to work (as decision or semi-decision procedures) for a wide range of temporal logics but others are quite specific. For a particular logic it is very useful to know of a decision procedure which has the best complexity. But this is not necessarily the end of the story. We might, for example, choose a different algorithm because we want more information such as a counter-model in the case that a formula is not valid. Also, an algorithm with optimal space complexity might not be optimal timewise, and vice versa.

5.1 *Hilbert style axiom systems*

Axiom systems have been presented for logics since the work of Frege [56]. Indeed, they predate semantic formalizations. The Hilbert style approach is the most common sort of axiom system. We assume the reader is familiar with the notions of axioms, rules and proofs in this approach.

In [149], basic axioms and rules are given for the simple propositional temporal logic K_t of F and P over the class of all flows of time. It turns out to be slightly neater to axiomatize the logic with G and H as operators (and F and P as abbreviations), so we will do that. The early work in the area of axiomatizations for the most basic temporal logics was undertaken by Prior, Kripke, Bull, Cochiarella and Burgess and was to a large extent not published. What follows is a distilled mixture that is hard to attribute correctly.

The rules of our system for K_t are modus ponens and temporal generalization,

$$\frac{\alpha, \alpha \to \beta}{\beta} \qquad \frac{\alpha}{G\alpha} \quad \frac{\alpha}{H\alpha}.$$

The axioms (with some redundancy) are all substitution instances of the following:

L0	any propositional tautology		
LF1	$G(\alpha \to \beta) \to (G\alpha \to G\beta)$	LP1	$H(\alpha \to \beta) \to (H\alpha \to H\beta)$
LF2	$G\alpha \to GG\alpha$	LP2	$H\alpha \to HH\alpha$
LF3	$\alpha \to GP\alpha$		
LP3	$\alpha \to HF\alpha$		

A straightforward induction on the lengths of proofs gives us the *soundness* of the axiom system, i.e. that

LEMMA 26. *If there is a proof of α in the above system then α is valid in K_t: i.e. α is true at every time point in every temporal structure.*

The converse is called the *completeness* of the logic.

LEMMA 27. *If α is valid in K_t then there is a proof of α in the above system.*

Proof. By considering negations it is enough to show that if α is consistent (in the system) then it is satisfiable. So suppose that α is consistent. We will build a model of α. There are two well known techniques for doing so: the step by step building of a *perfect chronicle* set out very clearly in [32] and via the *canonical model* as seen in [178] and [27]. We will sketch the latter method here.

By the method of the lemma of Lindenbaum allowing any consistent set of formulas (in such a system) to be extended to a maximal consistent set (MCS), it suffices to show that we can find a model of any MCS Γ.

The model we find is in fact the *canonical model* consisting of exactly all the MCS of our system. That is, let the set of time points be just the set T_0 of all maximal consistent sets.

We put $\Gamma <_0 \Delta$ iff for all $G\alpha \in \Gamma$ we have $\alpha \in \Delta$. It is straightforward to use $LF2$ and $LP2$ to show that this is a transitive relation. Thus $(T_0, <_0)$ is almost a flow of time. Unfortunately, $(T_0, <_0)$ may not be irreflexive. To make an irreflexive frame out of $(T_0, <_0)$ is slightly complicated and the technique of bull-dozing mentioned below is often used. We will skip the details here.

A valuation h_0 can be simply put on this frame via $h_0(p) = \{\Gamma \in T_0 \mid p \in \Gamma\}$.

Now an induction on the construction of formulas gives us a *truth lemma* that for all $\Gamma \in T_0$, for all formulas β, $\beta \in \Gamma$ iff $(T_0, <_0, h_0), \Gamma \models \beta$.

Thus we have our model and we are done. ❑

Note that the proof of the completeness lemma actually establishes that every consistent set of formulas, even an infinite one, is satisfiable. This property is known as the strong completeness of the axiom system for the logic. If we can only show that every consistent formula (or equivalently consistent finite set of formulas) is satisfiable then we only have the weak completeness of a system.

It should also be noted that the axioms for transitivity and the duality of F and P above are in the special form known as Sahlqvist axioms which we discuss shortly below.

1. (a) canonical models, for K_t:

   To axiomatize Prior's propositional language with G and H over some of the other important classes of frames often only involves a sensible choice of an additional few axioms and minor (but sometimes tricky) adjustments to the canonical model method (or equally the chronicle method). We can axiomatize

linearity, density and the lack of end points in this way. See for example, [72] or [64] for details.

For example, to axiomatize the irreflexive, linear frames we can add

L4 $\quad F\alpha \to G(F\alpha \vee \alpha \vee P\alpha)$

or equivalently L4' $\quad (H\alpha \wedge \alpha \wedge G\alpha) \to GH\alpha$

and the past-time mirror image to K_t. The canonical model for this system will not do as it stands for showing satisfiability of consistent formulas as it is not necessarily anti-symmetric or irreflexive. In fact it may well contain *clusters,* which are sets of MCSs such that for every Γ and Δ in the set, $\Gamma <_0 \Delta$ and $\Delta <_0 \Gamma$. In order to make a linear irreflexive structure from the canonical model we can use a technique of [178] called bull-dozing. This means that we replace each cluster by a linear order which is a kind of product of the integers with the cluster.

Note that the case of axiomatizing G and H over rational numbers time can be obtained easily (using some basic model theory and Cantor's characterization of the rationals) with a completeness proof using axioms for linearity, denseness, and lack of end points.

(b) $\mathbb{N}$:

For G and H over the natural numbers $\mathbb{N}$, we can show completeness for the system obtained by adding the following axioms to the system for linear temporal logic [72]:

$D_F \quad F\top$

$Z_F \quad G(G\alpha \to \alpha) \to (FG\alpha \to G\alpha)$

$W_P \quad H(H\alpha) \to H\alpha$

Z_F is a version of Dummett's axiom and allows us to show that between any two time points lie only a finite number of other points.

In attempting to axiomatise this logic one must face its lack of compactness: meaning there is an unsatisfiable set Γ of formulas such that every finite subset of Γ is satisfiable. For example, $\Gamma = \{Fp, FFp, FFFp, \ldots, FG\neg p\}$ is such a set. We are obviously not going to be able to find a point of time in a $\mathbb{N}$-flowed structure at which all the formulas in Γ hold. To show completeness of an axiom system for such a non-compact logic we need slightly different finitary techniques.

See [72] for details of the proof which uses the canonical model and a filtration followed by intricate "surgery". We will meet some of the same ideas and some alternative approaches shortly below when dealing with more expressive logics over natural numbers time.

(c) $\mathbb{R}$:

We will not go into details for the logic with G and H over the reals here, but essentially one uses the system for the rationals plus an axiom for Dedekind completeness

Cont: $\quad HG(H\alpha \to FH\alpha) \to (H\alpha \to G\alpha)$

i.e. that formulas don't highlight gaps in the flow of time. The completeness proof proceeds via the addition of irrational numbers to a rational flowed model with the specification of a maximal consistent set of formulas to hold at each irrational. See [72] for details.

$$

H(\alpha \rightarrow W\alpha) \rightarrow (\alpha \rightarrow H\alpha) & G(\alpha \rightarrow N\alpha) \rightarrow (\alpha \rightarrow G\alpha) \\
\alpha S\beta \leftrightarrow \beta \vee (\alpha \wedge Y(\alpha S\beta)) & \alpha U\beta \leftrightarrow \beta \vee (\alpha \wedge X(\alpha U\beta)) \\
P\mathbf{start} & \alpha U\beta \rightarrow F\beta
\end{array}
$$

Figure 3. The axiom schemas for TL

2. U and S:

   If we now consider the more expressive language with U and S then we see two traditions in the work on their axiom systems. For the class of all linear flows we have the Burgess–Xu axioms of [30, 215]. Extra axioms have been added to them to axiomatize U and S over the reals in [157] (interestingly using expressive completeness and techniques with lexicographic sums of orders from [62] and [33]) and the integers and natural numbers in [159] and [199].

   Separately, there has been the development of axiom systems for the discrete (i.e. natural numbers) time logics of PLTL [66] and the past-time version TL [124] which we now describe.

   The rules are modus ponens and temporal generalizations, past and future:

$$
\frac{\alpha, \alpha \rightarrow \beta}{\beta} \qquad \frac{\alpha}{H\alpha} \quad \frac{\alpha}{G\alpha}\ .
$$

   We also allow any substitution instance of any propositional tautology. This can be presented as a rule of inference (called R1 in [124]). Instead we could add all the standard axiom schemas for a complete system for classical propositional logic (see for example, that in [92]) and allow any TL substitution instance of any of them.

   The axioms are all substitution instances of the schemas given in figure 3 and in order to present them at their simplest we have made use of further abbreviations, $W\alpha \equiv \neg Y\neg\alpha$ for "weak yesterday", and $N\alpha \equiv \neg X\neg\alpha$ for "weak tomorrow". So, for example, the first axiom is just $\neg Y\alpha \leftrightarrow \neg Y\neg\neg\alpha$.

   From [124] we have:

   THEOREM 28. $\vdash_{TL}$ *is sound and complete for TL validity.*

   Proof. We give a rough sketch of the completeness proof. This style of proof is appropriate for weak completeness results where we just need to show that a formula which is consistent in the axiom system has a model.

   Suppose we are to find a model of the $\vdash_{TL}$-consistent TL formula ϕ. We will build the model from consistent sets of formulas as in the canonical model construction.

However, the sets will be finite. We specify a particular *closure* set of formulas dependent on ϕ and we make the model from subsets of the closure set. The closure set is usually just the set of subformulas of ϕ and their negations and possibly a few more formulas. In the TL case we also include, for example, $X(\alpha U \beta)$ in the closure set for ϕ iff $\alpha U \beta$ is in the set.

Next we define some of the subsets of the closure set to be *atoms*. The intention is for a set A to be an atom iff there "could" be some model M and some point t in it such that A contains exactly those formulas from the closure set which are true at t in M. The actual definition of an atom is just a set of simple syntactic criteria that rule out sets that could not possibly be satisfied in this sense. For example, we require an atom to include exactly one of α and $\neg\alpha$ for every $\neg\alpha$ in the closure set.

Let W_0 be the set of atoms. To turn W_0 into a graph, we now place a binary relation R_0 on W_0. The intention is for this to represent a successor relation between a time point and the next time. If $(A, B) \in R_0$ then we want it to be possible in some model for a point satisfying A to be followed by a point satisfying B. Again, we actually only use an approximate syntactic test with this aim. For example, if $X\alpha \in A$ then we want $\alpha \in B$.

The construction then proceeds by a series of modifications of (W_0, R_0) to (W_1, R_1), $(W_2, R_2), \ldots$ until we reach a final graph. The modifications are essentially just the removal of parts of W_i to get W_{i+1}. We remove a set of atoms under certain circumstances reflecting the global behaviour of possible models. For example, we look for certain parts of the graph which can not satisfy the eventualities which they contain: for example, an atom contains $\alpha U \beta$ and no R_i-path from here ever reaches an atom containing β.

When this process stabilizes it can be shown that we have ended up with a graph out of which can be read a model for ϕ: we find an infinite path of atoms (some repeated) through the graph. The steps of the process which justify this are themselves justified in terms of the atoms. For the details see [124]. ❑

3. Branching Time

The branching time logic CTL was axiomatized in [42] using a few rather intricate rules to capture inductive reasoning step by step along branches in a tree. The completeness proof is in some ways similar to that for TL above but also follows closely a tableau style decision procedure for CTL.

Axiomatizing CTL* was a much more difficult problem with difficulties raised by its limit closure property whereby any increasing sequence of prefixes of paths is part of one path. There is an axiomatization presented in [163] which uses a special rule motivated by automata-theoretic considerations.

A neater, more traditional axiomatization was shown to be possible in [162, 167] for PCTL*, the expansion of CTL* via past-time temporal operators. Our result is to find a Hilbert system capable of deriving exactly the valid formulas of $\models_P$. We describe that briefly.

There are five rules of inference. These include modus ponens (MP), future temporal generalization (FTG), past temporal generalization (PTG), and branch generalization (BG):

$$MP: \ \frac{\alpha, \alpha \rightarrow \beta}{\beta}\ ; \quad FTG: \ \frac{\alpha}{G\alpha}\ ; \quad PTG: \ \frac{\alpha}{H\alpha}\ ; \quad BG: \ \frac{\alpha}{A\alpha}\ .$$

Finally, there is a special rule, or axiom schema, *atomic non-futurity,* which says that propositional atoms only depend on states and not on fullpaths:
ANF: $p \rightarrow Ap$, for each atomic proposition p.

The axioms include all substitution instances of the following.
TL: the axioms of $\vdash_{TL}$ (including propositional tautologies),
plus a few which say that A acts as an S5 modality:
AK $A(\alpha \rightarrow \beta) \rightarrow (A\alpha \rightarrow A\beta)$
AT $A\alpha \rightarrow \alpha$
AE $E\alpha \rightarrow AE\alpha$
plus two which allow some interaction between modalities:
AX $AX\alpha \rightarrow XA\alpha$
AY[1] $YA\alpha \rightarrow AY\alpha$
and the limit closure axiom from [163]:
LC $AG(E\alpha \rightarrow EX((E\beta)U(E\alpha))) \rightarrow (E\alpha \rightarrow EG((E\beta)U(E\alpha)))$

The completeness proof in [167] is beyond the scope of this chapter but it involves a normal form for TL formulas in which the future time operators are much restricted. That in turn allows us to control the construction of an infinite model by finite sets of formulas from a closure set.

Axiomatic completeness results for many of the variations on logics of historical necessity can be found in [29, 216, 217, 78].

4. Predicate temporal logics are generally so highly undecidable (i.e. not recursively enumerable) that it is impossible to provide for them complete axiom systems [64]. Some rare exceptions include the predicate temporal logic of U and S over linear time [160] and monodic first-order temporal logic [214] which we consider further below.

For some of the temporal logics mentioned above and for many others, there exist alternative axiomatizations using the *Irreflexivity Rule* (IRR) of [60, 29] and variations on this. The IRR allows

$$\frac{q \wedge H(\neg q) \rightarrow \alpha}{\alpha} \text{ provided that the atom } q \text{ does not appear in the formula } \alpha.$$

A short proof shows that this is a valid rule over irreflexive linear frames. It is very useful to have this rule in an axiom system as it allows the construction of something like a canonical model which is irreflexive and in which every point has a unique "name" as the first time at which a particular atom is true. For some of the classes of frames we have seen (including the linear flows) complete axiomatizations can be obtained by using the

[1] A different axiom was mistakenly used in [167].

IRR rule along with the intricate and powerful Sahlqvist persistence theorem [173], [174] which gives us first-order conditions corresponding to validity of temporal formulas in a frame. See [64, chapter 6] for details of this, and of an IRR based axiom system for U and S over the reals.

5.2 Gentzen systems

Hilbert systems are not at all useful for actually carrying out reasoning. The alternative formal reasoning systems proposed by Gentzen in [69] are much better. Gentzen's sequent calculus allows more natural, modular reasoning. A sequent is just a pair consisting of a set of formulas, the premises and a formula which is the conclusion. The calculus allows us to make deductions about the validity of some sequent in terms of the validity of others. The general idea for propositional classical logic is well presented in [92] and [187]. These chapters also describe two popular variants on the sequent calculus, natural deduction and semantic tableaux which we describe below.

Traditional Gentzen style sequent calculi for temporal logics can be found in [145], [183], [114], [203], [108] and [146].

We will not consider sequent calculi in any detail here as the similar tableau systems below are of more interest. Note that for efficient automation, the cut rule is problematic.

5.3 Natural Deduction

Gentzen also introduced the natural deduction calculus for classical logic in [69]. The general idea is that we start at the top with some assumptions, and gradually work down, discharging assumptions as we go until we reach the desired conclusions. The calculus consists of rules of proof and they usually come in pairs governing the introduction or elimination respectively of any given connective. There are close connections to the cut-free sequent calculus and to tableau methods. Proofs can be arranged in a tree shape (Gentzen style) or they can be shaped in a linear way (Jaskowski style) via the use of certain "book-keeping" devices such as boxes and labels. Natural deduction calculi were developed for modal logics by Fitch in [53] with the inclusion of "strict subderivations" representing a jump to another world in a Kripke structure [54].

Indrzejczak [107] contains natural deduction systems for tense logics but a more interesting recent natural deduction calculus for Prior's linear tense logic appears in [109]. This system only uses analytic cut. By having only elimination rules for the temporal operators, by using the structure of labels in the proof to build a model and by generating non-branching proofs, it is able to be used as a decision procedure. There is a natural deduction system for an interval temporal logic in [197].

5.4 Tableaux

Tableaux, which are also closely related to cut-free Gentzen sequent systems [54], are one of the most popular methods for reasoning in modal logics and there has been a substantial amount of work on applying them to temporal logics. They can be presented in an intuitive way, they are often suitable for automated reasoning and it is often not hard to prove complexity results for their use. Tableaux were invented for classical propositional logic in [16] and [89] and they were used for modal logics in [103] and [54].

Standard tableau rules for propositional calculus with connectives just $\neg$ and $\wedge$ are:

$$\frac{\Sigma; \alpha; \neg\alpha}{}, \quad \frac{\Sigma; \neg\neg\alpha}{\Sigma; \alpha}, \quad \frac{\Sigma; \alpha \wedge \beta}{\Sigma; \alpha; \beta}, \quad \frac{\Sigma; \neg(\alpha \wedge \beta)}{\Sigma; \neg\alpha \mid \Sigma; \neg\beta}.$$

The ';' such as in $\Sigma; \alpha \wedge \beta$ represents set union and we omit the braces around singleton sets of formulas. To see whether a formula ϕ is satisfiable, i.e. if $\neg\phi$ is not valid, we use instances of these rules to construct a tree with nodes labelled by sets of formulas (in the language of ϕ). Start with a node labelled by $\{\phi\}$. At any stage there may be a choice of rules to apply. The first rule tells us that we can end a branch and make a leaf node if the label contains a formula and its negation. The second rule says that we can extend a branch by one node if it currently ends with a label $\Sigma \cup \{\neg\neg\alpha\}$ containing a formula $\neg\neg\alpha$ and add a node labelled by $\Sigma \cup \{\alpha\}$. Note that Σ itself may contain $\neg\neg\alpha$ or it may not. The third rule is similar. The fourth rule allows a branch to be formed, a node containing $\neg(\alpha \wedge \beta)$ may have two successor nodes, with the indicated labels.

Certain restrictions on the way we use the rules will guarantee termination of this tableau building process and so we have a decision procedure.

In tableaux for modal logics there are several differences. The labels of nodes can be thought of as representing a set of formulae which we know hold simultaneously in one "possible" world. Some rules can still be used to add propositional consequences and thus tell us more about a particular world. This is called a static rule. However, in the modal setting there are other, transitional rules, which represent movement along the accessibility relation and tell us what is true at a different world. For example, the following rule is appropriate for Prior's F and G over transitive frames:

$$\frac{G\alpha_1, G\alpha_2, \ldots, G\alpha_n, F\beta}{\alpha_1, \alpha_2, \ldots, \alpha_n, G\alpha_1, G\alpha_2, \ldots, G\alpha_n, \beta}$$

Tableau systems are unfortunately not completely straightforward for most temporal logics. The mirror-image past-time modalities and linearity seem to need messy rules. Furthermore, transitivity necessitates rules which can allow indefinite lengths of branches and temporal tableau systems thus often incorporate rules for checking "looping" and specifying that such branches are not closed. There are tableau systems for common propositional temporal logics in [39], [114], [176], [80], [177], [110] as well as the future only case in [79]. The tableau systems for temporal logics in [109] and [129] both have labels on sets of formulas as part of the reasoning process.

An alternative way of managing tableau generation has become popular for the discrete time logics of interest in computing. Instead of arranging the labelled nodes in a tree, a more general graph structure allows repetition of labels to be avoided. This can be more efficient. To use this technique to decide the satisfiability of a formula ϕ say, one must determine from ϕ a finite closure set of formulas of importance to the tableau reasoning. The closure set appropriate for many temporal languages is just the set of subformulas of ϕ and their negations but it may also include a few extra formulas—it depends on the nature of the tableau rules. The tableau initially consists of a graph with one node labelled with each of the maximally propositionally consistent subsets of the closure set. Directed edges (i.e. tableau transitions) are placed between nodes according to syntactic rules which attempt to capture a possible discrete step in time. For example, if $X\alpha$ and $G\beta$ are in the label at one node then a successor node will have to contain both α and β. Depending on exactly the expressiveness of the temporal language, the initial graph

is then subjected to a series of checks to remove unsatisfiable arrangements of nodes. A trivial example is the removal of a node with $X\alpha$ in its label if it has no successor at all. A more complex example is the removal of a node with $F\alpha$ in its label if from it can be found no path of nodes leading to a node labelled with α. For many useful logics, such a process can be defined which eventually terminates with a situation which correctly indicates whether ϕ is satisfiable or not. See [207] and [36] for PLTL, [15] for a fragment of PLTL, [115] for future and past-time operators over natural numbers time, [81] for past-time operators over integers, [42] and [41] for CTL.

For tableaux for first-order temporal logics see [117] and [132]. For intervals see [75]. There are overviews of the use of tableaux for temporal logic in [80] and [40]. See also Chapter 2 in this Handbook.

5.5 Resolution

Resolution for classical logic, predicate and propositional, was first described by Robinson in [170]. The general idea is a complete calculus based on a single rule of inference, the resolution rule, able to be used repeatedly. Formulas need to be in a *clausal form*, which involves rewriting them into conjunctive normal form. We start with a formula, ϕ say, the validity of which is in question, and rewrite $\neg\phi$ as an equivalent formula in the clausal form. Thus $\neg\phi$ is equivalent to the conjunction of a set of clauses, each of which is a disjunction of atomic formulas or their negations. Each application of the resolution rule should add another clause to the set, it being a consequence of two clauses already in the set. If we ever see that the set is inconsistent then we can conclude that $\neg\phi$ is too and so ϕ is valid. The resolution rule allows us to deduce $\alpha \vee \beta$ from $\alpha \vee p$ and $\beta \vee \neg p$ for an atomic formula p.

Resolution for modal logic is discussed in Chapter 4 of this Handbook. Existing methods of temporal resolution are mostly for temporal logics of discrete natural numbers time. The early approach in [34] is for a restricted sublanguage of PLTL without the until operator. There are a whole raft of resolution and transformation rules to be used.

In [1] a complete system for PLTL is presented. It also involves quite a variety of rules, including a "cut" style rule. The system in [202] is a little neater but still involves some initial rewriting followed by a choice of rules and operations to apply.

Perhaps most work has been done on the system first described in [50] and more recently in [52]. The PLTL formula is first translated to an essentially equivalent formula in what is called Separated Normal Form (SNF), which is a clausal form with only a much restricted use of the temporal operators. There are only two resolution rules, the classical one as above and one temporal that at its simplest allows something roughly like $\alpha \rightarrow F\gamma$ to be resolved with $G(\delta \rightarrow \neg\gamma)$ and $G(\delta \rightarrow X\delta)$ to give $\alpha \rightarrow \neg\delta$.

Extensions of these methods to CTL appear in [22], to first order temporal logic in [2] and monodic first-order temporal logic in [37]. Implementations of resolution theorem-provers perform well, even compared to the latest tableau provers [105].

5.6 Automata

Finite state automata are a popular way of carrying out reasoning about temporal logics. We will not give a detailed account here, though, as Chapter 17 in this Handbook is devoted to their use.

Automata have been used to formalize basic notions in computing since the time of Turing but Büchi in [25] was a pioneer of their use with infinite linear structures. Several important temporal reasoning tasks can be translated into tasks requiring manipulation of such automata. For example, a typical test of validity of a temporal formula, may be able to be accomplished by finding an equivalent automaton (to the negation of the formula) and checking to see if that automaton is empty. Here we say that an automaton is equivalent to a formula if the automaton accepts exactly the models of the formula. We say that the automaton is empty if it accepts no structures at all.

The task of finding automata equivalents to temporal formulas (over natural numbers time) is described in [182, 208, 195]. The states of the automaton are basically just nodes of the tableau graph for the formula, its transition relation follows the tableau successor relation and its acceptance criteria capture the need for eventuality formulas (from the closure set) to be fulfilled. Alternative routes for translation proceed via the second order logic $S1S$ (and McNaughton's determinization result [133]) or via the alternating automata of [139] and then on to a Büchi automaton.

The task of determining emptiness of an automaton is described in [45] and [195].

By putting together these results in the right way, a PSPACE decision procedure for PLTL validity can be obtained [195].

Automata are much used to reason about temporal logics on discrete trees—see for example, the Rabin tree automata used in [46, 194, 44] with CTL* but, of course, they are not suited to use with dense time structures unless special discreteness restrictions are imposed on the behaviour of atoms [8], [154].

5.7 Translation into first-order logic

We have seen, in Section 4.1 above, that we can easily translate formulas from many temporal logics into equivalent first-order formulas, via the so-called *standard translation.* If a propositional temporal logic has only connectives with first-order tables then we can do this. Say that temporal formula α using atoms $p_1, \ldots, p_n$ translates to first-order formula $\phi(t)$ with free variables t and predicate symbols $P_1, \ldots, P_n$. The validity of the temporal formula over a class of flows of time is thus equivalent to the validity of $\phi(t)$ over all structures with a frame $(T, <)$ from that class of flows of time and any interpretation for the P_i. That is, we want to assess the validity of $\forall P_1 \ldots \forall P_n \forall x \phi$, a formula from the universal monadic second-order logic over that class of frames.

One straightforward way to decide such a validity question is to use a first-order theorem-prover such as, amongst several other widely-used systems, Otter [111]. Using such a theorem-prover will of course require some syntactic formalization of the class of frames in question and this may or may not be possible. For example, we can axiomatize linearity in order to capture the class of all linear orders. The general validity question here, for first-order formulas, is undecidable but modern theorem-provers are impressively fast in obtaining results for many interesting theorems and non-theorems.

More conclusive decidability results have been obtained for many of the common temporal logics because the universal monadic second-order logic, or even the full monadic second-order logic, over the class of frames in question is itself decidable. There are many such results and we just list a few. Some more details can be found in [58] and [64, chapter 15].

Monadic second-order logic over $(\mathbb{N}, <)$ is known to be decidable [25]: there is an

algorithm to tell whether any given monadic second-order sentence is true on $(\mathbb{N}, <)$ or not. Gurevich [83, 33] showed the same for the universal monadic second-order theory of the class of all linear flows of time and of $(\mathbb{R}, <)$. From these results decidability of any usual temporal logic over those classes follows, where by a usual temporal logic we mean one in which the temporal operators all have first-order tables. The complexity of this decision problem is non-elementary (see, e.g., [153]), but since monadic second-order logic is so expressive, it is useful for proving bare decidability of other logics, by coding them into it.

Over the tree $({}^{<\omega}2, <)$, we sometimes beef up the expressive power by adding two unary function symbols l, r to define the left and right successors of each time point. Regarding ${}^{<\omega}2$ as the set of finite sequences of 0s and 1s, we let $l(s) = s0$ and $r(s) = s1$ for each $s \in {}^{<\omega}2$. The ordering $<$ is definable from l, r alone in monadic second-order logic, since

$$({}^{<\omega}2, <, l, r) \models \forall xy\big(x \leq y \leftrightarrow \forall X[\forall z[X(l(z)) \vee X(r(z)) \to X(z)] \wedge X(y) \to X(x)]\big).$$

So it suffices to work in $({}^{<\omega}2, l, r)$. Monadic second-order logic over this structure is known to be decidable by a theorem of Rabin [152]. It is extremely expressive, and a wide range of other logics can be shown decidable by coding them into it. For example, monadic second-order logic over $(\mathbb{Q}, <)$ can be shown decidable in this way, as can the monadic second-order theory of the class of all countable ω-trees. Decidability of temporal logics over trees was also shown [85] by a translation to a full monadic second-order logic of trees, but one in which the set quantifiers range only over branches of the tree.

Sometimes monadic second-order logic is too strong (for some purposes). For example, it was proved by Shelah in [181] that monadic second-order logic over $(\mathbb{R}, <)$ is undecidable. Shelah's use of the continuum hypothesis in this proof was later eliminated with Gurevich [84]. It follows quite easily that any class of flows of time containing one in which $(\mathbb{R}, <)$ is embeddable has undecidable full monadic second-order theory. So, for example, the monadic second-order theory of the class of all linear flows is undecidable.

5.8 Filtration and the finite model property

Filtration and variants of the finite model property are ideas which can be used together to give theoretical decidability or complexity results but they are not commonly used for practical reasoning.

Filtration is a technique used for, amongst other things, finding a second model of a formula given one model. The second model can often be made to be much smaller and, in particular, of finite size. Filtration is a traditional technique to use with modal logics tracing its origins to the work of Kripke, Lemmon and Segerberg [179]. Its importance for us here is that it can be used to show that if a formula in a temporal language has a model then it has a finite model. If all the formulas of a language have this property then we say that the language has the *finite model property* or *fmp*. As we will see below, the fact of the fmp, or closely related properties, can often be used to give a decision procedure for the logic.

Establishing the fmp is most natural with some non-temporal modal logics. With temporal logics, because of the requirement of irreflexivity, it is often the case that structures have to be infinite in size. Even if some formulas of a particular temporal logic can have finite models, such as with Prior's temporal language over the class of

all linear flows of time, it is often very easy to find a satisfiable formula which only has infinite models, such as say $Fp \wedge G(p \to Fp)$.

Luckily, we can step back from a direct use of the fmp here. Temporal languages can be given alternative semantics on other classes of Kripke structures. For example, Prior's propositional temporal language with F and P over linear flows of time, which we call CL for now, was, in Section 3.4 above, given semantics over any transitive irreflexive structure $(T, <, h)$ and the same clauses even give the formulas semantics on any Kripke structure $(T, <, h)$.

Ono and Nakamura [143] use filtrations and the fmp to assess the complexity of (deciding validity in) CL. Call a Kripke structure $(T, <, h)$ a CL-model of a formula α iff the structure is transitive and totally ordered (i.e. that for every x and y in T, either $x < y$, $y < x$ or $x = y$) and it contains some $t \in T$ such that $(T, <, h), t \models \alpha$. Such a structure generally contains clusters of points, each pair of which are related by $<$, i.e. $(T, <)$ is not generally anti-symmetric and so not a linear order. The main theorem is that a formula α with n temporal operators is satisfiable in an (anti-symmetric) linear model iff it is satisfiable in a finite CL-model containing at most $n + 1$ points.

It had been long established that formulas of Prior's language have linear models iff they have CL-models so the two main new steps in [143] are that if a formula with n operators has a CL-model then it has a finite CL-model and, furthermore, it has a model of size $n + 1$. The first step is via a filtration argument, the second, a clever pruning of a finite model down to a bare minimum of size which still preserves truth of the formula.

As an illustration of filtration let us assume that formula α has a CL-model $(T, <, h)$ and we will sketch how to find a finite model. Suppose $(T, <, h), t_0 \models \alpha$. Now define a binary relation $\sim$ on T by $s \sim t$ iff for all subformulas β of α, we have $(T, <, h), s \models \beta$ iff $(T, <, h), t \models \beta$. This is clearly an equivalence relation so we can define $M = T/\!\sim$ which will be a finite set. Now define an accessibility relation R on M by:

$[s]R[t]$ iff for all subformulas $F\beta$ of α, if $(T, <, h), s \models \neg F\beta$
then $(T, <, h), t \models \neg F\beta$
and $(T, <, h), t \models \neg\beta$; and
for all subformulas $P\beta$ of α, if $(T, <, h), t \models \neg P\beta$
then $(T, <, h), s \models \neg P\beta$
and $(T, <, h), s \models \neg\beta$.

It is not hard to show that R is well-defined, transitive and total. Finally we define a valuation g on (M, R) by $[s] \in g(p)$ iff p is a subformula of α and $s \in h(p)$. This is clearly well-defined. The CL-structure (M, R, g) is called a *filtration* of $(T, <, h)$. Now, a straightforward induction on the construction of β allows us to conclude that $(T, <, h), s \models \beta$ iff $(M, R, g), [s] \models \beta$. Thus we have a finite model of α as required.

We have just established the finite model property for the CL logic. As mentioned, [143] goes further and establish a *bounded model property* by giving an upper bound (in terms of the construction of the formula) on the minimum size of a finite model of the formula.

The finite model property can give us decidability of the logic. If we have an effective proof system, such as a Hilbert-style axiomatization for the logic then there is a way of listing systematically the valid formulas in the logic. If we also have the fmp and an effective way of determining whether finite structures are models of the logic, then we can also systematically consider all the finite structures and eventually list all the satisfiable formulas. Running the two algorithms in parallel thus allows us to eventually

find whether a given formula is valid or whether its negation is satisfiable.

The bounded model property gives a decision procedure itself, with no need of an axiom system, provided there is an effective way of recognizing finite models of the logic. Further, it gives us a complexity measure on a decision procedure. For example, suppose that we want to decide whether α of Prior's language is satisfiable over a linear flow of time. The results of [143] allow us to propose a non-deterministic algorithm in which a CL-model of α is guessed and checked in polynomial time. We can thus conclude that the complexity of satisfiability for CL is NP-complete.

Sistla and Clarke in [184] use another variation of filtrations and finite model properties to prove a PSPACE complexity result for PLTL. The presence of the "Until" operator makes the use of the techniques more intricate but we still identify points in a structure which agree on all the subformulas of the formula to decide. The main result establishes that every satisfiable formula will be satisfied in an ultimately periodic structure with bounds on its period and on the length of the non-periodic prefix. See Chapter 17 for details.

5.9 Other modal methods

We have only a little space to mention a powerful series of results by Wolter [209, 212, 211, 210, 213], extending to temporal logic deep work of Chagrov, Fine, Zakharyaschev, and others about modal logics above K4. The results offer the potential to extend modal reasoning (and other) methods to temporal logics with the Priorean F and P in a uniform and systematic way.

In [213], Wolter remarks that unlike in modal logic, the focus of work in temporal logic has been on specific systems such as the theory of $(\mathbb{N}, <)$, $(\mathbb{Z}, <)$, or $(\mathbb{R}, <)$. This is inappropriate for building a mathematical theory of the entirety of temporal logics, where "we are usually not interested in the properties of a specific system but in results which show why a specific system has a property by extracting concepts which allow to map out the boundaries of that property." Wolter investigates the preservation of properties (such as Kripke completeness, finite model property, decidability, finite axiomatizability, and canonicity) when we 'temporalize' a modal logic by adding a converse diamond (in the same sense that P is the converse of F). The frequent failure of the finite model property in temporal logics is the chief obstacle to such transfers, even when the corresponding modal logic does have the fmp. In fact, [209] proves that the temporalization of a modal logic $\Lambda \supseteq$ K4 whose frames are closed under taking cofinal subframes has the fmp precisely when the class of frames for Λ is elementary. [213] shows that the temporalization is decidable if Λ is finitely axiomatizable, and gives further results on transfer of fmp, Kripke completeness, and decidability, though a full characterization of when decidability transfers is left open. One of the main methods used is a replacement for the fmp. It involves replacing points of a finite frame by 'blocks', which in simple cases can be irreflexive points, copies of $(\mathbb{N}, >)$, and so on, but can also be general frames. Related lattice and algebraic results (for example, on canonicity) are presented in [212, 211].

5.10 Mosaics

Mosaics were used to prove decidability of certain theories of cylindric relativized set algebras in [140, 141] and have been used since quite generally in algebraic logic and

modal logic. Mosaics are small potential pieces of a model: in the temporal logic case, a small piece of a temporal structure. The main idea is to show that the existence of a model of a given formula is equivalent to the existence of a finite set of these small pieces, satisfying certain coherency conditions. The set of mosaics should also satisfy certain saturation conditions. This gives us a decision procedure, and, intuitively, a systematic procedure to check the theoremhood of a certain formula. It is possible to view some older approaches such as in [66] and [30] as specialisations of mosaics. However, recently the mosaic method has been applied to prove new decidability, Hilbert-style axiomatizability and complexity results for various modal and temporal logics: see, e.g., [90], [135], [161], [201], [129] and [166].

In [129], temporal mosaics are described which are appropriate for reasoning with Prior's logic with F and P over linear flows of time. To give a flavour of the mosaic method we present some of the details here.

Mosaics, for a particular purpose, are defined with respect to a fixed closure set of formulas, say X, which is closed under taking subformulas and such that if $\alpha \in X$ then either so is $\neg\alpha$ or $\alpha = \neg\beta$ and $\beta \in X$. Let X be such a closure set in the propositional temporal language with F and P (and $\neg$ and $\wedge$) and some countable set of atoms.

First the definition of a mosaic, via the coherency conditions:

DEFINITION 29. A mosaic is a pair (A, B) of subsets of X such that:

1 A and B are maximally propositionally consistent;

2 $G\alpha \in A$ implies α and $G\alpha$ in B;

3 similarly for $H\alpha \in B$.

Next, the so called saturation conditions on the whole set of mosaics:

DEFINITION 30. A set M of mosaics is a saturated set of mosaics (SSM) iff:

1 if $(A, B) \in M$ and $F\alpha \in B$ then there is a mosaic $(A', B') \in M$ such that $B = A'$ and $\alpha \in B'$;

2 if $(A, B) \in M$ and $F\alpha \in A$ then either $\alpha \in B$ or $F\alpha \in B$ or there are mosaics (A', B') and (A'', B'') in M such that $A = A'$, $\alpha \in B' = A''$ and $B'' = B$;

3 and 4 similarly for $P\alpha$.

The main lemma shows that satisfiability of a set Γ of formulas is equivalent to (either there being a one point model of Γ or) there being a saturated set of mosaics M containing one mosaic (A, B) with $\Gamma \subseteq A$ or $\Gamma \subseteq B$. The mosaics from an SSM can be re-used and glued together in a very intuitive manner to build a model.

From this main lemma follows a completeness proof for a Hilbert-style axiomatization (using the set of all formulas as X), a completeness result for a tableau system, and (using a finite set X) decidability and complexity results. The decision procedure is simply a systematic cropping of the set of all mosaics (for that X) down to a saturated set.

In [166], which contains the first detailed suggestions on how mosaics might be used for reasoning with dense time temporal logics, this general approach is used to determine the complexity of deciding validity of formulas of the temporal logic with "Until" (but not "Since") over the class of all linear flows of time. The mosaics and their coherency and saturation conditions are a little different but they still correspond to pieces of a model defined by two points in time. Here, finding an SSM is shown to be equivalent to the existence of a winning strategy for one player in a two-player game played with mosaics. The search for a winning strategy can be arranged into a search through a tree

of mosaics which we can proceed through in a depth-first manner. By establishing limits on the depth of the tree (a polynomial in terms of the length of the formula) and on the branching factor (exponential) we can ensure that we have a PSPACE algorithm as we only need to remember a small fixed amount of information about all the previous siblings of a given node.

The idea is again used in [168] to give a PSPACE complexity result for deciding valid formulas in the propositional temporal language with strict U and S over real-numbers flows.

5.11 Monodic fragments of first-order temporal logic

To end our survey, we look again very briefly at *first-order temporal logic.* The development of this subject has been slower than for propositional temporal logic, possibly in part because of the poor computational behaviour of first-order temporal logic. Unpublished results of Lindström and Scott in the 1960s showed that even very weak fragments of it can be (sometimes highly) undecidable. More results like this have been proved over the years. In [100, theorems 2, 73], for example, the two-variable monadic fragment and the two-variable guarded fragment of first-order temporal logic were shown to be non-recursively enumerable over $(\mathbb{N}, <)$ and $(\mathbb{Z}, <)$, by encoding a recurrent tiling problem. The first-order temporal logic with U and S can be axiomatised over linear time [160], but this is one of few positive results. The 'reason' for the high complexity is the product-like structure of models of first-order temporal logic. They combine a flow of time with a first-order structure, and the interaction between the two leads to very high expressive power.

Recently, however, some interesting *decidable fragments* of first-order temporal logic have come to light. One way to obtain such fragments is by limiting the interaction in the logic between time and the first-order structure. Lemma 22 gives us a clue how to do it. There, we saw that the standard translations of (one-dimensional) temporal formulas satisfied the restriction that any subformula $\exists x\varphi$, for a domain variable x, had at most one free time variable. This reflected the fact that temporal formulas are evaluated at a single time point. If we aim for a similar restriction on quantified temporal variables as well, we are on the way to obtaining decidable fragments — the so-called *monodic fragments* of [100].

DEFINITION 31. A formula α of first-order temporal logic is said to be *monodic* if every subformula of α beginning with a temporal connective has at most one free variable.

The Barcan formula, $\forall x G\varphi(x) \leftrightarrow G\forall x\varphi(x)$, gives an example of a monodic formula. Here, G applies to $\varphi(x)$ (one free variable) and to $\forall x\varphi(x)$ (no free variables). If φ is monodic then the above Barcan formula will be too. Another example, of Chomicki and Toman from databases, is to 'list all persons who have been unemployed between jobs':

$$P\exists y\ \mathit{WorksFor}(x, y) \wedge \neg\exists y\ \mathit{WorksFor}(x, y) \wedge F\exists y\ \mathit{WorksFor}(x, y).$$

A non-example is the sentence $\forall xy((R(x, y) \rightarrow GR(x, y)) \wedge (\neg R(x, y) \rightarrow G\neg R(x, y)))$ expressing rigidity of a binary relation. Here, the G applies to formulas with two free variables. So the sentence is not monodic.

The full monodic fragment is in general *undecidable,* since it contains first-order logic. So we need to make further restrictions to obtain decidable fragments. Some restrictions that have been found to work for many linear flows of time are:

1. The signature must have at most only relation symbols and constants (no function symbols).

2. The 'first-order part' of the formulas must come from a decidable fragment of first-order logic. Examples include the monadic fragment (i.e., the signature can have only unary relation symbols), the two-variable fragment, and the various guarded fragments.

3. Equality (=) must not occur [38], although this restriction is not necessary if we choose guarded fragments in (2) [96].

We can now obtain several decidable fragments of first-order temporal logic, depending on what fragment of first-order logic we pick in (2). For example, we could select the monodic monadic fragment, the monodic guarded fragment, etc. Which we choose may depend on what application we have in mind for our logic. A formula of one of these fragments can describe the evolution over time of only one domain object. But at any one time, the full power of the chosen fragment of first-order logic is available.

Under the above restrictions, it was shown in [100] that satisfiability of monodic formulas may be determined by combining an algorithm to decide the fragment chosen in (2) with a second algorithm to decide *monadic second-order logic* over the ambient flow of time. This procedure can be made to work whenever the flow of time is linear and its monadic second-order theory is decidable. This is true for many common flows of time, such as $(\mathbb{N}, <)$, $(\mathbb{Z}, <)$, and $(\mathbb{Q}, <)$: see Section 3.2.

The key idea in the proofs is the *quasimodel.* A quasimodel is essentially the result of filtrating a temporal structure over its first-order domain; the flow of time is left untouched. (See Section 5.8 and Chapter 1 for filtration.) Roughly, a quasimodel for a given monodic sentence φ written with the connectives U and S, say, contains the following ingredients:

1. A *type* is a description of a single domain point, in terms of which subformulas ψ of φ with one free variable are true at it. So a type is a subset of the set of subformulas of φ with one free variable together with their negations.

   The quasimodel contains, for each time t, a set Σ_t of types. It is required that Σ_t be the set of types of the elements of some first-order structure. For this purpose, maximal subformulas of ψ of the form $U(\alpha, \beta)$ and $S(\alpha, \beta)$ are regarded as atomic. In this way, only the *first-order part* of the description is kept.

2. The types in Σ_t are there to describe the domain elements at time t. To recover some information about the types of a single domain element over time, the quasimodel also contains a set of what are called *runs.* A run ρ is simply a choice of type $\rho(t) \in \Sigma_t$ at each time t, subject to the coherence conditions

   - for any subformula of φ of the form $U(\alpha, \beta)$, *which by monodicity has at most one free variable,* and for any time t, we have $U(\alpha, \beta) \in \rho(t)$ iff there is a time $u > t$ with $\alpha \in \rho(u)$ and $\beta \in \rho(v)$ for all times v strictly between t and u,
   - a mirror-image condition for S.

   The quasimodel must have *enough runs.* Formally for each t, each type in Σ_t must be the value at t of some run in the quasimodel.

It turns out that a monodic sentence has a genuine model iff it has a quasimodel, and that the existence of a quasimodel can be expressed in monadic second-order logic and hence is frequently decidable.

THEOREM 32 ([100, 96]). *Let $(T, <)$ be a flow of time with decidable monadic second-order theory (examples include $(\mathbb{N}, <)$, $(\mathbb{Z}, <)$, and $(\mathbb{Q}, <)$). Then for any of the following sets of sentences, the problem of whether a sentence from the set has a model with flow of time $(T, <)$ is decidable:*

1. *the monodic sentences with only unary relation symbols and no equality,*
2. *the monodic sentences involving at most two variables and no equality,*
3. *the monodic sentences with 'first-order part' in the guarded, loosely guarded, packed, or clique-guarded fragment of first-order logic (see Chapter 5 and [100] for precise definitions).*

We can easily generalise this to any first-order-definable class $\mathcal{C}$ of linear flows of time. This covers the class of all linear flows, the class of discrete linear flows, the class of dense linear flows, etc.

The case of $(\mathbb{R}, <)$ is special and interesting. The monadic second-order theory of $(\mathbb{R}, <)$ is undecidable, so the method described above does not work directly. As yet, it is not known whether monodic fragments are decidable over this flow. However, monodic fragments can be shown decidable over $(\mathbb{R}, <)$ if we restrict to *temporal structures with finite first-order domains* [100]. This is an interesting case in its own right (in databases, for example), and it yields, by reduction, decidability for finite domains over $(\mathbb{N}, <)$, $(\mathbb{Z}, <)$ $(\mathbb{Q}, <)$, linear flows, finite linear flows, and so on.

The complexity of these decision procedures is non-elementary, but in fact the satisfiability problem for monodic fragments can be shown to be typically the maximum of EXPSPACE and the complexity of the underlying first-order fragment — see [98] and [97], the second of which extends the mosaic methods in [168] to first-order temporal logic. Over $(\mathbb{N}, <)$, the full unrestricted monodic fragment has been axiomatised [214], and tableau and resolution decision procedures have been developed [117, 37, 116].

For *branching time,* we may want to use the logic CTL*, with temporal connectives Until and the path quantifier A (see Section 3.7). However, there are serious problems with this. Over ω-trees (trees with all branches isomorphic to $(\mathbb{N}, <)$: see Section 2.1), and even replacing Until by the weaker $F_{\leq}$ of Section 3.4, the one-variable fragment of CTL* is undecidable [102]; this is certainly monodic and its first-order part is decidable. Decidable fragments of CTL* can be found by requiring monodicity and that the first-order part of sentences comes from a decidable fragment of first-order logic, as above, but additionally, either that any subformula beginning with a temporal connective other than 'tomorrow' must be a sentence [102], or alternatively that first-order quantification is only applied to state formulas [14]. Some applications of monodic fragments are discussed in [101].

6 CONCLUSION

We have tasted a wide range of topics from half a century of development of temporal logic. The reader will now hopefully appreciate that temporal logics come in many forms

and that motivations from computing or linguistic applications and philosophical, theoretical or mathematical interests have driven temporal logic research in many disparate directions.

We must admit that owing to space limitations, we have not done justice to some topics (consider interval based temporal logics for example), and other topics have not even been mentioned — the reader may like to follow up on temporal bisimulations in [118] for example.

Other general references and surveys of the whole field, some of historical interest, include [21, 39, 51, 64, 67, 72, 126, 127, 142, 156, 185, 193, 192, 200].

The reader may also begin to appreciate that this is an active area of research and that there is still much to do. Particular directions of current interest include combinations of temporal and other modal logics, and the search for practical logics (or fragments of logics) which are amenable to affordable and usable reasoning techniques.

ACKNOWLEDGEMENTS

Much of the second author's work on this chapter was undertaken while he was employed by Murdoch University, Western Australia. Both the authors wish to thank V. Goranko and J. van Benthem for careful reading of the chapter and numerous insightful suggestions for improvement.

1 INTRODUCTION

Modal mu-calculus is a logic used extensively in certain areas of computer science, but also of considerable intrinsic mathematical and logical interest. Its defining feature is the addition of inductive definitions to modal logic; thereby it achieves a great increase in expressive power, and an equally great increase in difficulty of understanding. It includes many of the logics used in systems verification, and is quite straightforward to evaluate. It also provides one of the strongest examples of the connections between modal and temporal logics, automata theory and the theory of games.

In this chapter, we survey a range of the questions and results about the modal mu-calculus and related logics. For the most part, we remain at survey level, giving only outlines of proofs; but in places, determined partly by our own interests and partly by our sense of which problems have been — or had been — the longest-standing thorns in the side of the mu-calculus community, we go into more detail.

We start with an account of the historical context leading to the introduction of the modal mu-calculus. Then we define the logic formally, describe some approaches to gaining an intuitive understanding of formulae, and establish the main theorem about the semantics. Following that, we discuss how the modal mu-calculus has the tree model property and relates to some other temporal logics, to automata and to games. Next, an account of decidability is given — this is one of the thorns, at least for those who find automata prickly. We then consider briefly completeness, bisimulation invariance and then the concept of fixpoint alternation, which plays a part in several interesting questions about the logic. Finally, we look at some generalizations of the logic.

Before proceeding to the content of the chapter, we take this opportunity to thank Yde Venema and Johan van Benthem for extensive and helpful comments on drafts of this chapter.

Notation: $L\mu$ means the modal mu-calculus, considered as a logical language (not as a theory). In general, the notation follows as much as possible the standards for this book, but because $L\mu$ is mostly studied in a setting with rather different traditions, and because we also need to notate several other concepts, we have made some compromises. Few of these should cause any difficulty, but let us note the following. Since $\rightarrow$ is often used to represent the transition relation in models (alias the accessibility relation from modal logic), we use $\Rightarrow$ rather than $\rightarrow$ for boolean implication. Structures, frames and models for $L\mu$ are usually viewed as transition systems, and so are usually called $\mathfrak{T}$ with state space $\mathfrak{S}$. States within systems (i.e. worlds in the language of modal logic) are typically s, t, whereas p, q, r are states in an automaton. Hence we write atomic propositions with capital $P, Q, \ldots$ rather than $p, q, \ldots$, and similarly variables ranging over sets of states are written X, Y.

2 CONTEXTUAL BACKGROUND

The modal mu-calculus comes not from the philosophical tradition of modal logic, but from the application of modal and temporal logics to program verification. In this section, we outline the historical context for $L\mu$.

2.1 Modal logics in program verification

The application of modal and temporal logics to programs is part of a line of program verification going back to the 1960s and program schemes and Floyd–Hoare logic. Originally the emphasis was on *proof*: Floyd–Hoare logic allows one to make assertions about programs, and there is a proof system to verify these assertions. This line of work has, of course, continued and flourished, and today there are highly sophisticated theories for proving properties of programs, with equally sophisticated machine support for these theories. However, the use of proof systems has some disadvantages, and one hankers after a more purely algorithmic approach to simple problems. One technique was pioneered by Manna and Pnueli [48], who turned program properties into questions of satisfiability or validity in first order logic, which can then be attacked by means that are not just proof-theoretic; this idea was later applied by them to linear temporal logics.

During the 1970s, the theory of program correctness was extended by investigating more powerful logics, and studying them in a manner more similar to the traditions of mathematical logic. A family of logics which received much attention was that of dynamic logics, which can be seen as extending the ideas of Hoare logic [57]. Dynamic logics are modal logics, where the different modalities correspond to the execution of different programs — the formula $\langle\alpha\rangle\phi$ is read as 'it is possible for α to execute and result in a state satisfying ϕ'. The programs may be of any type of interest; the variety of dynamic logic most often referred to is a propositional language in which the programs are built from atomic programs by regular expression constructors; henceforth, Propositional Dynamic Logic, PDL, refers to this logic. PDL is interpreted with respect to a model on a Kripke structure, formalizing the notion of the global state in which programs execute and which they change — each point in the structure corresponds to a possible state, and programs determine a relation between states giving the changes effected by the programs.

Once one has the idea of a modal logic defined on a Kripke structure, it becomes quite natural to think of the finite case and write programs which just check whether a formula is satisfied. This idea was developed in the early 80s by Clarke, Emerson, Sistla and others. They worked with a logic that has much simpler modalities than PDL — in fact, it has just a single 'next state' modality — but which has built-in temporal connectives such as 'until'. This logic is CTL, and it and its extensions remain some of the most popular logics for expressing properties of systems.

Meanwhile, the theory of process calculi was being developed in the late 70s, most notably by Milner [50]. An essential component was the use of labelled Kripke structures ('labelled transition systems') as a raw model of concurrent behaviour. An important difference between the use of Kripke structures here and their use in program correctness was that the states are the behaviour expressions themselves, which model concurrent systems, and the labels on the accessibility relation (the transitions) are simple actions (and not programs). The criterion for behavioural equivalence of process expressions was defined in terms of observational equivalence (and later in terms of bisimulation relations). Hennessy and Milner introduced a primitive modal logic in which the modalities refer to actions: $\langle a\rangle\phi$ 'it is possible to do an a action and then have ϕ be true', and its dual $[a]\phi$ 'ϕ holds after every a action'. Together with the usual boolean connectives, this gives Hennessy–Milner logic [31], HML, which was introduced as an alternative exposition of observational equivalence. However, as a logic HML is obviously inadequate to express many properties, as it has no means of saying 'always in the future' or other temporal connectives — except by allowing infinitary conjunction. Using an infinitary

logic is undesirable both for the obvious reason that infinite formulae are not amenable to automatic processing, and because infinitary logic gives much more expressive power than is needed to express temporal properties.

In 1983, Dexter Kozen published a study of a logic that combined simple modalities, as in HML, with fixpoint operators to provide a form of recursion. This logic, the modal mu-calculus, has become probably the most studied of all temporal logics of programs. It has a simple syntax, an easily given semantics, and yet the fixpoint operators provide immense power. Most other temporal logics, such as the CTL family, can be seen as fragments of $L\mu$. Moreover, this logic lends itself to transparent model-checking algorithms.

Another 'root' to understanding modal logics is the work in the 60s on automata over infinite words and trees by Büchi [13] and Rabin [60]. The motivation was decision questions of monadic second-order logics. Büchi introduced automata as a normal form for such formulae. This work founded new connections to logic and automata theory. Later it was realised that modal logics are merely sublogics of appropriate monadic second-order logic, and that the automata normal forms provide a very powerful framework within which to study properties of modal logic. Moreover, automata theoretic algorithms often provide very efficient ways to solve problems (such as model-checking) in modal logic – see Chapter 17 of this Handbook. A further development was the use of games by Gurevich and Harrington [30] as an alternative to automata.

There is also an older game-theoretic tradition due to Ehrenfeucht and Fraïssé, for understanding the expressive power of logics. These techniques are also applicable within process calculi. For instance bisimulation equivalence can be naturally rendered as such a game, and expressivity of modal logics can be understood using game-theoretic techniques.

2.2 Precursors to modal mu-calculus

HML, Hennessy–Milner Logic [31], is a primitive modal logic of action. The syntax of HML has, in addition to the boolean operators, a modality $\langle a \rangle \phi$, where a is a process *action*. A structure for the logic is just a labelled transition system. Atomic formulas of the logic are the constants $\top$ and $\bot$. The meaning of $\langle a \rangle \phi$ is 'it is possible to do an a-action to a state where ϕ holds'. The formal semantics is given in the obvious way by inductively defining when a state of a transition system, or a state of a process, has a property; for example, $s \models \langle a \rangle \phi$ iff $\exists t. s \xrightarrow{a} t \wedge t \models \phi$. We may also add some notion of variable or atomic proposition to the logic, in which case we provide a valuation which maps a variable to the set of states at which it holds. The expressive power of HML in this form is quite weak: obviously a given HML formula can only make statements about a given finite number of steps into the future. HML was introduced not so much as a language to express properties, but rather as an aid to understanding process equivalence: two (image-finite) processes are equivalent iff they satisfy exactly the same HML formulae. To obtain the expressivity desired in practice, we need stronger logics.

The logic PDL, Propositional Dynamic Logic [57, 25], as mentioned above, is both a development of Floyd–Hoare style logics, and a development of modal logics. Recently, it has been used as a basis for description logics and logics of information. PDL is an extension of HML in the circumstance that the action set has some structure. There is room for variation in the meaning of action, but in the standard logic, a program is considered to have a number of *atomic actions*, which in process algebraic terms are just

process actions, and α is allowed to be a regular expression over the atomic actions: a, $\alpha;\beta$, $\alpha\cup\beta$, or α^*. We may consider atomic actions to be uninterpreted atoms; but in the development from Floyd–Hoare logics, one would see the atomic actions as, for example, assignment statements in a **while** program.

PDL enriches the labels in the modalities of HML. An alternative extension of HML is to include further modalities. The branching time logic CTL, Computation Tree Logic [14], can be described in this way as an extension of HML, with some extra 'temporal' operators which permit expression of liveness and safety properties. For the semantics we need to consider 'runs' of a system. A run from an initial state or process s_0 is a sequence $s_0 \xrightarrow{a_1} s_1 \xrightarrow{a_2} \ldots$ which may have finite or infinite length; if it has finite length then its final process is a 'sink' process which has no transitions. A run $s_0 \xrightarrow{a_1} s_1 \xrightarrow{a_2} \ldots$ has the property $\phi\,\mathbf{U}\,\psi$, 'ϕ until ψ', if there is an $i \geq 0$ such that $s_i \models \psi$ and for all $j : 0 \leq j < i$, $s_j \models \phi$.

$$\begin{array}{ccccccccc} s_0 & \xrightarrow{a_1} & s_1 & \xrightarrow{a_2} & \ldots & s_i & \xrightarrow{a_{i+1}} & \ldots \\ \models & & \models & & \ldots & \models & & \\ \phi & & \phi & & & \psi & & \end{array}$$

The formula $\mathbf{F}\phi = (\top\,\mathbf{U}\,\phi)$ means 'ϕ eventually holds' and $\mathbf{G}\phi = \neg(\top\,\mathbf{U}\,\neg\phi)$: '$\phi$ always holds'. For each 'temporal' operator such as $\mathbf{U}$ there are two modal variants, a strong variant ranging over all runs of a process and a weak variant ranging over some run of a process. We preface a strong version with $\forall$ and a weak version with $\exists$. If HML is extended with the two kinds of until operator the resulting logic is a slight but inessential variant of CTL (CTL does not in its standard form mention action labels in modalities). The formal semantics is given by inductively defining when a state (process) has a property. For instance $s \models \forall[\phi\,\mathbf{U}\,\psi]$ iff every run of s has the property $\phi\,\mathbf{U}\,\psi$.

CTL has variants and enrichments such as CTL* [24] and ECTL* [70]. These allow free mixing of path operators and quantifiers: for example, the CTL* formula $\forall[P\,\mathbf{U}\,\exists\mathbf{F}Q]$ is also a CTL formula, but $\forall[P\,\mathbf{U}\,\mathbf{F}Q]$ is not, because the $\mathbf{F}$ is not immediately governed by a quantifier. Hence extensions also cover the traditional temporal logics described in Chapter 11 of this Handbook — that is, literally logics of time — as advocated by Manna and Pnueli and others. In this view, time is a linear sequence of instants, corresponding to the states of just one execution path through the program. One can define a logic on paths which has operators $\bigcirc\phi$ 'in the next instant (on this path) ϕ is true', and $\phi\,\mathbf{U}\,\psi$ 'ϕ holds until ψ holds (on this path)'; and then a system satisfies a formula if all execution paths satisfy the formula — in CTL* terms, the specification is a path formula with a single outermost universal quantifier. One can also extend PDL with temporal operators, as in process logic.

There are extensions of all these logics to cover issues such as time and probability. The introduction of such real-valued quantities poses a number of problems, and such logics are still under active development.

2.3 The small model property

A general result about many modal logics is that they have the small model property; that is if a formula is satisfiable, then it is satisfiable by a model of some bounded size. Provided that model-checking is decidable, which is the case for almost all temporal

logics, this immediately gives decidability of satisfiability for the logic, as one need simply check every transition system up to the size bound.

The technique used to establish the small model property for PDL (and therefore HML) is a classical technique in modal logic, that of *filtration*. Let s be a state, satisfying property ϕ, in a possibly infinite transition system $\mathfrak{T}$. Let Γ be the set of all subformulas of ϕ and their negations: in the case of PDL one also counts $\langle\alpha\rangle\psi$ and $\langle\beta\rangle\psi$ as subformulas of $\langle\alpha \cup \beta\rangle\psi$, $\langle\beta\rangle\psi$ as a subformula of $\langle\alpha;\beta\rangle\psi$ and $\langle\alpha;\alpha^*\rangle\psi$, and $\langle\alpha\rangle\psi$ as subformulas of $\langle\alpha^*\rangle\psi$. The size of Γ is proportional to $|\phi|$ (the length of ϕ). One then filters $\mathfrak{T}$ through Γ by defining an equivalence relation on the states of $\mathfrak{T}$, $s \equiv t$ iff $\forall\psi \in \Gamma . s \models \psi \Leftrightarrow t \models \psi$. We define the filtered model to have states $\mathfrak{T}/\equiv$ and with atomic action relations given by $[s] \xrightarrow{a} [t]$ iff $\exists s' \in [s], t' \in [t]. s' \xrightarrow{a} t'$. The number of equivalence classes is at most $2^{|\Gamma|}$ and so is $O(2^{|\phi|})$. The rest of the proof shows that the filtered model is indeed a model, in that $[s] \models \psi$ iff $s \models \psi$ for $\psi \in \Gamma$. For PDL the only case requiring comment is the case $\langle\alpha^*\rangle\psi$, which proceeds by an induction on the length of the witnessing sequence of α's. Consequently if ϕ is a satisfiable PDL formula, then it has a model with size $O(2^{|\phi|})$, and in fact $2^{|\phi|}$ suffices — see [25] for full details.

In order to obtain an upper bound for satisfiability from the small model property, we also need to know the complexity of model-checking, that is, determining whether $s \models \phi$. It is straightforward to define an inductive procedure for this, which is polynomial in the size of the formula and of the system. For example, to determine the truth of $\langle\alpha^*\rangle\phi$, one computes the *-closure of the α relation, and then checks for an α^*-successor satisfying ϕ. These results give an NTIME(c^n) (where c is a constant and n the formula size) upper bound for the satisfiability problem. By a reduction to alternating Turing machines, [25] also gave a lower bound of DTIME($c^{n/\lg n}$). A closer to optimal technique for satisfiability due to Pratt uses tableaux [58].

Although CTL, CTL* and $L\mu$ all have the finite model property, the filtration technique does not apply. If one filters $\mathfrak{T}$ through a finite set Γ containing $\forall\mathbf{F}Q$ unintended loops may be added. For instance if $\mathfrak{T}$ is $s_i \xrightarrow{a} s_{i+1}$ for $1 \leq i < n$ and Q is only true at state s_n then $s_i \models \forall\mathbf{F}Q$ for each i. But when n is large enough the filtered model will have at least one transition $[s_j] \xrightarrow{a} [s_i]$ when $i \leq j < n$, with the consequence that $[s_i] \not\models \forall\mathbf{F}Q$. The initial approach to showing the finite model property utilized semantic tableaux where one explicitly builds a model for a satisfiable formula which has small size. But such a technique is very particular, and more sophisticated methods based on automata are used for optimal results, as we shall mention later.

3 SYNTAX AND SEMANTICS OF MODAL MU-CALCULUS

The defining feature of mu-calculi is the use of fixpoint operators. The use of fixpoint operators in program logics goes back at least to De Bakker, Park and Scott [56]. However, their use in modal logics of programs dates from work of Pratt, Emerson and Clarke and Kozen. Pratt's version [59] used a fixpoint operator like the minimization operator of recursion theory; although this is only superficially different, it seems to have dissuaded people from using the logic in that form. Emerson and Clarke added fixed points to a temporal logic to capture fairness and other correctness properties [21]. Kozen's [35] paper introduced $L\mu$ as we use it today, and established a number of basic results.

Fixpoint logics are traditionally considered hard to understand. Furthermore, their

semantics requires a familiarity with material that, although not difficult, is often omitted from undergraduate mathematics or logic programmes. Whether for practical purposes, or to guide oneself through the formal proofs, it is therefore worthwhile to spend a little time on discussing an intuitive understanding of $L\mu$ before going on to the definitions.

3.1 Fixpoints as recursion

Suppose that $\mathfrak{S}$ is the state space of some system. For example $\mathfrak{S}$ could be the set of all processes reachable by arbitrary length sequences of transitions from some initial process. One way to provide semantics of a state-based modal logic is to map formulae ϕ to sets of states, that is to elements of $\wp\mathfrak{S}$. For any formula ϕ this mapping is given by $\|\phi\|$[1]. The idea is that this mapping tells us at which states each formula holds. If we allow our logic to contain variables with interpretations ranging over $\wp\mathfrak{S}$, then we can view the semantics of a formula with a free variable, $\phi(Z)$, as a function $f \colon \wp\mathfrak{S} \to \wp\mathfrak{S}$. If $f(S) \subseteq f(S')$ whenever $S \subseteq S' \subseteq \mathfrak{S}$ then f is *monotonic*. If $f(S) = S$ then S is a *fixed point* of f (as repeated application of f leaves S unchanged). If we take the usual lattice structure on $\wp\mathfrak{S}$, given by set inclusion, and if f is a monotonic function, then by the Knaster–Tarski theorem we know that f has fixed points, and indeed has a unique maximal and a unique minimal fixed point. The maximal fixed-point is the union of *post-fixed points*, $\bigcup\{S \subset \mathfrak{S} \mid S \subseteq f(S)\}$, and the minimal fixed-point is the intersection of *pre-fixed points*, $\bigcap\{S \subset \mathfrak{S} \mid f(S) \subseteq S\}$. So we could extend our basic logic with a minimal fixpoint operator μ, so that $\mu Z.\phi(Z)$ is a formula whose semantics is the least fixed point of f; and similarly a maximal fixpoint operator ν, so that $\nu Z.\phi(Z)$ is a formula whose semantics is the greatest fixed point of f (when the semantics of $\phi(Z)$ is monotonic).

A good reason to do this is that it provides a semantics for *recursion*, and adding recursion to the usual modal logics provides a neat way of expressing all the usual operators of temporal logics. For example, consider the CTL formula $\forall\mathbf{G}\phi$, 'always ϕ'. Another way of expressing this is to say that it is a property X such that if X is true, then ϕ is true, and wherever we go next, X remains true; so X satisfies the modal implicational equation

$$X \Rightarrow \phi \wedge [-]X.$$

where $[-]X$ means that X is true at every immediate successor (see subsection 3.3). A solution to this equation is precisely a post-fixed point of the formula $\phi \wedge [-]X$. But which solution of the possibly many is appropriate? The only canonical post-fixed point is the largest, and this also makes sense, since if a state satisfies *some* solution, then it surely satisfies $\forall\mathbf{G}\phi$. Hence the meaning of the formula is the largest post-fixed point, which by standard theory is exactly the largest fixed point, $\nu X.\phi \wedge [-]Z$.

On the other hand, consider the CTL property $\exists\mathbf{F}\phi$, 'there exists a path on which ϕ eventually holds'. We could write this recursively as 'Y holds if either ϕ holds now, or there's some successor on which Y is true':

$$Y \Leftarrow \phi \vee \langle - \rangle Y.$$

Here we have a pre-fixed point of $\phi \vee \langle - \rangle Y$; the only canonical such is the least, and if a state satisfies $\exists\mathbf{F}\phi$, then it surely satisfies any solution Y' of the equation. Hence we want the least pre-fixed point, which is also the least fixed point, $\mu Y.\phi \vee \langle - \rangle Y$.

[1]The mapping can be either given directly (inductively) or indirectly as the set $\{s \in \mathfrak{S} : s \models \Phi\}$.

Finally, we observe that since we want the fixed points, we may replace the implications by equalities in the modal equations above, and get the same answers. It is therefore usual to cast modal fixpoint logics in terms of equations, rather than of implications.

3.2 Approximating fixpoints and μ as 'finitely'

The other key idea is that of approximants and unfolding. The standard theory tells us that if f is a monotonic function on a lattice, we can construct the least fixed point of f by applying f repeatedly on the bottom element $\perp$ of the lattice to form an increasing chain, whose limit is the fixed point. The length of the iteration is in general transfinite, but is bounded at worst by the cardinal after cardinality of the lattice, and in the special case of a powerset lattice $\wp\mathfrak{S}$, by the cardinal after the cardinality of $\mathfrak{S}$. So if f is monotonic on $\wp\mathfrak{S}$, we have the increasing chain $\emptyset \subseteq f(\emptyset) \subseteq f^2(\emptyset) \subseteq \ldots \subseteq f^\alpha(\emptyset) \ldots$ and the least fixed point is the limit of this chain

$$\mu f = \bigcup_{\alpha<\kappa} f^\alpha(\emptyset)$$

and similarly as there is the anti-chain, $\mathfrak{S} \supseteq f(\mathfrak{S}) \supseteq f^2(\mathfrak{S}) \supseteq \ldots \supseteq f^\alpha(\mathfrak{S}) \ldots$,

$$\nu f = \bigcap_{\alpha<\kappa} f^\alpha(\mathfrak{S})$$

—or in terms of a infinitary logic, $\mu Z.\phi(Z) = \bigvee_{\alpha<\kappa} \phi^\alpha(\perp)$—where κ is at worst $|\mathfrak{S}|+1$ for finite $\mathfrak{S}$, or $\aleph_1$ for countable $\mathfrak{S}$ (and $\nu Z.\phi(Z) = \bigwedge_{\alpha<\kappa} \phi^\alpha(\top)$). So for a minimal fixpoint $\mu Z.\phi(Z)$, if a state s satisfies the fixpoint, it satisfies some approximant, say for convenience the $\beta+1$th so that $s \models \phi^{\beta+1}(\perp)$. Now if we *unfold* this formula once, we get $s \models \phi(\phi^\beta(\perp))$. That is, the fact that s satisfies the fixpoint depends, via ϕ, on the fact that other states satisfy the fixpoint *at smaller approximants than s does.* So if one follows a chain of dependencies, the chain terminates. This is the strict meaning behind the slogan "μ means 'finite looping'", which, with a little refinement, is sufficient to understand $L\mu$.

On the other hand, for a maximal fixpoint $\nu Z.\phi(Z)$, there is no such decreasing chain: $s \models \nu Z.\phi(Z)$ iff $s \models \phi(\nu Z.\phi(Z))$, and we may loop for ever, as in the process $P \stackrel{\text{def}}{=} a.P$, which repeatedly does an a action, and so satisfies $\nu Z.\langle a\rangle Z$. (However, if a state *fails* a maximal fixpoint, then there is a descending chain of failures.) Instead, we have the principle of fixpoint induction: if by assuming that a set $S \models Z$, we can show that $S \models \phi(Z)$, then we have shown that $S \models \nu Z.\phi$ (compare the recursive formulation of $\forall\mathbf{G}\phi$ in the previous section).

So in summary, one may understand fixpoints by the slogan 'ν means looping, and μ means finite looping'. This slogan provides an alternative means of explaining why a minimal fixpoint is required in the translation of $\exists\mathbf{F}\phi$. This formula means that there is a path on which ϕ eventually holds: that is, on the chosen path, ϕ holds within finite time. Hence the 'equation' $Y = \phi \vee \langle -\rangle Y$ must only be applied a finite number of times, and so by the slogan we should use a minimal fixpoint.

In the case of formulae with alternating fixpoints (which we shall examine a little later), the slogan remains valid, but requires a little more care in application. It is essential to almost all proofs about $L\mu$: the notion of 'well-founded premodel' with which Streett

and Emerson [64] proved the finite model property, is an example of the slogan; so are the tableau model-checking approaches of Stirling and Walker [62], and Bradfield and Stirling [12].

3.3 Syntax of $L\mu$

Let Var be an (infinite) set of *variable names*, typically indicated by $Z, Y, \ldots$; let Prop be a set of *atomic propositions*, typically indicated by $P, Q, \ldots$; and let $\mathcal{L}$ be a set of *labels*, typically indicated by $a, b, \ldots$. The set of $L\mu$ formulae (with respect to $\mathrm{Var}, \mathrm{Prop}, \mathcal{L}$) is defined in parsimonious form as follows:

- P is a formula.
- Z is a formula.
- If ϕ_1 and ϕ_2 are formulae, so is $\phi_1 \wedge \phi_2$.
- If ϕ is a formula, so is $[a]\phi$.
- If ϕ is a formula, so is $\neg\phi$.
- If ϕ is a formula, then $\nu Z.\phi$ is a formula, provided that every free occurrence of Z in ϕ occurs positively, i.e. within the scope of an even number of negations. (The notions of free and bound variables are as usual, where ν is the only binding operator.)

If a formula is written as $\phi(Z)$, it is to be understood that the subsequent writing of $\phi(\psi)$ means ϕ with ψ substituted for all free occurrences of Z. There is no suggestion that Z is the only free variable of ϕ.

The positivity requirement on the fixpoint operator is a syntactic means of ensuring that $\phi(Z)$ denotes a functional monotonic in Z, and so has unique minimal and maximal fixpoint. It is usually more convenient to introduce derived operators defined by de Morgan duality, and work in positive form:

- $\phi_1 \vee \phi_2$ means $\neg(\neg\phi_1 \wedge \neg\phi_2)$.
- $\langle a\rangle\phi$ means $\neg[a]\neg\phi$.
- $\mu Z.\phi(Z)$ means $\neg\nu Z.\neg\phi(\neg Z)$.

Note the triple use of negation in μ, which is required to maintain the positivity. A formula is said to be in *positive form* if it is written with the derived operators so that $\neg$ only occurs applied to atomic propositions. It is in *positive normal form* if in addition all bound variables are distinct (and different from free variables). Any formula can be put into positive normal form by use of de Morgan laws and α-conversion. So we shall often assume positive normal form, and when doing structural induction on formulae will often take the derived operators as primitives.

For the concrete syntax, we shall assume that modal operators have higher precedence than boolean, and that fixpoint operators have lowest precedence, so that the scope of a fixpoint extends as far to the right as possible.

There are a few extensions to the syntax which are convenient in presenting examples, and in practice. The most useful is to allow modalities to refer not just to single actions, but to sets of actions. The most useful set is ‘all actions except a’. So:

- $s \models [K]\phi$ iff $\forall a \in K. s \models [a]\phi$, and $[a, b, \ldots]\phi$ is short for $[\{a, b, \ldots\}]\phi$.
- $[-K]\phi$ means $[\mathcal{L} - K]\phi$, and set braces may be omitted.

Thus $[-]\phi$ means just $[\mathcal{L}]\phi$. [2]

3.4 Semantics of $L\mu$

An *$L\mu$ structure* $\mathfrak{T}$ (over Prop, $\mathcal{L}$) is a labelled transition system, namely a set $\mathfrak{S}$ of states and a transition relation $\rightarrow \subseteq \mathfrak{S} \times \mathcal{L} \times \mathfrak{S}$ (as usual we write $s \xrightarrow{a} t$), together with an interpretation $\mathfrak{V}_{\mathrm{Prop}}\colon \mathrm{Prop} \rightarrow \wp\mathfrak{S}$ for the atomic propositions.

Given a structure $\mathfrak{T}$ and an interpretation $\mathfrak{V}\colon \mathrm{Var} \rightarrow \wp\mathfrak{S}$ of the variables, the set $\|\phi\|^{\mathfrak{T}}_{\mathfrak{V}}$ of states satisfying a formula ϕ is defined as follows:

$$
\begin{aligned}
\|P\|^{\mathfrak{T}}_{\mathfrak{V}} &= \mathfrak{V}_{\mathrm{Prop}}(P) \\
\|Z\|^{\mathfrak{T}}_{\mathfrak{V}} &= \mathfrak{V}(Z) \\
\|\neg\phi\|^{\mathfrak{T}}_{\mathfrak{V}} &= \mathfrak{S} - \|\phi\|^{\mathfrak{T}}_{\mathfrak{V}} \\
\|\phi_1 \wedge \phi_2\|^{\mathfrak{T}}_{\mathfrak{V}} &= \|\phi_1\|^{\mathfrak{T}}_{\mathfrak{V}} \cap \|\phi_2\|^{\mathfrak{T}}_{\mathfrak{V}} \\
\|[a]\phi\|^{\mathfrak{T}}_{\mathfrak{V}} &= \{\, s \mid \forall t. s \xrightarrow{a} t \Rightarrow t \in \|\phi\|^{\mathfrak{T}}_{\mathfrak{V}} \,\} \\
\|\nu Z.\phi\|^{\mathfrak{T}}_{\mathfrak{V}} &= \bigcup \left\{ S \subseteq \mathfrak{S} \mid S \subseteq \|\phi\|^{\mathfrak{T}}_{\mathfrak{V}[Z:=S]} \right\}
\end{aligned}
$$

where $\mathfrak{V}[Z := S]$ is the valuation which maps Z to S and otherwise agrees with $\mathfrak{V}$. If we are working in positive normal form, we may add definitions for the derived operators by duality:

$$
\begin{aligned}
\|\phi_1 \vee \phi_2\|^{\mathfrak{T}}_{\mathfrak{V}} &= \|\phi_1\|^{\mathfrak{T}}_{\mathfrak{V}} \cup \|\phi_2\|^{\mathfrak{T}}_{\mathfrak{V}} \\
\|\langle a\rangle\phi\|^{\mathfrak{T}}_{\mathfrak{V}} &= \{\, s \mid \exists t. s \xrightarrow{a} t \wedge t \in \|\phi\|^{\mathfrak{T}}_{\mathfrak{V}} \,\} \\
\|\mu Z.\phi\|^{\mathfrak{T}}_{\mathfrak{V}} &= \bigcap \left\{ S \subseteq \mathfrak{S} \mid S \supseteq \|\phi\|^{\mathfrak{T}}_{\mathfrak{V}[Z:=S]} \right\}
\end{aligned}
$$

We drop $^{\mathfrak{T}}$ and $_{\mathfrak{V}}$ whenever possible; and write $s \models \phi$ for $s \in \|\phi\|$.

We have discussed informally the importance of approximants; let us now define them. If $\mu Z.\phi(Z)$ is a formula, then for an ordinal α, let $\mu Z^{\alpha}.\phi$ and $\mu Z^{<\alpha}.\phi$ be formulae, with semantics given, with simultaneous induction on α, by:

$$
\begin{aligned}
\|\mu Z^{<\alpha}.\phi\|^{\mathfrak{T}}_{\mathfrak{V}} &= \bigcup_{\beta<\alpha} \|\mu Z^{\beta}.\phi\|^{\mathfrak{T}}_{\mathfrak{V}} \\
\|\mu Z^{\alpha}.\phi\|^{\mathfrak{T}}_{\mathfrak{V}} &= \|\phi\|^{\mathfrak{T}}_{\mathfrak{V}[Z:=\|\mu Z^{<\alpha}.\phi\|^{\mathfrak{T}}_{\mathfrak{V}}]}
\end{aligned}
$$

The approximants of a maximal fixpoint are defined dually:

$$
\begin{aligned}
\|\nu Z^{<\alpha}.\phi\|^{\mathfrak{T}}_{\mathfrak{V}} &= \bigcap_{\beta<\alpha} \|\nu Z^{\beta}.\phi\|^{\mathfrak{T}}_{\mathfrak{V}} \\
\|\nu Z^{\alpha}.\phi\|^{\mathfrak{T}}_{\mathfrak{V}} &= \|\phi\|^{\mathfrak{T}}_{\mathfrak{V}[Z:=\|\nu Z^{<\alpha}.\phi\|^{\mathfrak{T}}_{\mathfrak{V}}]}
\end{aligned}
$$

[2] Beware that many authors use '$[\,]\phi$' to mean '$[\mathcal{L}]\phi$', rather than the (vacuous) '$[\emptyset]\phi$' that it means in our notation.

Note that $\mu Z^{<0}.\phi \Leftrightarrow \bot$ and $\nu Z^{<0}.\phi \Leftrightarrow \top$. By abuse of notation, we write Z^α or ϕ^α to mean ${}^{\mu}_{\nu}Z^\alpha.\,\phi$; of course this only makes sense when one knows which fixpoint and variable is meant.

We should remark here that most literature on $L\mu$ uses a slightly different definition, putting $\mu Z^0.\phi = \bot$, $\mu Z^{\alpha+1}.\phi = \phi(\mu Z^\alpha.\phi)$, and $\mu Z^\lambda.\phi = \bigcup_{\beta<\lambda} \mu Z^\beta.\phi$ for limit λ—which in effect is writing α for our $<\alpha$. That notation is taken from set theory; its advantage is that a limit approximant is the limit of approximants. Our notation is taken from more recent set theoretic practice; its advantages are that it sometimes reduces the number of trivial case distinctions in inductive proofs. However, the difference is not significant.

Sometimes, we are interested in *rooted* structures $(\mathfrak{T}, s_0, \mathfrak{V}_{\text{Prop}})$ for $L\mu$ formulae that have a designated initial state s_0: ϕ is true of such a structure if $s_0 \models \phi$. We can, therefore, examine the set of all rooted structures where ϕ is true which allows comparison between $L\mu$ and other notations for classifying structures.

3.5 Examples

We have seen, both informally and in the formal semantics, the meaning of the fixpoint operators, and we have seen some simple examples of $L\mu$ translating CTL. We now consider some examples of $L\mu$ formulae in their own right, which express properties one might meet in practice.

There is a well-known ‘classification’ [42] of basic properties into safety and liveness. In terms of $L\mu$, it is not unreasonable to say that μ is liveness and ν is safety. Consider first simple ν formulae. For example:

$$\nu Z.P \wedge [a]Z$$

is a relativized ‘always’ formula: ‘P is true along every a-path’. Slightly more complex is the relativized ‘while’ formula

$$\nu Z.Q \vee (P \wedge [a]Z)$$

‘on every a-path, P holds while Q fails’. Both formulae can be understood directly via the fixpoint construction, or via the idea of ‘ν as looping’: for example the second formula is true if either Q holds, or if P holds and wherever we go next (via a), the formula is true, and ..., and because the fixpoint is maximal, we can repeat forever. So in particular, if P is always true, and Q never holds, the formula is true.

μ formulae, in contrast, require something to happen, and thus are liveness properties. For example

$$\mu Z.P \vee [a]Z$$

is ‘on all infinite length a-paths, P eventually holds’; and

$$\mu Z.Q \vee (P \wedge \langle a\rangle Z)$$

is ‘on some a-path, P holds until Q holds (and Q *does* eventually hold)’. Again, these can be understood by ‘μ as finite looping’: in the second case, we are no longer allowed to repeat the unfolding forever, so we must eventually ‘bottom out’ in the Q disjunct.

This level of complexity suffices to translate CTL, since we have $\mu Z.Q \vee (P \wedge \langle -\rangle Z)$ as a translation of $\exists[P\,\mathbf{U}\,Q]$, and $\mu Z.Q \vee (P \wedge [-]Z \wedge \langle -\rangle\top)$ as a translation of $\forall[P\,\mathbf{U}\,Q]$

(the conjunct $\langle - \rangle \top$ ensures that Q is actually reached, since $[-]Z$ is true at deadlock states); and obviously we can nest formulae inside one another, such as

$$\nu Z.(\mu Y.P \vee \langle - \rangle Y) \wedge [-]Z$$

'it is always possible that P will hold', or $\forall \mathbf{G}(\exists \mathbf{F} P)$. Equally obviously, we can write formulae with no CTL translation, such as

$$\mu Z.[a]\bot \vee \langle a \rangle \langle a \rangle Z$$

which asserts the existence of a maximal a-path of even length; a formula which is, incidentally, expressible in PDL. This is, however, a fairly simple extension; much more interesting is the power one gets from mixing fixpoints that depend on one another. Consider the formula

$$\mu Y.\nu Z.(P \wedge [a]Y) \vee (\neg P \wedge [a]Z).$$

This formula usually gives pause for thought, but it has a simple meaning, which can be seen by using the slogans. $\mu Y\ldots$ is true if $\nu Z\ldots$ is true if $(P \wedge [a]Y) \vee (\neg P \wedge [a]Z)$, which is true if either P holds and at the next (a)-states we loop back to $\mu Y\ldots$, or P fails, and at the next states we loop back to $\nu Z\ldots$. By the slogan 'μ means finitely', we can only loop through $\mu Y\ldots$ finitely many times on any path, and hence P is true only finitely often on any path.

We shall see in a later section that this so-called alternation of fixpoint operators does indeed give ever more expressive power as the number of alternations increases. It also appears to increase the complexity of model-checking: all known algorithms are exponential in the alternation, but whether this is necessarily the case is the main remaining open problem about $L\mu$.

3.6 Fixpoint regeneration and the 'fundamental semantic theorem'

In the informal description of the meaning of fixpoints, we used the idea of the dependency of s at ϕ on t at ψ. We now make this precise. Assume a structure $\mathfrak{T}$, and a formula ϕ. Suppose that we annotate the states with sets of subformulae, such that the sets are locally consistent: that is, s is annotated with a conjunction iff it is annotated with both conjuncts; s is annotated with a disjunction iff it is annotated with at least one disjunct; if s is annotated with $[a]\psi$ (resp. $\langle a \rangle \psi$), then each (resp. at least one) a-successor is annotated with ψ; if s is annotated with a fixpoint or fixpoint variable, it is annotated with the body of the fixpoint. We call such an annotated structure a *quasi-model*.

A *choice function* f is a function which for every disjunctive subformula $\psi_1 \vee \psi_2$ and every state annotated with $\psi_1 \vee \psi_2$ chooses one disjunct $f(s, \psi_1 \vee \psi_2)$; and for every subformula $\langle a \rangle \psi$ and every state s annotated with $\langle a \rangle \psi$ chooses one a-successor $t = f(s, \langle a \rangle \psi)$ annotated with ψ.

A *pre-model* is a quasi-model equipped with a choice function.

Given a pre-model with choice function f, the *dependencies* of a state s that satisfies a subformula ψ are defined thus: $s@\psi_1 \wedge \psi_2 \succ s@\psi_i$ for $i = 1, 2$; $s@[a]\psi \succ t@\psi$ for every t such that $s \xrightarrow{a} t$; $s@\psi_1 \vee \psi_2 \succ s@f(s, \psi_1 \vee \psi_2)$; $s@\langle a \rangle \psi \succ f(s, \langle a \rangle \psi)@\psi$; $s@{}^{\mu}_{\nu}Z.\,\psi \succ s@\psi$; $s@Z \succ s@\psi$ where Z is bound by ${}^{\mu}_{\nu}Z.\,\psi$. A *trail* is a maximal chain of dependencies.

If every trail has the property that the highest (i.e. with the outermost binding fixpoint) variable occurring infinitely often is a ν-variable, the pre-model is *well-founded*.

(Equivalently: in any trail, a μ-variable can only occur finitely often unless a higher variable is encountered.)

The fundamental theorem on the semantics of $L\mu$ can now be stated:

THEOREM 1. A well-founded pre-model is a model: in a well-founded pre-model, if s is annotated with ψ, then indeed $s \models \psi$.

The theorem in this form is due to Streett and Emerson in [64], from which the term 'well-founded pre-model' is taken. Stirling and Walker [63] presented a tableau system for model-checking on finite structures, and the soundness theorem for that system is essentially a finite version of the fundamental theorem using a more relaxed notion of choice; the later infinite-state version of [12, 7] is the fundamental theorem, again with a slight relaxation on choice.

A converse is also true:

THEOREM 2. If in some structure $s \models \phi$, then there is a *locally consistent* annotation of the structure and a choice function which make the structure a well-founded pre-model.

The fundamental theorem, in its various guises, is the precise statement of the slogan 'μ means finite looping'. To explain why it is true, and to define the term 'locally consistent', we need to make a finer analysis of approximants.

Assume a structure $\mathfrak{T}$, valuation $\mathfrak{V}$, and formula ϕ in positive normal form. Let $Y_1, \ldots, Y_n$ be the μ-variables of ϕ, in an order compatible with formula inclusion: that is, if $\mu Y_j.\psi_j$ is a subformula of $\mu Y_i.\psi_i$, then $i \leq j$. If Y_i is some inner fixpoint, then its denotation depends on the meaning of the fixpoints enclosing it: for example, in the formula $\mu Y_1.\langle a\rangle \mu Y_2.(P \vee Y_1) \vee \langle b\rangle Y_2$, to calculate the inner fixpoint μY_2 we need to know the denotation of Y_1. We may ask: what is the least approximant of Y_1 that could be plugged in to make the formula true? Having fixed that, we can then ask what approximant of Y_2 is required. This idea is the notion of *signature*. A signature is a sequence $\sigma = \alpha_1, \ldots, \alpha_n$ of ordinals, such that the i least fixpoint will be interpreted by its α_ith approximant (calculated relative to the outer approximants).

The definition and use of signatures inevitably involves some slightly irritating book-keeping, and they appear in several forms in the literature. In [64], the Fischer–Ladner closure of ϕ was used, rather than the set of subformulae. The closure is defined by starting with ϕ and closing under the operations of taking the immediate components of formulae with boolean or modal top-level connectives, together with the rule that if ${}^{\mu}_{\nu}Z.\,\psi(Z) \in \mathrm{cl}(\phi)$, then $\psi({}^{\mu}_{\nu}Z.\,\psi) \in \mathrm{cl}(\phi)$. The signatures were defined by syntactically unfolding fixpoints, rather than by semantic approximants. In [63] and following work, a notion of *constant* was used, which allows some of the book-keeping to be moved into the logic. Although all the notions and proofs using them are interconvertible, the 'constant' variant is perhaps easier to follow, and has the advantage that it adapts easily to the modal equation system presentation of $L\mu$, which we shall see below. Indeed, it arises more naturally from that system.

Add to the language a countable set of *constants* $U, V, \ldots$. Constants will be defined to stand for maximal fixpoints or approximants of minimal fixpoints. Specifically, given a formula ϕ, let $Y_1, \ldots, Y_n$ be the μ-variables as above, let $Z_1, \ldots, Z_m$ be the ν-variables, let $\sigma = \alpha_1, \ldots, \alpha_n$ be a signature, and let $U_1, \ldots, U_n, V_1, \ldots, V_m$ be constants, which will be associated with the corresponding variables. They are given semantics thus: if Y_i is bound by $\mu Y_i.\psi_i$, then $\|U_i\|_\sigma$ is $\|\mu Y_i^{\alpha_i}.\psi_i'\|_\sigma$, where ψ_i' is obtained from ψ_i by substituting the corresponding constants for the free fixpoint variables of $\mu Y_i.\psi_i$. If Z_i is bound by

$\nu Z_i.\psi_i$, its semantics is $\|\nu Z_i.\psi_i'\|_\sigma$. Given an arbitrary subformula ψ of ϕ, we say a state s satisfies ψ with signature σ, written $s \models_\sigma \psi$, if $s \in \|\psi'\|_\sigma$, where ψ' is ψ with its free fixpoint variables substituted by the corresponding constants.

Order signatures lexicographically. Now, given a pre-model for ϕ, extend the annotations so that each subformula at s is accompanied by a signature – write $s@\psi[\sigma]$. Such an extended annotation is said to be locally consistent if the signature is unchanged or decreases by passing through boolean, modal, or ν-variable dependencies, and when passing through $s@Y_i$ it strictly decreases in the ith component and is unchanged in the $1, \ldots, i-1$'th components.

It can now be shown, by a slightly delicate but not too difficult induction on ψ and σ, that if $s@\psi[\sigma]$, then $s \models_\sigma \psi$. The proof proceeds by contradiction: suppose that $s@\psi[\sigma]$ and $s \not\models_\sigma \psi$. If ψ is $\psi_1 \vee \psi_2$ ($\psi_1 \wedge \psi_2$) then for some $i \in \{1,2\}$, $s@\psi_1[\sigma]$ and $s \not\models_\sigma \psi_i$. If ψ is $[a]\psi'$ ($\langle a\rangle\psi'$) then for some s', $s \xrightarrow{a} s'$, $s'@\psi'[\sigma]$ and $s' \not\models_\sigma \psi'$. If ψ is a least fixpoint variable Y_i, then we pass through the unfolding rule to $s@\psi_i[\sigma']$ where $\sigma' < \sigma$ and $s \not\models_{\sigma'} \psi_i$. (Hence we can only pass through least fixpoints finitely often.) The key case is when ψ is a greatest fixpoint variable Z_i. In this case, the hypothesis is that $s@Z_i[\sigma]$ and $s \not\models_\sigma Z_i$. Then s fails some approximant Z_i^β (and $s@Z_i^\beta[\sigma]$); and then passing through the unfolding rule gives s fails $\psi_i^{\beta'}$ for $\beta' < \beta$ (and $s@\psi_i^{\beta'}[\sigma]$). Continuing to chase the falsehood down the pre-model, we eventually arrive at a state failing the zero'th approximant of a greatest fixpoint formula, which is impossible.

Furthermore, given a well-founded pre-model, one can construct a locally consistent signature annotation—essentially, the Y_i component of σ in $s@\psi[\sigma]$ is the maximum 'number' (in the transfinite sense) of Y_i occurrences without meeting a higher variable in trails from $s@\psi$, and so on; the well-foundedness of the pre-model guarantees that this is well-defined. This gives the fundamental theorem.

The converse is quite easy: given a model, annotate the states by the subformulae they satisfy; for $s@\psi$ assign the least σ such that $s \models_\sigma \psi$; and choose a choice function that always chooses the successor with least signature. It is easy to show that this is a well-founded pre-model and signature assignment.

3.7 Modal equation systems

The presentation of $L\mu$ so far is a traditional logical formulation. However, in several circumstances it can be useful to think in terms of systems of recursive equations for the fixpoint variables, as follows.

A *modal equation system* comprises a sequence $B_0; \ldots; B_n$ of *blocks*; each B_i may be a *μ-block* (we write B_i^μ) or a *ν-block* (we write B_i^ν). Each block $B_i^{\mu/\nu}$ is a sequence of equations $X_{i0} \stackrel{\mu/\nu}{=} \phi_{i0}, \ldots, X_{ik_i} \stackrel{\mu/\nu}{=} \phi_{ik_i}$, where each ϕ_{ij} is a modal formula which may contain any of the variables $X_{i'j'}$ positively.

Thus each block B_i defines a functional on vectors $(S_{i0}, \ldots, S_{ik_i}) \in (\wp\mathfrak{S})^{k_i}$. This functional is relative to valuations of the variables in earlier blocks, and refers to the solutions of later blocks. If B_i^μ, then take the least fixpoint (in the componentwise ordering) of this functional, and if B_i^ν, take the greatest. Conventionally, the solution of the entire equation system is taken to be the solution for the first variable X_{00}.

There is an obvious transformations from $L\mu$ to modal equation systems: for example,

$\mu X.P \vee \nu Y.[a]Y \wedge [b]X$ translates to

$$X_{00} \stackrel{\mu}{=} P \vee X_{10} \quad ; \quad X_{10} \stackrel{\nu}{=} [a]X_{10} \wedge [b]X_{00}.$$

Similarly, there is a reasonably obvious reverse transformation: for example, the equation system

$$X_{00} \stackrel{\mu}{=} \langle a \rangle X_{10} \vee [b]X_{10} \quad ; \quad X_{10} \stackrel{\nu}{=} P \wedge [a](X_{00} \vee X_{10})$$

translates to $\mu X.\langle a \rangle(\nu Y.P \wedge [a](X \vee Y)) \vee [b](\nu Y.P \wedge [a](X \vee Y))$. These translations, known from finite model theory, show that modal equation systems and $L\mu$ are equi-expressive. Note that in the second example, the formula duplicates the second equation: by extending such examples, one can see that the translation from equation systems to formulae may introduce an exponential blow-up. However, this blow-up results in formulae with many identical sub-formulae, which can in any case be optimized away during model-checking, and in general problems in modal equation systems are of the same complexity as in $L\mu$.

A block in a modal equation system is to be understood as a *simultaneous* fixpoint. $L\mu$ could be directly presented with simultaneous fixed points: for instance, $s \models \mu Z_1 \ldots Z_n.(\phi_1, \ldots, \phi_n)$ iff $s \in S_1$ where $(S_1, \ldots, S_n) = \bigcap \{(S'_1, \ldots, S'_n) \mid S'_j \supseteq \|\phi_j\|^{\mathfrak{T}}_{\mathfrak{V}[Z_1:=S'_1,\ldots,Z_n:=S'_n]}\}$.

One of the main applications of modal equation systems is in the development of fast model-checking algorithms: modal equation systems can be easily translated to *boolean equation systems* (defined as above, but with boolean variables and just propositional equations) by having one boolean variable for each (modal variable, state) pair. Then graph-theoretic or matrix-theoretic techniques can be employed to solve the boolean equation systems. For more on this topic, see [46].

4 EXPRESSIVE POWER

As we noted earlier in this article, there are many temporal logics used in practice, some of which are also historical precursors to $L\mu$. We said that most of them could be seen as fragments of $L\mu$. In this section we consider questions of expressivity and related topics, and start by showing how a number of other logics can be translated into $L\mu$.

4.1 CTL and friends as fragments of $L\mu$

PDL can be easily translated into $L\mu$ by unpacking the modal operators $\langle \alpha \rangle$: $\langle \alpha \cup \beta \rangle \psi = \langle \alpha \rangle \psi \vee \langle \beta \rangle \psi$, $\langle \alpha ; \beta \rangle \psi = \langle \alpha \rangle \langle \beta \rangle \psi$ and $\langle \alpha^* \rangle \psi = \mu Z.\psi \vee \langle \alpha \rangle Z$. The logic CTL is one of the simplest temporal logics, and its translation is also simple. Recall the syntax and semantics of CTL from 2.2. The two basic operators are $\forall[\phi \mathbf{U} \psi]$ and $\exists[\phi \mathbf{U} \psi]$. Assuming that there are no deadlocked states, these can be simply translated as:

$$\mu Z.\psi \vee [-]\phi \qquad \text{and} \qquad \mu Z.\psi \vee \langle - \rangle \phi$$

with the proof of the equivalence being a straightforward application of the semantics. For both PDL and CTL, only a fragment of $L\mu$ is necessary where there is no essential alternation of fixpoints (as described in 7).

A much less trivial case is the logic CTL*. CTL* is the logic obtained by removing the syntactic constraint of CTL that requires every $\mathbf{U}$ to be immediately quantified by $\forall$ or $\exists$, so that in CTL* one can write formulae such as $\forall[(\phi\,\mathbf{U}\,\psi)\vee\neg(\phi'\,\mathbf{U}\,\psi')]$. Consequently, not all CTL* formulae have meanings purely in terms of states, and the question of translation into a purely state-based logic like $L\mu$ becomes problematic. However, one can ask the question, is every state formula of CTL* (that is, boolean combinations of atoms and quantified formulae) equivalent to an $L\mu$ formula? The answer is 'yes', but it is a harder problem. Wolper, in an unpublished note from the early 1980s, noted that state formulas of CTL* can be translated via automata theory into PDL over a single label with looping (which, in turn, is directly translatable into $L\mu$). The first explicit translation was given by Dam [17], but the translation is very difficult, and gives a doubly exponential blowup in the formula size. The latter means that the translation is of no use for model-checking, as existing CTL* algorithms are much faster than a double exponential blowup of $L\mu$ model-checking. A few years later, Bhat and Cleaveland [6] gave a single exponential translation into the equational variant of $L\mu$. Although still quite complex, utilising a so-called Büchi tableau automaton as an intermediary, this translation is efficient enough to give competitive model-checking of CTL* via translation.

4.2 Bisimulation and tree model property

Bisimulation or back-and-forth equivalence or zig-zag equivalence is the equivalence associated with modal logic. In our setting, a *bisimulation* between two $L\mu$ structures $\mathfrak{T}_1$ and $\mathfrak{T}_2$ over the same proposition set Prop and label set $\mathcal{L}$ is a relation R such that for all propositions P, if $P(s_1)$ and $s_1 R s_2$, then $P(s_2)$, and conversely; and if $s_1 R s_2$, and $s_1 \xrightarrow{a} s_1'$, then for some s_2', $s_2 \xrightarrow{a} s_2'$ and $s_1' R s_2'$, and conversely. Two states s_1 and s_2 are *bisimilar* if there is some bisimulation R such that $s_1 R s_2$.

Recall that HML is the fixpoint-free part of $L\mu$. The following is easily shown by structural induction on formulae:

THEOREM 3. If two states (in the same or different systems) are bisimilar, they satisfy the same HML formulae.

By an induction on approximants, it is also straightforward to extend this to

THEOREM 4. If two states (in the same or different systems) are bisimilar, they satisfy the same $L\mu$ formulae.

A system is *image-finite* if for all states s and labels a, the set $\{\, s' \mid s \xrightarrow{a} s' \,\}$ is finite. The following theorem holds:

THEOREM 5. If two states in image-finite systems satisfy the same HML (or $L\mu$) formulae, then they are bisimilar.

To prove this, one observes that bisimulation itself is a maximal fixpoint, namely the maximal fixpoint of the map $R \mapsto \{\, (s_1, s_2) \mid \big(s_1 \xrightarrow{a} s_1' \Rightarrow \exists s_2'. s_2 \xrightarrow{a} s_2' \wedge (s_1', s_2') \in R\big) \wedge \big(s_2 \xrightarrow{a} s_2' \Rightarrow \exists s_1'. s_1 \xrightarrow{a} s_1' \wedge (s_1', s_2') \in R\big) \,\}$ (ignoring the propositions, which can be dealt with by an additional clause); shows that in an image-finite system the approximants to this fixpoint close at ω; and then deduce that if two states are not bisimilar, there is a finite modal formula distinguishing them. The latter theorem does not hold for general systems: there are systems which satisfy the same $L\mu$ formulae, but are not bisimilar. The following example is based on one by Roope Kaivola. Let

$\phi_1, \phi_2, \ldots$ be an enumeration of all $L\mu$ formulae over some finite label set $\mathcal{L}$. Let $\mathfrak{T}_i$, with initial state s_i, be a finite model for ϕ_i, with all $\mathfrak{T}_i$ disjoint. Let $\mathfrak{T}_0$ be constructed by taking an initial state s_0 and making $s_0 \xrightarrow{a} s_i$ for all $i > 0$. Let $\mathfrak{T}'_0$ be $\mathfrak{T}_0$ with the addition of a transition $s_0 \xrightarrow{a} s_0$. $\mathfrak{T}_0$ and $\mathfrak{T}'_0$ are clearly not bisimilar, because in $\mathfrak{T}'_0$ it is possible to defer indefinitely the choice of which $\mathfrak{T}_i$ to enter. On the other hand, suppose that ψ is a formula, and w.l.o.g. assume the topmost operator is a modality. If the modality is $[b]$, ψ is true of both $\mathfrak{T}_0$ and $\mathfrak{T}'_0$; if it is $\langle b \rangle$, ψ is false of both; if ψ is $\langle a \rangle \psi'$, then ψ is false at both $\mathfrak{T}_0$ and $\mathfrak{T}'_0$ iff ψ' is unsatisfiable, and true at both otherwise; if ψ is $[a]\psi'$, then ψ is true at both $\mathfrak{T}_0$ and $\mathfrak{T}'_0$ iff ψ' is valid, and false at both otherwise.

A simple corollary of theorem 4 is that $L\mu$ has the *tree model property.*

Proposition 6. If a formula has a model, it has a model that is a tree.

Just unravel the original model, thereby preserving bisimulation. This can be strengthened to the *bounded branching degree* tree model property (just cut off all the branches that are not actually required by some diamond subformula; this leaves at most (number of diamond subformulae) branches at each node).

For a more detailed look at bisimulation, see Chapter 5 of this Handbook.

4.3 $L\mu$ and automata

$L\mu$ is intimately related to automata theory, and the equivalence between various automata, particularly alternating parity automata, as described in section 5, and $L\mu$ is a key technique in many results. The first connexion between $L\mu$ and automata was tree automata, which we now briefly review.

Let us start with the notion of an automaton familiar from introductory computer science courses. A finite automaton $\mathcal{A} = (Q, \Sigma, \delta, q_0, F)$ consists of a finite set of states Q, a finite alphabet Σ, a transition function δ, an initial state $q_0 \in Q$ and an acceptance condition F. Classical nondeterministic automata recognise languages, subsets of Σ^*, where the transition function $\delta : Q \times \Sigma \to \wp Q$. Given a word $w = a_0 \ldots a_n \in \Sigma^*$, a *run* of $\mathcal{A}$ on w is a sequence of states $q_0 \ldots q_n$ that traverses w, so $q_{i+1} \in \delta(q_i, a_{i+1})$. The run is *accepting* if the sequence $q_0 \ldots q_n$ obeys F: classically, $F \subseteq Q$ and $q_0 \ldots q_n$ is accepting if the last state $q_n \in F$. There may be many different runs of $\mathcal{A}$ on w, some accepting the others rejecting, or no runs at all. The language *recognised* by $\mathcal{A}$ is the set of words for which there is at least one accepting run. A simple extension is to allow recognition of infinite length words. A run of $\mathcal{A}$ on $w = a_1 \ldots a_i \ldots$ is an infinite sequence of states $\pi = q_0 \ldots q_i \ldots$ that travels over w, so $q_{i+1} \in \delta(q_i, a_{i+1})$ and it is accepting if it obeys the condition F. Let $\mathit{inf}(\pi) \subseteq Q$ contain exactly the states that occur infinitely often in π. Classically, $F \subseteq Q$ and π is accepting if $\mathit{inf}(\pi) \cap F \neq \emptyset$ which is the Büchi acceptance condition.

Büchi automata are an alternative notation for characterizing infinite runs of systems. Assume Prop is a finite set. The alphabet $\Sigma = \wp\mathrm{Prop}$. If $\pi = s_0 \xrightarrow{a_1} s_1 \xrightarrow{a_2} \ldots$ is an infinite run, then $\pi \models \mathcal{A}$ if the automaton accepts the word $\mathrm{Prop}(s_0)\,\mathrm{Prop}(s_1) \ldots$ where $\mathrm{Prop}(s_i)$ is the subset of Prop that is true at s_i. For example, if $\mathrm{Prop} = \{P\}$, $Q = \{p, q\}$, $\delta(p, \{P\}) = \{q\}$, $\delta(p, \emptyset) = \{p\}$, $\delta(q, \{P\}) = \{q\}$ and $\delta(q, \emptyset) = \{q\}$, $q_0 = p$ and $F = \{q\}$, then this automaton is equivalent to the temporal formula $\mathbf{F}P$. (In fact, Büchi automata coincide with the *linear-time μ-calculus* where fixpoints are added to simple next time temporal logic that has the sole modality $\bigcirc$.)

When formulae are equivalent to automata, satisfiability checking reduces to the *non-emptiness* problem for the automata: that is, whether the automaton accepts something. If $\mathcal{A}$ is a Büchi automaton, then it is non-empty if there is a transition path $q_0 \longrightarrow^* q \in F$ and a cycle $q \longrightarrow^* q$ (equivalent to an eventually cyclic model).

The notion of bounded branching *tree automaton* extends the definition of automaton to accept n-branching infinite trees whose nodes are labelled with elements of Σ. Previously, states q' belonged to $\delta(q, a)$; now it is tuples $(q'_1, \ldots, q'_n)$ that belong to $\delta(q, a)$. A tree automaton traverses the tree, descending from a node to all n-child nodes, so the automaton splits itself into n copies, and proceeds independently. A run of the automaton is then an n-branching infinite tree labelled with states of the automaton. A run is accepting if *every* path through this tree satisfies the acceptance condition F. In the case of Rabin acceptance $F = \{(G_1, R_1), \ldots (G_k, R_k)\}$ where each $G_i, R_i \subseteq Q$ and π obeys F if there is a j such that $\mathit{inf}(\pi) \cap G_j \neq \emptyset$ and $\mathit{inf}(\pi) \cap R_j = \emptyset$. A variant definition is *parity* acceptance first introduced (not under that name) by Mostowski [52] where F maps each state q of the automaton to a *priority* $F(q) \in \mathbb{N}$. We say that a path satisfies F if the least priority seen infinitely often is even. It is not hard to see that a parity condition is a special case of a Rabin condition; it is also true, though somewhat trickier, that a Rabin automaton can be translated to an equivalent parity automaton.

Assuming Prop is finite, tree automata characterize rooted n-branching infinite tree models $(\mathfrak{T}, s_0, \mathfrak{V}_{\mathrm{Prop}})$ for $L\mu$ formulae where s_0 is the root of the tree: $(\mathfrak{T}, s_0, \mathfrak{V}_{\mathrm{Prop}}) \models \mathcal{A}$ if $\mathcal{A}$ accepts the behaviour tree $\mathfrak{T}'$ that replaces each state $s \in \mathfrak{T}$ with $\mathrm{Prop}(s)$. For example, let $\mathrm{Prop} = \{P\}$, $Q = \{p, q\}$, $\delta(p, \{P\}) = \{(p, p)\}$, $\delta(p, \emptyset) = \{(q, q)\}$, $\delta(q, \{P\}) = \{(p, p)\}$ and $\delta(q, \emptyset) = \{(q, q)\}$ and $q_0 = p$. This automaton $\mathcal{A}$ with parity acceptance $F(p) = 1$ and $F(q) = 2$ is equivalent to $\mu Y. \nu Z. (P \wedge [a]Y) \vee (\neg P \wedge [a]Z)$ over infinite binary-tree models: the fixed point μY is 'coded' by p and νZ is coded by q.

The use of priorities looks very much like the definition of well-founded pre-model from section 3.6, if we assign priorities to the subformulae of an $L\mu$ formula in such a way that the priority of a fixpoint formula is lower than any of its subformulae (and the priority of a least fixpoint is odd). Indeed, it is essentially the same thing. Tree automata and $L\mu$ are equivalent [64]:

THEOREM 7. A family of n-branching infinite tree models is defined by some tree automaton iff it is the set of n-branching infinite tree models of some corresponding $L\mu$ formula. Consequently, determining whether a system satisfies an $L\mu$ formula is equivalent to determining whether its behaviour trees are accepted by the corresponding automaton.

Decidability of satisfiability of $L\mu$ formulae reduces to the non-emptiness problem for tree automata. This problem is more difficult than for Büchi automata. However, there is an exponential decision procedure that is inductive in the *index* of the automaton (which is the number of parities or pairs in F, in the case of a Rabin automaton).

This illustrates the potency of the automata-theoretic approach to temporal logic that has become popular in recent years. Satisfiability of formulae is reduced to the non-emptiness problem for a class of automata. There is also the virtue that automata sustain combinatorial transformations, such as determinization, and closure operations, such as intersection, that are not in the logical repertoire. Occasionally, logics are easier: one of the hardest automata-theoretic proofs is that tree automata are closed under complementation. We shall see more of automata in later sections.

4.4 $L\mu$ and games

$L\mu$ is also intimately related to games, as are automata. We can view the relationship at different levels.

The fundamental semantic theorem can be presented as a simple two player *model-checking* game. Assume a rooted model $(\mathfrak{T}, s_0, \mathfrak{V})$ and formula ϕ_0 in positive normal form. The game $G(s_0, \phi_0)$ is defined on an *arena* that is a set of pairs (s, ψ) where s is a state of $\mathfrak{T}$ and ψ is a subformula of ϕ_0. The initial position is (s_0, ϕ_0). There are two players, whom we will call simply $\forall$ and $\exists$. (Other popular names include Player II/Player I, Abelard/Eloise, Opponent/Proponent, Refuter/Verifier.) $\forall$ is responsible for making a move from a position $(s, \phi \wedge \psi)$, the available choices are $\{(s, \phi), (s, \psi)\}$, and from a position $(s, [a]\phi)$ whose available choices are $\{(t, \phi) \mid s \xrightarrow{a} t \in \mathfrak{T}\}$. Similarly, $\exists$ is responsible for $(s, \phi \vee \psi)$ and $(s, \langle a \rangle \phi)$. There are final positions (s, ψ) where $\psi \in \{P, \neg P, [a]\phi, \langle a \rangle \phi\}$: $(s, [a]\psi)$ and $(s, \langle a \rangle \phi)$ are only final if there is no state t such that $s \xrightarrow{a} t$. A final position (s, ψ) is winning for $\exists$ if $s \models \psi$; otherwise it is winning for $\forall$.

A play of $G(s_0, \phi_0)$ is a finite or infinite sequence of positions starting with (s_0, ϕ_0). $\exists$ wins a finite play if the final position is winning for $\exists$. She wins an infinite play if the outermost fixed point variable Y that occurs infinitely often in the play is a ν-variable. Otherwise, $\forall$ wins. There may be many different plays; $\exists$ may win some and lose others. A *strategy* for a player is a function which, given a play so far and a position where there is a choice, returns a specific choice and so tells the player how to move. A *history-free* (positional or memoryless) strategy only depends on the current position and not on the previous history of the play: for $\exists$ it is just a choice function. A *winning strategy* is one which, if followed, guarantees that the player will win all plays of the game. Now the fundamental semantic theorems, theorems 1 and 2, are equivalent to the following.

THEOREM 8. $s \models \phi$ iff $\exists$ has a history-free winning strategy for the game $G(s, \phi)$.

The model checking game on finite structures can be abstracted into a simple two player graph game, called *the parity game*. The state set Q of the graph are the positions and are partitioned into $Q_\forall$ and $Q_\exists$. There is an initial state $q_0 \in Q$. Edges decide possible next positions; for instance, $\exists$ chooses a successor from a vertex $q \in Q_\exists$ and to ensure play is always infinite winning positions have self-loops. The acceptance condition F is just given as a parity condition: F maps each state q of the automaton to a priority $F(q) \in \mathbb{N}$ and $\exists$ wins an infinite play if the least priority that occurs infinitely often is even. The *model-checking* problem for $L\mu$ over finite structures, whether $s_0 \models \phi_0$, is equivalent to solving the parity game (does $\exists$ win q_0 ?). Parity games are determined (i.e. either $\exists$ or $\forall$ has a winning strategy), and a winning strategy is history-free. However, the exact complexity of solving a parity game is a significant open problem.

There is a more intimate connection between $L\mu$ and parity games. An $L\mu$ formula, itself, *is* a parity game as we shall see in section 5; alternating automata are games. Tree automata are games following Gurevich and Harrington [30]. Consider a run of a tree automaton on an n-branching infinite tree whose nodes are labelled with elements of Σ. It starts at the root of the tree with the initial automaton state. If the automaton is in state q examining a node v of the tree labelled with $a \in \Sigma$ then $\exists$ chooses a tuple $(q'_1, \ldots, q'_n)$ that belong to $\delta(q, a)$. Now $\forall$ chooses a direction $i : 1 \leq i \leq n$ so the next position is the ith child of v in state q'_i. The play continues forever. The play is won by $\exists$ if it obeys the acceptance condition. Clearly, $\exists$ has a winning strategy, iff the automaton accepts the tree. (If the acceptance condition is a Rabin condition, this strategy is not

history-free; however, it only depends on the 'latest appearance record', an ordering of the automaton states capturing the last time each automaton state occurred in the current play.)

5 DECIDABILITY OF SATISFIABILITY

As with any logic, a key question is decidability of satisfiability, that is, deciding whether a closed formula has a model. A connected property is the *finite model property (fmp)*, that is, if a formula has a model, then it has a finite model. If a logic has the fmp (and the size of the finite model for a formula is effectively bounded), then decidability follows, since one can just check all models up to the size bound. $L\mu$, as we have seen, has the tree model property.

A direct approach to proving decidability of satisfiability is to employ semantic tableaux, to begin with an initial closed formula ϕ in positive normal form and then to build a tree model for it whose states are labelled with locally consistent subsets of the Fisher-Ladner closure of ϕ, $\mathrm{cl}(\phi)$: for instance, if $\psi \wedge \gamma \in s$ then $\psi \in s$ and $\gamma \in s$. Children of a node s are generated using modal successor principles. For each $\langle a \rangle\psi \in s$ create a child node t such that $s \xrightarrow{a} t$ and $\psi \in t$: in turn, $s \xrightarrow{a} t$ when $[a]\psi \in s$ implies $\psi \in t$ and $\psi \in t$ and $\langle a \rangle\psi \in \mathrm{cl}(\phi)$ implies $\langle a \rangle\psi \in s$. This guarantees that the tree has bounded branching degree because $\mathrm{cl}(\phi)$ is finite. Fixed point formulae are "unfolded": ${}^{\mu}_{\nu}X.\,\psi \in s$ implies $\psi({}^{\mu}_{\nu}X.\,\psi) \in s$. The valuation $\mathfrak{V}_{\mathrm{Prop}}$ is then defined: $s \in \mathfrak{V}_{\mathrm{Prop}}(P)$ if and only if $P \in s$.

If ϕ is satisfiable then the construction will generate a finite tree model or an infinite tree that is a pre-model. In the latter case, the problem is how to ensure that it is well-founded. So far, there is no distinction between least and greatest fixed points. As mentioned, an important semantic principle is Park's fixed point induction rule, if $\models \phi(\psi) \Rightarrow \psi$ then $\models \mu X.\phi(X) \Rightarrow \psi$: it follows directly from the semantics because μ is indeed the least pre-fixed point. A question is how to use this semantic principle to guide the tableau construction in such a way that if the starting formula is satisfiable then a model is generable. The following proposition is useful.

Proposition 9. If $\gamma \wedge \mu X.\psi(X)$ is satisfiable and X is not free in γ, then $\gamma \wedge \psi(\mu X.\neg\gamma \wedge \psi)$ is satisfiable.

Proof. Assume that $\gamma \wedge \mu X.\psi(X)$ is satisfiable but $\models \psi(\mu X.\neg\gamma \wedge \psi) \Rightarrow \neg\gamma$. Therefore, $\models \psi(\mu X.\neg\gamma \wedge \psi) \Rightarrow \neg\gamma \wedge \psi(\mu X.\neg\gamma \wedge \psi)$. Using the fact that $\models \phi'(\mu X.\phi'(X)) \Rightarrow \mu X.\phi'(X)$ and propositional reasoning, $\models \psi(\mu X.\neg\gamma \wedge \psi) \Rightarrow \mu X.\neg\gamma \wedge \psi$. By fixed point induction, $\models \mu X.\psi \Rightarrow \mu X.\neg\gamma \wedge \psi$ and consequently $\models \mu X.\psi \Rightarrow \neg\gamma$ which is a contradiction. ❑

5.1 *The aconjunctive fragment*

The tableau approach was employed by Kozen [35] to decide satisfiability. Unfortunately, he could only prove the result for a sublogic of $L\mu$, when the starting formula ϕ is *aconjunctive*: that is, if $\mu X.\psi$ is a subformula of ϕ and $\psi_1 \wedge \psi_2 \in \mathrm{cl}(\mu X.\psi)$ then for at most one ψ_i is it the case that $\mu X.\psi \in \mathrm{cl}(\psi_i)$. For instance, $\nu Z.\mu X.([a]X \vee \langle b \rangle Z) \wedge \langle a \rangle Z$ is aconjunctive: the subformula $\gamma = \mu X.([a]X \vee \langle b \rangle Z) \wedge \langle a \rangle Z$ has one conjunction in its closure $([a]\gamma \vee \langle b \rangle Z) \wedge \langle a \rangle Z$ and γ is only in the closure of the first conjunct. In contrast, $\gamma = \mu X.\nu Z.([a]X \vee \langle b \rangle Z) \wedge \langle a \rangle Z$ fails to be aconjunctive: γ is in the closure of both conjuncts $([a]\gamma \vee \langle b \rangle(\nu Z.[a]\gamma \wedge \langle a \rangle Z)) \wedge \langle a \rangle(\nu Z.[a]\gamma \wedge \langle a \rangle Z)$. Aconjunctivity restricts

how a formula $\mu X.\psi \in \mathrm{cl}(\phi)$ can regenerate itself in the tableau construction: there can only be a linear pattern of regeneration (as opposed to the more general branching pattern for full $L\mu$). In the case of $\gamma = \nu Z.\mu X.([a]X \vee \langle b\rangle Z) \wedge \langle a\rangle Z$, the relevant formula $\gamma' = \mu X.([a]X \vee \langle b\rangle \gamma) \wedge \langle a\rangle \gamma$ can only regenerate itself through the the subformula $[a]X$: so, multiple regenerations of γ' happen only as part of a linear sequence. On the other hand, $\gamma = \mu X.\nu Z.([a]X \vee \langle b\rangle Z) \wedge \langle a\rangle Z$ can regenerate itself through both subformulae $([a]X \vee \langle b\rangle Z)$ and $\langle a\rangle Z$: so, multiple regenerations of γ form a tree.

Given the aconjunctive restriction, one can guide the construction of the tree model by applying proposition 9 to $\mu X.\psi \in s$: as it is unfolded its interpretation is strengthened to $\psi(\mu X.\neg s \wedge \psi)$ where s abbreviates the conjunction of all formulas in s. The strengthening interpretation is extended as $\mu X.\psi$ regenerates itself in descendent states t of s, so that an unfolding in t is re-interpreted as $\psi(\mu X.\neg s \wedge \ldots \wedge \neg t \wedge \psi)$ thereby ensuring that a descendent state within which $\mu X.\psi$ is regenerated cannot have the same labelling as the ascendent state (and because the starting formula is aconjunctive this will guarantee a well-founded pre-model). To do this, one needs a careful ordering on fixed point subformulae (in terms of which are more outermost) to ensure that the set of labellings remains finite. Kozen showed that the decision procedure for this fragment (that contains PDL and CTL) works in exponential time and at the same time the proof delivers the finite model property. In fact, the construction works for a more generous fragment of the logic, called the *weak* aconjunctive fragment in [71]. One only needs to guarantee that there is a linear pattern of regeneration of least fixed point subformulae relative to each individual branch in the tree model. The formula $\gamma = \mu X.\nu Z.\langle a\rangle X \wedge \langle a\rangle Z$ belongs to this more generous fragment because the regenerations of γ through the subformulae $\langle a\rangle X$ and $\langle a\rangle Z$ happen in different branches: the formula $\mu X.\nu Z.([a]X \vee \langle b\rangle Z) \wedge \langle a\rangle Z$ does not belong to it. In fact, every closed formula of $L\mu$ is semantically equivalent to a weak aconjunctive formula (which follows from results below). However, it is an open question whether the tableau technique can be made to work directly for all formulae.

5.2 Towards automata

The first decision procedure for full $L\mu$ reduced the problem to SnS, the second-order theory of n-successors, [38]. The structure for SnS is the transition system (tree) with state space $\{0, \ldots, n-1\}^*$ and transition relations $w \xrightarrow{i} wi$ for each $i < n$. Büchi showed that the monadic second-order (MSO) theory of S1S is decidable [13]: besides first-order constructs, MSO has quantifiers over sets of states. S1S is a weak form of arithmetic where, in this presentation, the number n is 0^n and $\xrightarrow{0}$ is the $+1$ function. Rabin extended Büchi's result by showing that the MSO theory of SnS is decidable for any $n > 0$ [60]. Kozen and Parikh's proof of decidability of satisfiability for full $L\mu$ uses the tree model property with bounded branching degree. Given a formula ϕ the maximum required branching degree n can be calculated from $\mathrm{cl}(\phi)$. The formula ϕ can then be translated almost directly into SnS by examining its semantics: for instance, $\|\nu X.\phi\|_{\mathfrak{V}} = \exists S.S \subseteq \|\phi\|_{\mathfrak{V}[X:=S]}$ and $\|X\|_{\mathfrak{V}} = \mathfrak{V}(X)$. Elements of Prop are treated as variables (and are existentially quantified over). Labels in diamond modalities are judiciously mapped to "directions" $i < n$ and labels in box modalities to sets of directions. For example, $\nu X.\langle a\rangle(X \wedge \neg P) \wedge \langle a\rangle(X \wedge P)$ is translatable into the S2S formula

$$\exists P.\exists S.\forall x.\exists y.\exists z.(x \in S \Rightarrow x \xrightarrow{1} y \wedge y \in S \wedge y \notin P) \wedge (x \in S \Rightarrow x \xrightarrow{2} z \wedge z \in S \wedge z \in P)$$

The formula ϕ is satisfiable if and only if its translation is true in SnS: for instance, the S2S formula above is true. The key feature in the MSO decidability proofs is that in a formula $\exists X.\phi$, quantification can be restricted to "regular" sets of states which leads to quantifier elimination when the normal form is a nondeterministic finite state automaton. In the case of S1S it is a Büchi word automaton and in the more general setting of SnS it is a Rabin tree automaton: these automata are defined in section 4.3. The automaton normal form for $\forall X.\phi$, that is $\neg\exists X\neg\phi$, involves an exponential increase in size because of complementation. Consequently, the decision procedure for SnS, $n > 0$, is (and must be) non-elementary. Because $\mu X_1.\nu X_2.\ldots\mu X_m.\nu X_{m+1}.\psi$ is translated into the MSO formula $\forall S_1.\exists S_2\ldots\forall S_m.\exists S_{m+1}.\psi'$, Kozen and Parikh's decision procedure for $L\mu$ is also non-elementary.

MSO formulae with second-order quantification, unlike fixed point formulae, are expressively succinct. A direct translation of $L\mu$ formulae into finite state automata, without intervening MSO formulae, could lead to a more efficient decision procedure. With this technique Streett provided an elementary time decision procedure for PDL with looping and converse [65]. With Emerson he employed the same technique for $L\mu$ and obtained a decision procedure for satisfiability and a proof of the finite model property at once [64]. The procedure is in elementary time. The central ingredient (besides the tree model property) is the relationship between $L\mu$ and Rabin automata, which is established using the fundamental semantic theorem. For, the constraint on fixpoint regeneration and infinite repetition is expressible as a Rabin acceptance condition. Now we can construct an automaton that accepts such bounded-branching tree models, by combining a finite-state automaton to check the local consistency (that is, to check that the putative model is a pre-model), and a Rabin automaton to check that the pre-model is well-founded. Thus the formula is satisfiable if this product automaton accepts some tree. Now automata theory, see for instance [66], tells us that (a) this question is decidable (b) if such an automaton accepts some tree, it accepts a regular tree, that is, one that is the unravelling of a finite system; this gives the results. Later, Emerson and Jutla provided an exponential time decision procedure (which is optimal) using an improved determinization construction and an improved tree automata emptiness test [22]: there is an exponential (in the size of the formula) bound on the size of the model.

5.3 Alternating parity automata

There is a slight mismatch between $L\mu$ models and SnS models because of the fixed branching degree and the explicit indexed successors. However, it is possible to define automata that can directly recognise $L\mu$ models by navigating through their transition graphs. We define *alternating parity automata* for this purpose following, for example, [40]. The only restriction is that we assume that Prop is a finite set (those propositions that appear in a starting formula ϕ). A rooted model for a closed formula ϕ is a triple $(\mathfrak{T}, s_0, \mathfrak{V})$.

Recall the notion of automaton $\mathcal{A} = (Q, \Sigma, \delta, q_0, F)$ as defined in section 4.3. Now think of the transition function of an automaton as a logical formula. For a word automaton, if $\delta(q, a) = \{q_1, \ldots, q_m\}$ then it is the formula $q_1 \vee \ldots \vee q_n$. For a tree automaton if $\delta(q, a) = \{(q_1^1, \ldots, q_n^1), \ldots, (q_1^m, \ldots, q_n^m)\}$ then it is $((1, q_1^1) \wedge \ldots \wedge (n, q_n^1)) \vee \ldots \vee ((1, q_1^m) \wedge \ldots \wedge (n, q_n^m))$: here the element (i, q') means create an *ith*-child with label q'. A word or tree is accepted if there exists an accepting run for that word or tree; hence, the disjuncts.

However, for a tree, every path through it must be accepting; hence the conjuncts. In *alternating* word automata, the transition function is given as an arbitrary boolean expression over states: for instance, $\delta(q,a) = q_1 \wedge (q_2 \vee q_3)$. In alternating tree automata it is a boolean expression over directions and states: for instance, $((1,q_1) \wedge (1,q_2)) \vee (2,q_3)$. Now the definition of a run becomes a tree in which, successor transitions obey the boolean formula. In particular, even for an alternating automaton on words, a run is a tree, and not just a word. The acceptance criterion is as before, that every path of the run must be accepting. An alternating automaton is just a game too where $\forall$ is responsible for $\wedge$ choices and $\exists$ for $\vee$ choices (as in section 4.4).

The idea now is to replace pairs (i,q') with simple modal formulae. We define *modal* automata whose transition functions appeal to a modal language (similar to modal equation systems). Formally, a modal automaton $\mathcal{A} = (Q, \Sigma, \delta, q_0, F)$ where Q is a finite set of states, Σ is the set $\wp$Prop and F is the parity acceptance condition. The transition function $\delta : Q \times \Sigma \rightarrow B$ where B is the following set of positive modal formulae (with modal depth at most 1).

- $\top$, $\perp$ are in B
- If $q \in Q$ and $a \in \mathcal{L}$ then $\langle a \rangle q$ and $[a]q$ are in B
- If B_1 and B_2 are in B then $B_1 \vee B_2$ and $B_1 \wedge B_2$ are in B

The automaton traverses the modal model, starting at s_0 and moving from a state s to successor states t such that $s \xrightarrow{a} t$ for some $a \in \mathcal{L}$, according to the transition function. However, not every successor may be included and some successors may be included multiple times: for instance, if q is the current automaton state for s and $\delta(q, \mathrm{Prop}(s)) = \langle a \rangle p_1 \wedge [c]p_2$[3] and $s \xrightarrow{a} s_1$, $s \xrightarrow{b} s_2$, $s \xrightarrow{c} s_1$ and $s \xrightarrow{c} s$ then the automaton changes state to p_1 and moves to s_1 in the model, changes to p_2 and also moves to s_1 in the model and changes to p_2 and remains at s. As with tree automata, a run of $\mathcal{A}$ on a model is a a labelled tree $(N, \xrightarrow{i}, L')$ where $N \subseteq \omega^*$ that obeys the tree property that if $wi \in N$ then $w \in N$ and $w \xrightarrow{i} wi$: a node $x \in N$ may have infinitely many successors $xi \in N$, as models have no bound on their branching degree. Unlike tree automata, there is no requirement that complete branches should have infinite length.

In more detail, a run of $\mathcal{A}$ on a modal model is a projection of an intermediate structure, a tree with composite labels $(N, \xrightarrow{i}, L)$. The labelling $L : N \rightarrow S \times Q$ where S is the state space of the model: for the root of the tree, $L(\epsilon) = (s_0, q_0)$. The labels of a node and its successors have to obey the transition function. First, given a state s of the model let M_s range over mixture subsets $\{(t,q') \mid s \xrightarrow{a} t \text{ for some } a \text{ and } q' \in Q\}$. Next, we define when a subset M_s satisfies a modal formula B, which we write $M_s \models B$.

$$
\begin{array}{lll}
M_s \models \top & & M_s \not\models \perp \\
M_s \models \langle a \rangle p & \text{iff} & \exists t. s \xrightarrow{a} t \text{ and } (t,p) \in M_s \\
M_s \models [a]p & \text{iff} & \forall t. \text{ if } s \xrightarrow{a} t \text{ then } (t,p) \in M_s \\
M_s \models B_1 \vee B_2 & \text{iff} & M_s \models B_1 \text{ or } M_s \models B_2 \\
M_s \models B_1 \wedge B_2 & \text{iff} & M_s \models B_1 \text{ and } M_s \models B_2
\end{array}
$$

Given $\mathcal{A}$ and a rooted model, one grows a labelled tree from the root ϵ with $L(\epsilon) = (s_0, q_0)$. If $L(x) = (s,q)$ and $\delta(q, \mathrm{Prop}(s)) = B$ then there is a (possibly empty) set M_s such that

[3]Prop(s) is the subset of Prop true at s.

$M_s \models B$. A child of x is produced for each element of M_s: that is, $M_s = \{L(xi) \mid xi \in N\}$. For example, if $L(x) = (s, q)$ and $\delta(q, \mathrm{Prop}(s)) = \langle a\rangle q_1 \wedge [a]q_2 \wedge \langle a\rangle q_3$ and in the model $s \xrightarrow{a} s_i$ for all $i \geq 0$ then a candidate M_s is $\{(s_0, q_1), (s_1, q_3), (s_0, q_2), \ldots, (s_i, q_2), \ldots\}$: here there are infinitely many such candidates. The required run is the projection of the tree to states in Q, the tree $(N, \xrightarrow{i}, L')$ whose labelling $L'(x) = q$ if $L(x) = (s, q)$ for some s. A run is *accepting* if all (labellings of) infinite branches starting from the root obey the parity acceptance condition F.

Given a rooted model $(\mathfrak{T}, s_0, \mathfrak{V})$, $s_0 \models \mathcal{A}$ if there is an accepting run of $\mathcal{A}$ on that model. The following is relatively straightforward (and is reminiscent of translating to and from boolean equation systems).

THEOREM 10. For each modal automaton there is an equivalent closed formula of $L\mu$, and for each closed formula of $L\mu$ there is an equivalent modal automaton.

5.4 Automaton normal form

We can now extract a semantic *normal form* for $L\mu$ due to Walukiewicz [71, 32]. If Γ is a finite set of formulae, $(a)\Gamma$ abbreviates $\bigwedge_{\phi\in\Gamma}\langle a\rangle\phi \wedge [a]\bigvee_{\phi\in\Gamma}\phi$. Every modal automaton is equivalent to a *restricted* modal automaton. Let $\Sigma = \{a_1, \ldots, a_n\}$. The transition function is restricted: formulae of B are disjunctions of conjuncts of the form $(a_1)B_1 \wedge \ldots \wedge (a_n)B_n$ where each $B_i \subseteq Q \cup \{\top\}$. The proof of the following is far from trivial and depends on the combinatorial features of automata, especially determinization.

THEOREM 11. For each modal automaton there is an equivalent restricted modal automaton.

A formula is in *automaton normal form (anf)*[4], if it belongs to the following sublogic, where

- P, $\neg P$ and Z are anfs
- If ϕ_1 and ϕ_2 are anfs, so is $\phi_1 \vee \phi_2$
- If ϕ is an anf, then so are $\nu Z.\phi$, $\mu Z.\phi$
- If each Γ_i is a finite set of anfs and $a_i \neq a_j$ when $i \neq j$ and α^+ is a finite set of atomic propositions and their negations, then $(a_1)\Gamma_1 \wedge \ldots \wedge (a_n)\Gamma_n \wedge \alpha^+$ is an anf

Anf formulae are the characteristic formulae for restricted automata. For instance, a clause $\{\langle a\rangle p, \langle a\rangle q\}$ with respect to labels a, b becomes the formula $\langle a\rangle p \wedge \langle a\rangle q \wedge [a](p \vee q) \wedge [b]\bot$.

Proposition 12. For each restricted automaton there is an equivalent anf formula.

Therefore, anfs are semantic normal forms for $L\mu$. We can effectively construct the anf normal form for a formula ϕ in positive normal form. First, use Theorem 10 to build an equivalent modal automaton $\mathcal{A}_\phi$ for ϕ. Next, use Theorem 11 to transform $\mathcal{A}_\phi$ into an equivalent restricted automaton $\mathcal{A}^+_\phi$. Finally, use Proposition 12 to convert $\mathcal{A}^+_\phi$ into an equivalent anf formula ϕ'.

An anf formula is weakly aconjunctive (although not necessarily aconjunctive). After simplification, the anf normal form of the earlier formula $\mu X.\nu Z.([a]X \vee \langle b\rangle Z) \wedge \langle a\rangle Z$

[4] Walukiewicz terms them "disjunctive formulae".

that is not aconjunctive is $\mu X.\nu Z.(a)\{X\} \vee ((a)\{Z, \top\} \wedge (b)\{Z, \top\})$. In fact, conjunction is even more constraining in anf formulae. Consider, the semantic tableau construction for an anf formula ϕ. The only time we need to apply $\wedge$ decomposition is just before the application of modal successors: assume a state s is labelled with the formula $(a_1)\Gamma_1 \wedge \ldots \wedge (a_n)\Gamma_n \wedge \alpha^+ \in \mathrm{cl}(\phi)$. At s it reduces to its components $(a_1)\Gamma_1, \ldots, (a_n)\Gamma_n, \alpha^+$. If α^+ is consistent then modal children $s \xrightarrow{a_i} t$ are created: however, by the definition of (a) each modal successor t is labelled with a single anf formula in $\mathrm{cl}(\phi)$. Therefore, as shown by Walukiewicz, ϕ is satisfiable iff all its fixed point subformulae $\mu X.\psi(X)$ are replaced with $\psi(\bot)$ and all subformulae $\nu X.\psi(X)$ are replaced with $\psi(\top)$. To illustrate this, assume $\phi = \mu X.\psi$ is satisfiable. Consider a rooted model and a least ordinal o such that $s_0 \models \mu X^o.\psi$. Consider its semantic tableau with initial state s_0 labelled with ϕ. If there is a descendent state t that is also labelled with ϕ then $t \models \mu X^{o'}.\psi$ with $o' < o$ which contradicts that o is least. Therefore, there is a model for ϕ such that no descendent state is labelled with ϕ, which is, therefore, also a model for $\psi(\bot)$. Consequently, satisfiability checking for an anf formula can be done in linear time [32]. To obtain the fmp for anf ϕ, replace each subformulae $\mu X.\psi(X)$ with $\psi(\bot)$ and build a semantic tableaux for it. For modal successors, if at state s, $\nu X.\psi \in \Gamma$ and $(a)\Gamma \in s$ and some state t is on the path from the root to s and t is labelled with $\nu X.\psi$ then let $s \xrightarrow{a} t$: in this way, a finite model for ϕ is constructed.

6 COMPLETE AXIOMATIZATION

A related problem to decidability is the question of providing an axiomatization of the theory of the modal mu-calculus. In his original paper, Kozen presented the axiomatization as an equational theory which is equivalent to the following.

1. axioms and rules for minimal multi-modal logic K
2. $\phi(\mu X.\phi(X)) \Rightarrow \mu X.\phi(X)$
3. $\dfrac{\phi(\psi) \Rightarrow \psi}{\mu X.\phi(X) \Rightarrow \psi}$

Axiom 2 is the axiom for a least fixed point that its "unfolding" implies it and rule 3 is Park's fixed point induction rule. The duals of this axiom and rule for greatest fixed points are; $\nu X.\phi(X) \Rightarrow \phi(\mu X.\phi(X))$ and if $\psi \Rightarrow \phi(\psi)$ then $\psi \Rightarrow \nu X.\phi(X)$.

However, despite the naturalness of this axiomatization, Kozen was unable to show that it was complete. He was, however, able to show completeness for the aconjunctive fragment. In fact, a proof works for *weak* aconjunctive formulae using the consistency version of proposition 9: if $\gamma \wedge \mu X.\psi(X)$ is consistent[5] and X is not free in γ, then $\gamma \wedge \psi(\mu X.\neg\gamma \wedge \psi)$ is consistent. The proof is similar to the tableau construction described in section 5.1. Given an initial consistent formula in positive normal form one builds a tree model: the construction is guided by the proposition above as in the satisfiability proof.

[5]A formula ϕ is consistent with respect to an axiom system if $\phi \Rightarrow \bot$ is not derivable within the axiom system. Completeness of an axiom system is equivalent to the statement that every consistent formula has a model (is satisfiable).

Completeness for the full language remained open for more than a decade, until it was finally solved by Walukiewicz in [71], who established that Kozen's axiomatization is indeed complete. The proof is very involved and, in effect, internalises the automata theoretic satisfiability proof described earlier. It utilises automata normal form and weak aconjunctivity. It is more straightforward (as with satisifiability) to show using tableaux that if an anf formula is consistent then it has a model. Much harder to prove is that every (closed) formula is provably equivalent within the axiom system to an anf formula. Walukiewicz utilises games on infinite tableaux to show this.

The following are valid fixpoint principles (which, by duality also are true for ν).

$$\mu X.\mu Y.\phi(X,Y) \iff \mu X.\phi(X,X) \iff \mu Y.\mu X.\phi(X,Y)$$

Arnold and Niwinski call these "the golden lemma" of μ-calculus [5]. Other interesting valid fixpoint principles include $\mu X.\phi(X) \Rightarrow \nu X.\phi(X)$, by monotonicity, and the following, due to Niwinski, that generalises that 'almost always' implies 'infinitely often'.

$$\mu X.\nu Y.\phi(X,Y) \Rightarrow \nu Y.\mu X.\phi(X,Y)$$

Deriving these principles deductively from Kozen's complete axiom system is by no means easy (as opposed to their derivations using the semantics).

7 ALTERNATION

As we said earlier, the alternation of fixpoints is what gives $L\mu$ its expressive power, and also what appears to generate the computation complexity of model-checking. In this section, we study alternation in more detail. As we have said, the idea is to count alternations of minimal and maximal fixpoint operators, but to do so in a way that only counts real dependency. The paradigm is 'always eventually' versus 'infinitely often': the 'always eventually' formula

$$\nu Y.(\mu Z.P \vee \langle a\rangle Z) \wedge \langle a\rangle Y$$

is, using a straightforward model-checking algorithm, really no worse to compute than two disjoint fixpoints, since the inner fixpoint can be computed once and for all, rather than separately on each outer approximant; on the other hand, the 'infinitely often' formula

$$\nu Y.\mu Z.(P \vee \langle a\rangle Z) \wedge \langle a\rangle Y$$

really does need the full double induction on approximants.

The definition of Emerson and Lei takes care of this by observing that the 'eventually' subformula is a closed subformula, and giving a definition that ignores closed subformulae when counting alternations. The stronger notion of Niwiński, which also has the advantage of being robust under translation to modal equation systems, also observes that, for example, $\mu X.\nu Y.[-]Y \wedge \mu Z.[-](X \vee Z)$ although it looks like a $\mu/\nu/\mu$ formula, is morally a μ/ν formula, since the inner fixpoint does not refer to the middle fixpoint.

The alternation depth referred to in the complexity of model-checking is a measure of alternation that is symmetric in μ and ν. It is possible to give algorithms that compute the alternation depth of a formula [24, 1, 34], and this is how the notion was presented by

Emerson and Lei. However, for our purposes it is easier to start from a definition of classes for formula, formalizing the idea of 'a $\mu/\nu/\mu$ formula' etc.; such a definition is analogous to the usual definition of quantifer alternation for predicate logic, an analogy which will be exploited later. This was how Niwiński [53] presented the notion of alternation, and we follow his presentation.

Assuming positive form, a formula ϕ is said to be in the classes $\Sigma_0^{N\mu}$ and $\Pi_0^{N\mu}$ iff it contains no fixpoint operators. To form the class $\Sigma_{n+1}^{N\mu}$ (resp. $\Pi_{n+1}^{N\mu}$), take $\Sigma_n^{N\mu} \cup \Pi_n^{N\mu}$, and close under the following rules:

1. if $\phi_1, \phi_2 \in \Sigma_{n+1}^{N\mu}$ (resp. $\Pi_{n+1}^{N\mu}$), then $\phi_1 \vee \phi_2, \phi_1 \wedge \phi_2, \langle a\rangle\phi_1, [a]\phi_1 \in \Sigma_{n+1}^{N\mu}$ (resp. $\Pi_{n+1}^{N\mu}$);
2. if $\phi \in \Sigma_{n+1}^{N\mu}$ (resp. $\Pi_{n+1}^{N\mu}$), then $\mu Z.\phi \in \Sigma_{n+1}^{N\mu}$ (resp. $\nu Z.\phi \in \Pi_{n+1}^{N\mu}$);
3. if $\phi(Z), \psi \in \Sigma_{n+1}^{N\mu}$ (resp. $\Pi_{n+1}^{N\mu}$), then $\phi(\psi) \in \Sigma_{n+1}^{N\mu}$ (resp. $\Pi_{n+1}^{N\mu}$), *provided* that no free variable of ψ is captured by a fixpoint operator in ϕ.

If we omit the last clause, we get the definition of 'simple-minded' alternation $\Sigma_n^{S\mu}$, that just counts syntactic alternation; if we modify the last clause to read '... *provided* that ψ is a closed formula', we obtain the Emerson–Lei notion $\Sigma_n^{EL\mu}$. (We write just Σ_n^{μ} when the distinctions are not important, or when we are making a statement that applies to all versions.)

To get the symmetrical notion of *alternation depth* of ϕ, we can define it to be the least n such that $\phi \in \Sigma_{n+1}^{\mu} \cap \Pi_{n+1}^{\mu}$. To make these definitions clear, consider the following examples:

- The 'always eventually' formula is $\Pi_2^{S\mu}$, but not $\Sigma_2^{S\mu}$, and so its simple alternation depth is 2. However, in the Emerson–Lei notion, it is also $\Sigma_2^{EL\mu}$, since $\nu Y.W \wedge \langle a\rangle Y$ is $\Pi_1^{EL\mu}$ and so $\Sigma_2^{EL\mu}$, and by substituting the closed $\Sigma_2^{EL\mu}$ (and in fact $\Sigma_1^{EL\mu}$) formula $\mu Z.P \vee \langle a\rangle Z$ for W we get 'always eventually' in $\Sigma_2^{EL\mu}$; hence its Emerson–Lei (and Niwiński) alternation depth is 1.
- The 'infinitely often' formula is Σ_2^{μ} but not Π_2^{μ}, in all three definitions, and so has alternation depth 2.
- The formula $\mu X.\nu Y.[-]Y \wedge \mu Z.[-](X \vee Z)$ is $\Sigma_3^{S\mu}$, but not $\Pi_3^{S\mu}$; it is also $\Sigma_3^{EL\mu}$ but not $\Pi_3^{EL\mu}$, since there are no closed subformulae to bring the substitution clause into play. However, in the Niwiński definition, it is actually $\Sigma_2^{N\mu}$: $\nu Y.[-]Y \wedge W$ is $\Pi_1^{N\mu}$ and so $\Sigma_2^{N\mu}$; we can substitute the $\Sigma_1^{N\mu}$ formula $\mu Z.[-](X \vee Z)$ for W without variable capture, and so $\nu Y.[-]Y \wedge \mu Z.[-](X \vee Z)$ is $\Sigma_2^{N\mu}$; and now we can add the outer fixpoint, still remaining in $\Sigma_2^{N\mu}$.

A natural question is whether the hierarchy of properties definable by Σ_n^{μ} formulae is actually a strict hierarchy, or whether the hierarchy collapses at some point so that no further alternation is needed. This problem remained open for a while; by 1990, it was known that $\Sigma_2^{N\mu} \neq \Pi_2^{N\mu}$ [4]. No further advance was made until 1996, when the strictness of the hierarchy was established by Bradfield [8, 9, 11].

THEOREM 13. For every n, there is a formula $\phi \in \Sigma_n^{\mu}$ which is not equivalent to any Π_n^{μ} formula.

Bradfield established this for $\Sigma_n^{N\mu}$, which implies the result for the other two notions. At the same time, Lenzi [43] independently established a slightly weaker hierarchy theorem for $\Sigma_n^{EL\mu}$.

Lenzi's proof is technically complex, and the underlying stratagem is not easy. Bradfield's proof appears technically complex, but most of the complexity is really just routine recursion-theoretic coding; the underlying stratagem is quite simple, and in some ways surprising. If one takes first-order arithmetic, one can add fixpoint operators to it, and one can then define a fixpoint alternation hierarchy in arithmetic. A standard coding and diagonalization argument shows that this hierarchy is strict [9]. The trick now is to transfer this hierarchy to $L\mu$. Simply by writing down the semantics, it is clear (give or take some work to deal with the more complex notions of alternation) that if one takes a recursively presented transition system and codes it into the integers, then for a modal formula $\phi \in \Sigma_n^\mu$, its denotation $\|\phi\|$ is describable by an arithmetic Σ_n^μ formula. However, it is also possible, given any arithmetic fixpoint formula χ, to build a transition system and a modal formula ϕ, of the same alternation depth as χ, such that $\|\phi\|$ is characterized by χ. If we take χ to be a strict Σ_n^μ arithmetic formula, then no Π_n^μ arithmetic formula is equivalent to it, and therefore no Π_n^μ modal formula can be equivalent to ϕ. The transition system that is constructed is infinite, but by the finite model property, the hierarchy transfers down to the class of finite models.

Both proof techniques construct explicit examples of hard formulae. Bradfield's examples have the form

$$\mu X_n.\nu X_{n-1}.\ldots.\mu X_1.[c]X_1 \vee \langle a_1\rangle X_1 \vee \ldots \vee \langle a_n\rangle X_n.$$

There are further questions one can ask about the alternation hierarchy. For example, is it still strict even on the binary tree? The answer is yes, given independently by Bradfield [10, 11] and Arnold [3] – the latter also gives a nice alternative proof of the main theorem, using topological methods rather than computability methods.

A more interesting question, and one that is still open, is: given a formula, what is its 'semantic' alternation depth? That is, what is the least alternation depth of any equivalent formula? Otto [55] showed that it is decidable whether a formula is equivalent to an alternation-free formula, and then Küsters and Wilke showed [41] it for alternation depth 1. Decidability is not known for higher levels.

8 BISIMULATION INVARIANCE

A hallmark of modal logic is bisimulation invariance: if $s \models \phi$ and s and s' are bisimulation equivalent then $s' \models \phi$. As we have seen, this remains true for $L\mu$ formulae. In logic, in general, structures are viewed as equivalent when they are isomorphic. However, in computation when structures represent behaviour of systems weaker forms of equivalence, such as automata acceptance equivalence or bisimulation equivalence, are more appropriate; see, for example, Milner [51].

8.1 $L\mu$ and MSOL

A modal formula can be translated into an equivalent bisimulation invariant first-order logic formula (over transition graphs) with one free variable. The translation is merely

the semantics. Let $\phi[x]$ be the translation of ϕ with free variable x: for instance, $P[x] = P(x)$ and $\langle a \rangle \phi[x] = \exists y.\, x \xrightarrow{a} y \wedge \phi[y]$. Clearly, $s \models \phi$ iff $\phi[s]$ holds. Van Benthem proved the converse: a bisimulation invariant first-order logic formula with one free variable is equivalent to a modal formula. Modal logic is the bisimulation invariant fragment of first-order logic.

The question is whether there is a similar result for closed formulae of $L\mu$. As we have seen, there is an intimate relationship between $L\mu$ and automata, games or SnS. None of these notations provide an obvious semantics for $L\mu$ formulae. Monadic second-order logic (MSOL) of transition graphs extends first-order logic with quantification over monadic predicates. With this addition we can translate $L\mu$.

$$\nu Z.\phi[x] \quad = \quad \exists Z.(\forall y.Z(y) \Rightarrow \phi[y]) \Rightarrow Z(x)$$

So, an $L\mu$ formula is translated into an equivalent bisimulation invariant MSOL formula with one free variable. Remarkably, the converse is also true, as proved by Janin and Walukiewicz [33].

THEOREM 14. A bisimulation invariant MSOL formula with one free variable is equivalent to an $L\mu$ formula.

In other words, $L\mu$ is the bisimulation invariant fragment of MSOL.

The proof of this theorem is intricate and again illustrates the potency of automata. The authors define an *ω-expansion* of a rooted model which is like the usual unravelling of the system into a tree, with the addition that the tree contains ω-many copies of every successor node. If $\phi(x)$ is a bisimulation invariant MSOL formula and $\phi(s)$ holds where s is the root of a model then $\phi(s)$ remains true for the ω-expanded model.

The proof uses modal automata from section 5.3. The transition function is defined using a simple modal language. If the automaton is in state q and at state s in the modal model and $\delta(q, \mathrm{Prop}(s)) = B$ then there is a mixture set $M_s \models B$ where $M_s \subseteq \{(t, q') \mid s \xrightarrow{a} t$ for some a and $q' \in Q\}$. Instead of simple modal formulae B, the automaton could employ first-order formulae with one free variable $B[x]$. Now, for instance, $M_s \models \exists y.x \xrightarrow{a} y \wedge p[y]$ iff $(t, p) \in M_s$ for some t such that $s \xrightarrow{a} t$. Critically, there is also a similar automata characterisation of MSOL formulae on trees. The transition function $\delta : Q \times \Sigma \to B'$ where B' is very similar to $B[x]$ except that it involves inequalites. When in CNF, formulae $B'[x]$ have the form

$$\exists y_1, \ldots y_n.(\bigwedge_{i \neq j} y_i \neq y_j \wedge x \xrightarrow{a_1} y_1 \wedge p_1[y_1] \wedge \ldots \wedge x \xrightarrow{a_n} y_n \wedge p_n[y_n] \wedge \forall z. \bigwedge z \neq y_i \wedge \psi(z, x)$$

where $\psi(z, x)$ captures the "box" formulae. The inequalities are effectively redundant in an ω-expanded model. The formulae $B'[x]$ collapse to $B[x]$ with respect to these models.

Van Benthem's theorem also holds for finite models: modal logic is the bisimulation invariant fragment of first-order logic with respect to finite models. It is an open question if this is true for $L\mu$ and MSOL.

8.2 Multi-dimensional $L\mu$ and Ptime

A major interest is classifying logics according to their expressive power. Computationally, we can ask whether there are logics that characterize complexity classes. A classic

result is that existential second-order logic exactly captures NP properties of finite structures. A key open problem is whether there is such a logic for PTIME properties. (For finite structures *with a linear ordering* the PTIME properties are exactly captured by least fixed point logic of section 9.2.) However, Otto shows that *bisimulation invariant* monadic PTIME properties (of modal structures) is logically characterizable by a multi-dimensional $L\mu$ [54].

For simplicity, assume finite $L\mu$ rooted structures whose label set is a singleton and let Prop be finite. Formulas of $L\mu$ are interpreted with respect to a single state. Consider instead k-tuples of states $(s_1, \ldots, s_k)$. Given such tuples we can define transition relations $\xrightarrow{i}$, for each $i : 1 \leq i \leq k$: $(s_1, \ldots, s_k) \xrightarrow{i} (t_1, \ldots, t_k)$ if $s_i \longrightarrow t_i$ and $s_j = t_j$ for all $j \neq i$. Otto defines the logic $L\mu^k$ (with $L\mu = L\mu^1$). Formulae may contain variables x_i, $1 \leq i \leq k$. Atomic formulae have the form Px_i: $(s_1, \ldots, s_k) \models Px_i$ iff $P \in \mathrm{Prop}(s_i)$. Modal formulae have the form $\langle i \rangle \phi$ and $[i]\phi$. Formulae are closed under boolean connectives. There is a substitution operation $\sigma : \{1, \ldots, k\} \to \{1, \ldots, k\}$: $\phi\sigma$ is the formula $\phi\{x_{\sigma(1)}/x_1, \ldots, x_{\sigma(k)}/x_k\}$. Finally, fixed points are k-ary: $\mu X(x_1, \ldots, x_k).\phi$ (and are interpreted as in section 9.2). Formulae of $L\mu^k$ are bisimulation invariant. The logic that characterizes bisimulation invariant monadic PTIME are the monadic formulae of $\bigcup_{k>0} L\mu^k$. Crucially, for $k > 1$, bisimulation equivalence is definable in $L\mu^k$.

$$\nu X(x_1, \ldots, x_k). \bigwedge_{P \in \mathrm{Prop}} Px_1 \Leftrightarrow Px_2 \wedge [1]\langle 2 \rangle X(x_1, \ldots, x_k) \wedge [2]\langle 1 \rangle X(x_1, \ldots, x_k)$$

For canonical finite rooted models (rooted models quotiented with respect to bisimulation equivalence) one can define a linear ordering on states via bisimulation *in*equivalence. So, each PTIME property is definable in least fixed point logic and, in fact, in some $L\mu^k$.

8.3 Bisimulation quantifiers and interpolation

In previous sections, a number of standard logical questions about the $L\mu$ have been covered, such as satisfiability, completeness, etc. These were all addressed, if not solved, early in the history of the logic. There are other standard questions about logics which, perhaps surprisingly, were not addressed until quite recently. In this subsection, we describe briefly work on interpolation theorems and related issues. A key ingredient in these proofs is again alternating parity automata; another ingredient is an interesting notion of 'bisimulation quantifier'.

A logic enjoys the *Craig interpolation property* if whenever $\phi \Rightarrow \psi$, then there is a third formula χ, using only those atomic symbols occurring in both ϕ and ψ, such that $\phi \Rightarrow \chi \Rightarrow \psi$. The *uniform interpolation property* requires further that to find χ, it suffices to know only one of ϕ or ψ and what the common language is. (That is, one can construct the strongest formula implied by ϕ in a given language, or the weakest formula implying ψ in a given language.) Maksimova showed [47] that most common temporal logics do not have interpolation. In [16], d'Agostino and Hollenberg show that $L\mu$ has interpolation, and even uniform interpolation, as we now sketch.

Let ϕ be a sentence, and P an atomic proposition occurring in ϕ. The aim is to construct a formula $\widetilde{\exists} P.\phi$ which is the strongest implicate of ϕ in the language omitting P. This can be done by using results of the Janin–Walukiewicz paper discussed earlier: translate ϕ into an MSOL sentence $\tilde{\phi}$, quantify it (in MSOL) to form $\exists P.\tilde{\phi}$, and then apply the construction mentioned to produce again an $L\mu$ formula $(\exists P.\tilde{\phi})^\vee$, which is true in

any rooted structure whose ω-expansion satisfies $\exists P.\tilde{\phi}$; but if a structure satisfies ϕ, then its ω-expansion satisfies $\exists P.\tilde{\phi}$, since the original valuation of P provides a witness. With some more technical lemmas, it is shown that $(\exists P.\tilde{\phi})^{\vee}$ is indeed the uniform interpolant of ϕ with respect to the vocabulary omitting P, and this is the definition of $\widetilde{\exists} P.\phi$. A similar definition and construction also works for action labels: $\widetilde{\exists} a.\phi$ is the strongest implicate of ϕ in the language omitting the label a.

The reason for the notation $\widetilde{\exists} P.\phi$ is that from the construction, it can be seen that a rooted structure satisfies $\widetilde{\exists} P.\phi$ iff there is a bisimlation equivalent rooted structure in the vocabulary excluding P that satisfies ϕ.

In the above, $\widetilde{\exists} P.\phi$ was, by definition, an $L\mu$ formula. It is natural to ask whether bisimulation quantifiers can give the same expressive power as the fixpoint operators. It turns out to be not sufficient to add $\widetilde{\exists}$ to modal logic; but [16] does show that adding $\widetilde{\exists}$ to PDL gives $L\mu$.

The techniques used here also give further results. One of the most satisfying is a Lyndon theorem: if an $L\mu$ sentence is monotone in a proposition P, then it is equivalent to a sentence positive in P. The proof is intricate.

9 GENERALIZED MU-CALCULI

We have seen that $L\mu$ has many nice properties. One interesting thread of research in recent years has been the investigation of why it enjoys these properties – is it because it is a *modal* fixpoint logic, because it is a *fixpoint* logic, or what else? In this section, we will briefly survey some of these investigations, and some of the more interesting generalizations of $L\mu$.

9.1 $L\mu$ with past

A simple extension of $L\mu$ is to include converse labels $\overline{a}$: $t \xrightarrow{\overline{a}} s$ iff $s \xrightarrow{a} t$. Modalities can now include converses. $L\mu$ with converse fails to have the finite model property: $\nu X.\langle a\rangle(X \wedge \mu Y.[\overline{a}]Y)$ is only satisfiable in an infinite state model. However, it retains both the tree model property and decidability of satisfiability (without an increase in complexity). The decidability proof uses two-way automata, alternating parity automata of section 5.3 whose modal language is extended with converse modalities [69].

9.2 Least fixpoint logic

Modal logic is a monadic fragment of first-order logic. $L\mu$ is such a fragment of least fixpoint logic, or LFP, obtained by adding fixpoint constructors to first order logic. It is primarily studied in the field of finite model theory; in the realm of infinite models, it is relatively little used, though occasionally used by set theorists as part of the theory of inductive definability. Finite model theorists use various notations, but usually do not use μ and ν, preferring to write LFP/GFP or **lfp/gfp**. We shall stick to a mu-calculus-like notation.

Assume the usual apparatus of first order logic over some structure S. *LFP* is obtained by adding *relation variables* $X, Y, \ldots$ of given arities, and a *least fixpoint operator* μ which forms *relation terms* $\mu X, \vec{x}.\phi$, where $\vec{x}$ is a tuple of arity(X) individual variables, and the relation variable X occurs only positively in ϕ. Assuming a valuation for the other free

variables of ϕ, the semantics of $\mu X, \vec{x}.\phi$ is the least fixpoint of the map $S^n \to S^n$, where n is the arity of X, given by $T \mapsto \{\vec{x} : \phi[X := T]\}$.

LFP has the following properties (refer to a textbook such as [19] for proofs, and for details of results mentioned in this section without citations):

- On finite models with a built-in linear order, LFP captures polynomial time, which makes it useful for complexity theorists. (A logic L captures a complexity class C if every set in C can be defined by a formula of L, and conversely every L-definable set is in C.)
- On finite models, the fixpoint alternation hierarchy collapses, so that any LFP property can be expressed with a single fixpoint; provided that the arity of relation symbols is not bounded. If the arity is bounded, then the fixpoint hierarchy does not collapse.
- LFP does not have the finite model property.
- Satisfiability is undecidable.

LFP retains a fundamental semantic theorem which can be presented as a model-checking game as in section 4.4. The game is now played on an arena of formulae $\phi[s_1, \ldots, s_n]$ with elements s_i of the model for individual variables. The initial position is the starting closed formula ϕ_0 in positive normal form. $\forall$ is responsible for making a move from a position $(\phi \wedge \psi)[s_1, \ldots, s_n]$, where the available choices are $\{\phi[s_1, \ldots, s_n], \psi[s_1, \ldots, s_n]\}$, and from a position $\forall x_{n+1}.\phi[s_1, \ldots, s_n]$, where the available choices are the set $\{\phi[s_1, \ldots, s_n, s] \mid s \in \mathfrak{S}\}$. $\exists$ is responsible for $\vee$ and existential quantification. Final positions are of the form $P[s_1, \ldots, s_n]$ and $\neg P[s_1, \ldots, s_n]$. $\exists$ wins such a position if it is true. Again, $\exists$ wins an infinite play if the outermost fixed point variable Y that occurs infinitely often in the play is a ν-variable. $\exists$ has a history-free winning strategy iff the initial formula is true of the structure.

9.3 Finite variable fixpoint logics

One of the topics studied in finite model theory is the *finite variable* fragments of FOL. These are the fragments FOL^k where the number of distinct variable names in a formula is restricted to a finite value k. Ordinary modal logic is obviously embeddable in FOL^2; there are several features of modal logic that are generalizable in some sense to FOL^2; and by adding certain operators to modal logic, one can regain FOL^2, albeit less succinctly [45]. Moreover, FOL^2 is reasonably tractable, and the decidability of modal logic follows from the decidability of FOL^2, which in turn follows from the fact that, like modal logic and $L\mu$, it enjoys the finite model property.

It is therefore natural to wonder if the good properties of modal mu-calculus might be explained by considering the finite variable fragments of LFP.

However, in a well-known paper 'Why is modal logic so robustly decidable?' [68], Vardi analysed the relationship between modal logic and FOL^2 more carefully, and argued that it does not adequately explain the good properties of modal logic. Furthermore, when one passes to the fixpoint version, it is even more inadequate: for example, although $L\mu$ is decidable, LFP^2 (and $L\mu^2$) is not decidable.

It appears, then, that finite variable fixpoint logics have little to say about $L\mu$. So what are the more useful related logics?

9.4 Guarded fragments

In [68], Vardi argued that the *tree model property* is responsible for the good behaviour of $L\mu$, and CTL. FOL^2 does not have this property. However, it turns out that there are fragments of FOL which do retain the tree model property or some suitable generalization of it. The discovery of these fragments needed a new perception of the characteristic features of modal logic seen as a fragment of FOL.

The fact that modal logic lies in FOL^2 is obvious. Somewhat less obvious is another property of the FO translations of modal logic formulae: *guardedness*. A FO quantification is *guarded* if it has the form $\forall \vec{y}.\alpha(\vec{x}, \vec{y}) \Rightarrow \phi(\vec{x}, \vec{y})$ or $\exists \vec{y}.\alpha(\vec{x}, \vec{y}) \wedge \phi(\vec{x}, \vec{y})$, where $\alpha(\ldots)$ is an atomic formula (i.e. α is a relation symbol or the equality symbol), and $\vec{x}$ includes all the free variables of ϕ. That is, when a quantified variable is introduced, its values must be connected by some relation to the values of the other variables mentioned in the formula. In the case of modal logic, the guards are the edge relations.

Guardedness was proposed by Andréka, van Benthem and Németi [2] as a better explanation of the robust decidability of modal logic. The guarded fragment GF of first-order logic has many of the nice properties of modal logic, for example

- GF is decidable.
- GF has the finite model property.
- GF has the appropriate generalization of the tree model property, namely that if a formula has a model, it has a model of 'bounded tree-width'. (Tree width is a graph-theoretic definition which measures how far a graph is from being a tree.)
- GF-equivalence can be characterized by a *guarded bisimulation*, as modal equivalence is characterized by bisimulation.

Grädel and Walukiewicz [29] studied the guarded fragment GFP of LFP. The syntactic formation rule for fixed points is: if $\phi(Y, \vec{x})$ is a guarded formula, Y occurs positively and not in the guards and all free variables of $\phi(Y, \vec{x})$ are contained in $\vec{x}$ then $\mu Y(\vec{x}).\phi(Y, \vec{x})$ is a formula of the guarded fragment of LFP. This fragment retains the tree model property but not the finite model property, making it a better meta-language for $L\mu$ than LFP^2. An interesting first result concerned the complexity: satisfiability for GFP is 2EXPTIME-complete. Grädel had earlier shown [27] that GF itself has 2EXPTIME satisfiability, so this is a situation where adding fixpoints does not increase complexity - a surprising result. However, it turns out that this depends on the unbounded *width* of formulae - the number of free variables in subformulae. If the width is bounded, then satisfiability drops to EXPTIME-complete, which agrees with that of $L\mu$. The decidability proof uses two-way alternating parity automata.

9.5 Inflationary mu-calculus

In finite model theory, as well as to some extent in classical definability theory, extensions of LFP have been studied which relax the requirement for the body of a fixpoint operator to be monotone. One such is *inflationary fixpoint logic* (IFP). In IFP, the semantics of the fixpoint operator (usually written **ifp** in the finite model theory literature, but here

written μ_{I}) is modified. Rather than being defined as a fixpoint, it is defined in terms of approximants; and then at each approximant, the previous approximant is unioned in:

$$\|\mu_{\mathrm{I}} Z^{\alpha}.\phi\|^{\mathfrak{T}}_{\mathfrak{V}} = Z^{<\alpha} \cup \|\phi\|^{\mathfrak{T}}_{\mathfrak{V}[Z:=Z^{<\alpha}]}$$

On finite structures, IFP and LFP have long been known to be equi-expressive, and recently Kreutzer showed [39] that indeed they are equi-expressive on arbitrary structures. In [18] Dawar, Grädel and Kreutzer define inflationary modal mu-calculus, by using the above definition for fixpoints, and show that it is more powerful than $L\mu$, and complex in many ways. It does not have the finite model property, and it can express non-regular properties. Satisfiability is undecidable and even non-arithmetic, since it is possible to interpret arithmetic, by using the height of nodes in a well-founded tree as numbers. On the class of finite models, the increased power results in a model-checking complexity of PSPACE.

1 INTRODUCTION

Description logics (DLs) [12] are a family of knowledge representation languages which can be used to represent the terminological knowledge of an application domain in a structured and formally well-understood way. The name *description logics* is motivated by the fact that, on the one hand, the important notions of the domain are described by *concept descriptions*, i.e., expressions that are built from atomic concepts (unary predicates) and atomic roles (binary predicates) using the concept and role constructors provided by the particular DL. For example, the concept of "a man that is married to a doctor, and has only happy children" can be expressed using the concept description

$$\mathsf{Man} \sqcap \exists \mathsf{married}.\mathsf{Doctor} \sqcap \forall \mathsf{child}.\mathsf{Happy}.$$

On the other hand, DLs differ from their predecessors in that they are equipped with a formal, *logic*-based semantics, which can, e.g., be given by a translation into first-order predicate logic. For example, the above concept description can be translated into the following first-order formula (with one free variable x):

$$\mathsf{Man}(x) \wedge \exists y(\mathsf{married}(x,y) \wedge \mathsf{Doctor}(y)) \wedge \forall y(\mathsf{child}(x,y) \rightarrow \mathsf{Happy}(y)).$$

The motivation for introducing the early predecessors of DLs, such as semantic networks and frames [133, 125], actually was to develop means of representation that are closer to the way humans represent knowledge than a representation in formal logics, like first-order predicate logic. Minsky [125] even combined his introduction of the frame idea with a general rejection of logic as an appropriate formalism for representing knowledge. However, once people tried to equip these "formalisms" with a formal semantics, it turned out that they can be seen as syntactic variants of (subclasses of) first-order predicate logic [83, 144].

The immediate precursors of DLs, Brachman's structured inheritance networks [42], were an attempt to define a formalism that allows for a structured representation of knowledge in the spirit of semantics networks and frames, but nevertheless is equipped with a formal semantics. The original description logics used in systems that implemented these ideas in the 1980ies [45, 132, 124, 123] turned out to correspond to rather inexpressive and somewhat unusual subclasses of first-order predicate logic. On the one hand, none of them was propositionally closed since they did not allow for disjunction or negation. On the other hand, they were equipped with certain other complex constructors (like number restrictions and role-value-maps), which, though expressible in first-order predicate logic, are not considered as atomic constructors there. For example, the number restriction $(\geqslant 5\,\mathsf{child})$ describes people having at least five children, and the role-value-map $\mathsf{child} \circ \mathsf{friend} \subseteq \mathsf{know}$ describes people that know all their children's friends.

The main inference problem to be solved in description logics is the subsumption problem, i.e., deciding whether one concept is a subconcept of another one. The early DL systems cited above employed so-called structural subsumption algorithms, which first normalise the concept descriptions, and then recursively compare the syntactic structure of the normalised descriptions. These algorithms are usually very efficient (polynomial), but they have the disadvantage that they are complete only for rather inexpressive DLs, i.e., for more expressive DLs they cannot detect all the existing subsumption relationships. To overcome this problem, Schmidt-Schauß and Smolka [143] made DLs into "real" logics by introducing negation. Their main motivation for this was that they wanted to reduce the subsumption problem to the satisfiability problem. They introduced a basic propositionally closed DL, which they called $\mathcal{ALC}$, developed a tableau-like algorithm for satisfiability in $\mathcal{ALC}$, and showed that the subsumption and satisfiability problem in $\mathcal{ALC}$ are PSPACE-complete.

A reader of the Handbook of Modal Logic who followed us so far may rightfully ask: *And what has all this to do with Modal Logic?* The answer was given by Schild, who noticed that $\mathcal{ALC}$ is just a syntactic variant of multi-modal K, i.e., the basic modal logic of Kripke frames with several accessibility relations (and thus several pairs of box- and diamond operators). In fact, the translations of $\mathcal{ALC}$ and of K into first-order predicate logic yield exactly the same class of first-order formulae. This connection between DLs and modal logic was used by Schild and others (see, e.g., [139, 140, 54, 55]) to transfer decidability and complexity results from modal logic to DLs, but also to extend these

results to logics with other DL constructors. At the same time, tableau-based algorithms were developed for more and more expressive DLs (see [30] for an overview), and highly-optimized implementations of these algorithms [92] turned out to behave quite well on artificial benchmarks from modal logic [131] and also in practice [78].

Though there is a very close connection between DLs and modal logics (MLs), the underlying intuition as well as the intended applications differ significantly. As a consequence, the focus of research in DL and in modal logic also differs. While mentioning the similarities, this chapter will focus on topics that are specific for DLs.

Section 2 formally introduces syntax and semantics of the basic DL $\mathcal{ALC}$, and shows its relationship to multi-modal K. It then introduces additional DL constructors, and describes their ML counterparts. In addition to these constructors, DLs provide their users with a terminological formalism, which (in its simplest form) allows to introduce names for complex concepts, and an assertional formalism, which allows to state facts about specific individuals/objects. Though these components are usually not available in ML, there are some connections to things known in ML (such as nominals, the universal modality, fixpoint operators, etc.).

In *Section 3*, we introduce the standard inference problems in description logics, show how they can be reduced to each other, and how they relate to inference problems in ML. The standard way of solving these problems in propositionally closed DLs is using tableau-based algorithms. Since these algorithms are treated in other chapters, we only give some references to the relevant chapters.

Section 4 considers DLs that are not propositionally closed, and where consequently subsumption cannot be reduced to satisfiability. We review the known complexity results for such DLs, and then describe (complete) structural subsumption algorithms for some of them. In addition, we mention bi-simulation characterizations of the corresponding ML fragments.

Section 5 is concerned with so-called non-standard inferences in DLs, like computing the least common subsumer and the most specific concept, and rewriting, unification, and matching of concepts. These inferences have been introduced with the goal of supporting the user when building and maintaining large DL knowledge bases. With the exception of unification, none of them have been investigated in ML.

Finally, *Section 6* introduces means of expressiveness that do not have immediate ML counterparts.

2 BASIC DEFINITIONS AND CONNECTION TO MODAL LOGIC

In this section, we introduce the basic components of description logics: concept languages, terminological formalisms, and assertional formalisms.

2.1 Concept Languages

We first define the basic propositionally closed concept language $\mathcal{ALC}$ introduced by Schmidt-Schauß and Smolka [143], and then describe a number of natural extensions that are important for many applications and offered by modern DL reasoners. Assume that a countably infinite supply of *concept names*, usually denoted A and B, and of *role names*, usually denoted r and s, are available. *Concept descriptions* in $\mathcal{ALC}$ are formed

Name	Syntax	Semantics
top concept	$\top$	$\Delta^{\mathcal{I}}$
bottom concept	$\bot$	$\emptyset$
negation	$\neg C$	$\Delta^{\mathcal{I}} \setminus C^{\mathcal{I}}$
conjunction	$C \sqcap D$	$C^{\mathcal{I}} \cap D^{\mathcal{I}}$
disjunction	$C \sqcup D$	$C^{\mathcal{I}} \cup D^{\mathcal{I}}$
value restriction	$\forall r.C$	$\{d \in \Delta^{\mathcal{I}} \mid \forall e.(d,e) \in r^{\mathcal{I}} \rightarrow e \in C^{\mathcal{I}}\}$
existential restriction	$\exists r.C$	$\{d \in \Delta^{\mathcal{I}} \mid \exists e.(d,e) \in r^{\mathcal{I}} \wedge e \in C^{\mathcal{I}}\}$
transitive role	r	$r^{\mathcal{I}}$ transitive
inverse role	r^{-}	$\{(d,e) \mid (e,d) \in r^{\mathcal{I}}\}$
nominal	I	$I^{\mathcal{I}}$ singleton
qualifying number restrictions	$\leqslant n\ r\ C$ $\geqslant n\ r\ C$	$\{d \in \Delta^{\mathcal{I}} \mid \#\{(d,e) \in r^{\mathcal{I}} \mid d \in C^{\mathcal{I}}\} \leq n\}$ $\{d \in \Delta^{\mathcal{I}} \mid \#\{(d,e) \in r^{\mathcal{I}} \mid e \in C^{\mathcal{I}}\} \geq n\}$
number restrictions	$\leqslant n\ r$ $\geqslant n\ r$	$\{d \in \Delta^{\mathcal{I}} \mid \#\{(d,e) \in r^{\mathcal{I}}\} \leq n\}$ $\{d \in \Delta^{\mathcal{I}} \mid \#\{(d,e) \in r^{\mathcal{I}}\} \geq n\}$

Figure 1. Semantics of concept and role constructors

according to the following syntax rule:

$$C, D \longrightarrow A \mid \top \mid \bot \mid \neg C \mid C \sqcap D \mid C \sqcup D \mid \forall r.C \mid \exists r.C$$

where A ranges over concept names and r ranges over role names. In examples, we will usually use uppercase names for concept names and lowercase names for role names, thus obtaining $\mathcal{ALC}$ concept descriptions such as the one given in the introduction:

$$\mathsf{Man} \sqcap \exists \mathsf{married}.\mathsf{Doctor} \sqcap \forall \mathsf{child}.\mathsf{Happy}.$$

The semantics of $\mathcal{ALC}$ is based on *interpretations*, i.e., pairs $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ where $\Delta^{\mathcal{I}}$ is a non-empty set (the *domain* of $\mathcal{I}$), and $\cdot^{\mathcal{I}}$ is the *interpretation function*, assigning to each concept name A a set $A^{\mathcal{I}} \subseteq \Delta^{\mathcal{I}}$ and to each role name r a binary relation $r^{\mathcal{I}} \subseteq \Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}}$. The interpretation function is inductively extended to concept descriptions as shown in (the upper part of) Figure 1, which also lists the names that we use for $\mathcal{ALC}$ constructors. An interpretation $\mathcal{I}$ is a *model* of a concept description C if $C^{\mathcal{I}} \neq \emptyset$. In the following, we will sometimes call concept languages "description logics", ignoring further ingredients to DLs such as the terminological formalism.

As first observed by Schild [138], $\mathcal{ALC}$ is a notational variant of the multi-modal logic K. Syntactically, concept names can simply be viewed as propositional variables and role names can be viewed as names for accessibility relations. Then, interpretations of $\mathcal{ALC}$ are obviously just Kripke structures with $\Delta^{\mathcal{I}}$ the set of worlds and $\cdot^{\mathcal{I}}$ providing both the accessibility relations and the valuation of the propositional variables. With this reading, the value restriction $\forall r.C$ becomes a box operator $\Box_r C$ referring to the accessibility relation denoted by r, and $\exists r.C$ becomes a diamond operator $\Diamond_r C$. This connection is also witnessed by the usual translation of $\mathcal{ALC}$ to first-order predicate logic [37, 38], which is identical to the standard translation for modal logic presented in Chapter 1.

The concept language $\mathcal{ALC}$ is only one member of a large family of concept languages. These languages can be obtained from $\mathcal{ALC}$ by disallowing certain constructors (thus obtaining the *sub-Boolean* description logics discussed in Section 4) and/or adding various combinations of additional constructors. Such additional constructors can be concept constructors, or they can be role constructors allowing to construct compound *role descriptions* to be used in place of role names. We now discuss several additional constructors that are related to expressive means common in modal logic. Constructors that have been considered in the context of description logics, but lack a modal counterpart will be discussed in more depth in Section 6.

When the connection between DLs and modal logic was discovered, one of it's first uses was to transfer results from propositional dynamic logic (PDL) to description logics [138, 139, 54]. The description logic counterpart of PDL is called $\mathcal{ALC}_{reg}$, which stands for "$\mathcal{ALC}$ with *reg*ular expressions on roles" [3, 138]. $\mathcal{ALC}_{reg}$ extends $\mathcal{ALC}$ by allowing compound role descriptions inside value restrictions and existential restrictions. Such role descriptions are built using the binary constructors for union ("$\sqcup$") and composition (";") and a unary constructor for reflexive-transitive closure ("$\cdot^*$"). The semantics is given in the straightforward way by interpreting the constructors using the corresponding relational operations. For example, the additional constructors could be used in the concept description

$$\mathsf{Man} \sqcap \exists \mathsf{child}.\mathsf{Human} \sqcap \forall(\mathsf{child};\mathsf{child}^*).\mathsf{Happy}$$

where $(\mathsf{child};\mathsf{child}^*)$ describes the transitive closure of the role child, i.e., the $\mathsf{descendant}$ relation. The work on $\mathcal{ALC}_{reg}$ has led to several variants and extensions whose expressive power goes beyond that of PDL [54, 56, 57]. However, many of today's most used concept languages do not include the role constructors of $\mathcal{ALC}_{reg}$. The main reason is that applications demand an implementation of description logic reasoning, and the presence of the reflexive-transitive closure constructor makes obtaining efficient implementations much harder.

Another important family of description logics is obtained by considering fragments of the concept language $\mathcal{SHOIQ}$ [94, 98, 95], which extends $\mathcal{ALC}$ with several expressive means that are discussed in detail below.[1] The importance of $\mathcal{SHOIQ}$ stems from the fact that it and its fragments are used in two of the most influential application areas of description logics: reasoning about conceptual database models [52] and reasoning in the semantic web [19]. In the latter application, the fragment $\mathcal{SHOIN}$ roughly corresponds to the ontology language OWL-DL [93], which was recommended by the W3C as the standard web ontology language. The fragment $\mathcal{SHIQ}$ is the concept language supported by modern description logic systems such as FaCT and RACER [91, 79]. A tableau algorithm for full $\mathcal{SHOIQ}$ was introduced in [97], and optimized implementations of this algorithm are under development.

Compared to $\mathcal{ALC}$, the additional expressive means provided by $\mathcal{SHOIQ}$ are transitive roles, role hierarchies, inverse roles, qualifying number restrictions, and nominals. With the exception of role hierarchies, the formal semantics of these extensions can be found in the lower part of Figure 1. Below, we discuss each means of expressiveness in more detail. Before that, a remark on the naming scheme used to describe fragments of $\mathcal{SHOIQ}$ is in order. To avoid long sequences of letters, the abbreviation $\mathcal{S}$ was introduced for $\mathcal{ALC}$

[1] The naming of description logics is historically grown, and there are several naming schema in use; see the Appendix of [12].

Symbol	Syntax	$\mathcal{SHIQ}$	$\mathcal{SHOIQ}$	$\mathcal{SHIN}$	$\mathcal{SHOIN}$
$\mathcal{H}$	$r \sqsubseteq s$	x	x	x	x
$\mathcal{I}$	r^-	x	x	x	x
$\mathcal{N}$	$(\leqslant n\, r), (\geqslant n\, r)$	x	x	x	x
$\mathcal{Q}$	$(\leqslant n\ r\ C), (\geqslant n\ r\ C)$	x	x		
$\mathcal{O}$	I		x		x

Figure 2. Some members of the $\mathcal{S}$ family of DLs.

with transitive roles. The additional presence of role hierarchies is indicated by the letter $\mathcal{H}$, of inverse roles by $\mathcal{I}$, of (qualifying) number restrictions by $\mathcal{N}$ ($\mathcal{Q}$), and of nominals by $\mathcal{O}$ (see Figure 2).

Transitive roles. $\mathcal{ALC}$ can be extended with transitive roles by adding a new sort of role names whose interpretation is required to be transitive [135]. The resulting description logic is a notational variant of the fusion of multi-modal K and multi-modal K4. One of the most important uses of transitive roles is for the representation of knowledge about parts and wholes by means of a transitive role part-of [136].

Inverse roles extend $\mathcal{ALC}$ with a unary role constructor $\cdot^-$. Roles of the form r^- correspond to "backwards modalities" as known from temporal logic and converse PDL [154]. They allow, for example, to define the converse parent of the relation child, and the converse has-part of part-of.

Role hierarchies are not a part of the concept language, but rather "external" to it [91]. Formally, a role hierarchy is a finite set of inclusion statement $r \sqsubseteq s$ with r and s role descriptions. Intuitively, the presence of a role hierarchy puts constraints on the class of accepted interpretations: if $r \sqsubseteq s$ is in the hierarchy, then we only accept interpretations in which $r^{\mathcal{I}} \subseteq s^{\mathcal{I}}$. Thus, role hierarchies are much closer in spirit to TBoxes (see below) than to concept or role constructors. The connection between role hierarchies and modal logics will be discussed in a more general context in Section 6.2.

Nominals are an additional sort of concept names that are required to be interpreted as singleton sets. The name has been adopted from modal logics, where nominals appear e.g. in the context of hybrid logic, c.f. Chapter 14 and [1, 74]. There are several natural concepts, such as Pope, that require nominals for an adequate modelling. In description logics, nominals sometimes occur in the form of two concept constructors called "one of" and "fills", see [44] for more details.

Qualifying number restrictions. Corresponding to graded modalities in modal logic [70, 71, 153], qualifying number restrictions allow to put *counting* constraints on the number of domain elements that are related via a certain role and belong to a certain concept [88]. This constructor allows, e.g., the formulation of concepts such as Father $\sqcap$ ($\leqslant$ 1 child Female) describing fathers that have at most one daughter (but arbitrarily many sons). Number restrictions also appear in a non-qualifying variant $\leqslant n\ r$ and $\geqslant n\ r$, in which the third argument implicitly is the top concept. They are a very important means of expressivity that appeared already in early description logic systems such as KL-ONE [45]. In the case of $\mathcal{SHOIQ}$ and its fragments, number restrictions are usually restricted to *simple* roles, i.e. roles having no transitive subroles according to the role hierarchy. If this syntactic restriction is not adopted, reasoning in $\mathcal{SHOIQ}$ is undecidable [98].

For the sake of brevity, the list of concept and role constructors given above is not

$$
\begin{array}{rclcrcl}
\mathsf{Woman} & \equiv & \mathsf{Person} \sqcap \mathsf{Female} & \qquad & \mathsf{Man} & \equiv & \mathsf{Person} \sqcap \neg\mathsf{Woman} \\
\mathsf{Mother} & \equiv & \mathsf{Woman} \sqcap \exists \mathsf{child}.\mathsf{Person} & & \mathsf{Father} & \equiv & \mathsf{Man} \sqcap \exists \mathsf{child}.\mathsf{Person} \\
\mathsf{Parent} & \equiv & \mathsf{Mother} \sqcup \mathsf{Father} & & & &
\end{array}
$$

Figure 3. An example TBox formulated in $\mathcal{ALC}$.

exhaustive. For example, $\mathcal{ALC}$ has also been extended with Boolean role constructors, which corresponds to going from multi-modal K to Boolean modal logic [101, 122, 121].

2.2 Terminological Formalisms

The concept language is only one part of description logics. To capture the terminological knowledge of application domains in a structured way, it is not sufficient to formulate single concept descriptions. Additionally, we must be able to organize and interrelate multiple concept descriptions in a suitable way. This is achieved through the terminological formalism. Just like concept languages, terminological formalisms come in several flavors. One of the most fundamental variants is the following: a *TBox (terminological box)* $\mathcal{T}$ is a finite set of *concept definitions*

$$A \equiv C$$

with A a concept name and C a concept description, such that no concept name appears on the left-hand side of two different concept definitions in $\mathcal{T}$. An example of a TBox formulated in $\mathcal{ALC}$ is displayed in Figure 3. A concept name is called a *defined concept* if it appears on the left-hand side of a concept definition, and a *primitive concept* otherwise.

When defining the semantics, we face the difficulty of treating terminological cycles which may occur in the kind of TBoxes considered here. We say that a concept name A *directly uses* a concept name B w.r.t. a TBox $\mathcal{T}$ if there is a concept definition $A \equiv C \in \mathcal{T}$ with B occurring C. Let *uses* be the transitive closure of directly uses. Then a TBox $\mathcal{T}$ contains a *terminological cycle* if there is a concept name that uses itself w.r.t. $\mathcal{T}$; otherwise $\mathcal{T}$ is called *acyclic*. For example, the TBox displayed in Figure 3 is acyclic, whereas the following concept definition induces a terminological cycle (Adam and Eve are nominals):

$$\mathsf{Human} \equiv \mathsf{Adam} \sqcup \mathsf{Eve} \sqcup \exists \mathsf{parent}.\mathsf{Human}.$$

In the following, we sometimes call the general form of TBoxes introduced above *cyclic TBoxes* to distinguish them from acyclic ones. However, this does not imply that the TBoxes in question *necessarily* contains a terminological cycle.

For acyclic TBoxes, the natural semantics is *descriptive semantics*: an interpretation $\mathcal{I}$ *satisfies* a concept definition $A \equiv C$ if $A^{\mathcal{I}} = C^{\mathcal{I}}$, and $\mathcal{I}$ is a *model* of the TBox $\mathcal{T}$ if it satisfies all concept definitions in $\mathcal{T}$. Intuitively, acyclic TBoxes merely state that defined concepts are abbreviations for certain compound concept descriptions. These compound concepts can be made explicit by *expanding* the acyclic TBox $\mathcal{T}$: exhaustively replace all concept names A on the left-hand side of concept definitions $A \equiv C$ by their defining concept descriptions C. After this expansion, the compound concept abbreviated by a

defined concept can simply be read off from the corresponding concept definition. For example, the defined concept Father in Figure 3 abbreviates the compound concept

$$\mathsf{Person} \sqcap \neg(\mathsf{Person} \sqcap \mathsf{Female}) \sqcap \exists \mathsf{child}.\mathsf{Person}.$$

A *primitive interpretation* for a TBox $\mathcal{T}$ is an interpretation that interprets only the primitive concept names and role names, but not the defined concepts. A (full) interpretation $\mathcal{I}$ is called an *extension* of a primitive interpretation $\mathcal{J}$ if it agrees with $\mathcal{J}$ on the domain and the interpretation of the primitive concepts and role names. We say that $\mathcal{T}$ is *definitorial* if every primitive interpretation has exactly one extension that is a model of $\mathcal{T}$. Since we can expand them, acyclic TBoxes are clearly definitorial: if $\mathcal{T}$ is an acyclic TBox and $\mathcal{T}' = \{A_1 \equiv C_1, \ldots, A_k \equiv C_k\}$ has been obtained from $\mathcal{T}$ by expansion, then the unique extension of a primitive interpretation $\mathcal{J}$ that is a model of $\mathcal{T}$ is obtained by setting $A_i^{\mathcal{I}} := C_i^{\mathcal{J}}$ for $1 \leq i \leq k$.

If we do not require TBoxes to be acyclic, then TBoxes are no longer definitorial under descriptive semantics. For example, the TBox

$$\mathcal{T} \equiv \{\mathsf{Human} \equiv \forall \mathsf{parent}.\mathsf{Human}\}$$

has no primitive concept, and the primitive interpretation $\mathcal{J}$ with $\Delta^{\mathcal{J}} = \{d\}$ and $\mathsf{parent}^{\mathcal{J}} = \{(d,d)\}$ can be extended to two different models of $\mathcal{T}$. Thus, the above TBox does not provide an unequivocal definition of Human. To obtain definitorial TBoxes in the presence of terminological cycles, two steps are necessary [129]: first, descriptive semantics is changed to a (least/greatest) fixpoint semantics; and second, the syntax of TBoxes is restricted to ensure that least and greatest fixpoints indeed exist. To illustrate why fixpoints are a natural choice for defining TBox semantics, we note that they can be used to characterize models of a TBox in a straightforward way. Let $\mathcal{T}$ be a TBox and $\mathcal{J}$ a primitive interpretation for $\mathcal{T}$. We write $\mathcal{T}(A)$ to denote the concept description C if $A \equiv C \in \mathcal{T}$. With $Ext_{\mathcal{J}}$, we denote the set of all extensions of $\mathcal{J}$. Let $\mathcal{T}_{\mathcal{J}} : Ext_{\mathcal{J}} \to Ext_{\mathcal{J}}$ be the mapping that maps the extension $\mathcal{I}$ of $\mathcal{J}$ to the extension $\mathcal{T}_{\mathcal{J}}(\mathcal{I})$ of $\mathcal{J}$ defined by setting $A^{\mathcal{T}_{\mathcal{J}}(\mathcal{I})} := (\mathcal{T}(A))^{\mathcal{I}}$ for each defined concept A. It is trivial to verify that an interpretation $\mathcal{I}$ is a model of $\mathcal{T}$ if and only if $\mathcal{I}$ is a fixpoint of $\mathcal{T}_{\mathcal{J}}$ with $\mathcal{J}$ the restriction of $\mathcal{I}$ to a primitive interpretation.

To make the TBox formalism definitorial in the presence of terminological cycles, we restrict the set of fixpoints of $\mathcal{T}_{\mathcal{J}}$ that are intended as models. Let $\mathcal{I}$ be a model of $\mathcal{T}$ and $\mathcal{J}$ the restriction of $\mathcal{I}$ to a primitive interpretation. Then $\mathcal{I}$ is a *least fixpoint model* (*greatest fixpoint model*) of $\mathcal{T}$ if $A^{\mathcal{I}} \subseteq A^{\mathcal{I}'}$ ($A^{\mathcal{I}} \supseteq A^{\mathcal{I}'}$) for every defined concept A and every fixpoint $\mathcal{I}'$ of $\mathcal{T}_{\mathcal{J}}$. We obtain the *least fixpoint semantics* (*greatest fixpoint semantics*) by admitting only the least fixpoint models (greatest fixpoint models) of $\mathcal{T}$ as intended models. However, the obtained semantics is still not definitorial, at least not for all TBoxes: let $\mathcal{T} = \{A \equiv \forall r.\neg A\}$ and $\mathcal{J}$ the primitive interpretation with $\Delta^{\mathcal{J}} = \{d\}$ and $r^{\mathcal{J}} = \{(d,d)\}$. Then $\mathcal{J}$ has no extension that is a model of $\mathcal{T}$. The usual way to get around such a problem, as e.g. used in the modal μ-calculus [104], is to adopt a syntactic monotonicity restriction. In the setting of cyclic TBoxes, this restriction can be formulated as follows: a TBox $\mathcal{T}$ is called *monotone* if, on the right-hand side of concept definitions in $\mathcal{T}$, defined concepts appear only under an even number of negations. It is easy to show that, according to least or greatest fixpoint semantics every monotone TBox is definitorial: every primitive interpretation can be *uniquely* extended to a least or greatest fixpoint model of the TBox.

Whether least fixpoint semantics or greatest fixpoint semantics is preferable depends on the concept definition at hand: for the concept definition $\mathsf{Human} \equiv \mathsf{Adam} \sqcup \mathsf{Eve} \sqcup \exists \mathsf{parent}.\mathsf{Human}$ from above, we should use the least fixpoint semantics to avoid that individuals on cyclic or infinite parent-paths have to be Humans. In other cases, greatest fixpoint semantics can be more appropriate: say we want to define top researchers (in a somewhat incestuous way) as researchers who are renowned and collaborate only with top researchers:

$$\mathsf{TopResearcher} \equiv \mathsf{Researcher} \sqcap \mathsf{Renowned} \sqcap \forall \mathsf{collaborates\text{-}with}.\mathsf{TopResearcher}.$$

Then least fixpoint semantics is not convincing since two renowned researchers who collaborate mutually (but not with anybody else) will not be classified as top researchers. In contrast, greatest fixpoint semantics yields the intended models. These two examples illustrate that the most flexible solution is to use a mixed semantics: least fixpoints for some defined concepts, and greatest fixpoints for others [140]. Note that, in the case of an acyclic TBox, least fixpoint semantics, greatest fixpoint semantics, and descriptive semantics coincide in the sense that they admit exactly the same models.

It is also possible to use descriptive semantics for cyclic TBoxes. As discussed above, this implies that TBoxes will no longer be definitorial. While this is inappropriate if the goal is to *define* concepts, it poses no problem if we view TBoxes simply as formulating *constraints* on the intended models. This view of TBoxes, which is rather natural in a number of applications, leads to the idea of *general concept inclusion axioms (GCIs)*. A GCI is an expression of the form

$$C \sqsubseteq D,$$

where both C and D are (possibly compound) concept descriptions. An interpretation $\mathcal{I}$ *satisfies* the GCI $C \sqsubseteq D$ if $C^{\mathcal{I}} \subseteq D^{\mathcal{I}}$. When working with GCIs as constraints on models, no syntactic restrictions such as unique left-hand sides, acyclicity, or monotonicity needs to be adopted. For example, we could use a GCI to state that all persons having an uncle who is a father also have a cousin:[2]

$$\mathsf{Person} \sqcap \exists \mathsf{uncle}.\mathsf{Father} \sqsubseteq \exists \mathsf{cousin}.\mathsf{Person}$$

Since the concept definition $A \equiv C$ can be rewritten as the pair of GCIs $A \sqsubseteq C$ and $C \sqsubseteq A$, GCIs strictly generalize acyclic TBoxes as well as cyclic TBoxes with descriptive semantics. It should be noted that GCIs are the terminological formalism that is usually supported by modern description logic systems.

We now discuss the relation between terminological formalisms and modal logic. In the case of descriptive semantics, there is a close relationship to the universal modality: let $\mathcal{T}$ be a set of GCIs and U the universal role, i.e. $U^{\mathcal{I}} = \Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}}$ for all interpretations $\mathcal{I}$. Then we can translate $\mathcal{T}$ into a concept $C_{\mathcal{T}}$ by setting

$$C_{\mathcal{T}} := \forall U. \bigsqcap_{D \sqsubseteq E \in \mathcal{T}} \neg D \sqcup E.$$

Then we have the following: if an interpretation $\mathcal{I}$ is a model of $\mathcal{T}$, then $C_{\mathcal{T}}^{\mathcal{I}} := \Delta^{\mathcal{I}}$; and if $C_{\mathcal{T}}^{\mathcal{I}} \neq \emptyset$, then $\mathcal{I}$ is a model of $\mathcal{T}$. We will see in Section 3.1 that this translation can sometimes be used to reduce reasoning with TBoxes to reasoning without TBoxes.

[2] This could be modelled in an even better way using role value maps, c.f. Section 6.

$\mathsf{Logician}(\mathsf{DAVID})$	$\mathsf{supervisor}(\mathsf{DONALD}, \mathsf{VAUGHAN})$
$\mathsf{supervisor}(\mathsf{VAUGHAN}, \mathsf{DAVID})$	$(\mathsf{Man} \sqcap \exists \mathsf{child}.\mathsf{Woman})(\mathsf{DONALD})$

Figure 4. An example ABox formulated in $\mathcal{ALC}$.

In a weaker sense, we can also do the converse translation, i.e. simulate the universal modality using GCIs—see Section 2.2.1 of [112] for more details.

In the case of fixpoint semantics, Schild [140] observed that there is a direct correspondence between TBoxes and (an alternation-free fragment of) Vardi and Wolper's version of the propositional μ-calculus [155]. In contrast to the standard μ-calculus as proposed by Kozen [104], this variant provides for multiple fixpoints that correspond to constructing fixpoints for all defined concepts of a TBox simultaneously.

Finally, there is an intimate connection between our notion of definitorial TBoxes and the Beth definability property as known from modal logic [72]. Roughly, a description logic has the Beth definability property if and only if every TBox that is definitorial under descriptive semantics is equivalent to an acyclic TBox (see also [29]).

2.3 Assertional Formalisms

Apart from the concept language and the terminological formalism, there is one more important ingredient to description logics. This is the *assertional formalism*, which allows to describe (a snapshot of) the world by means of individuals populating the world, conceptual memberships of individuals, and roles relating individuals. The combination of a TBox and an ABox is commonly called a *knowledge base*. Assume that a countably infinite supply of individual names, usually denoted by a, b, c, is available. An *ABox (assertional box)* is a finite set of assertions of the form

$$\begin{array}{rl} C(a) & \quad \text{(concept assertion)} \\ r(a,b) & \quad \text{(role assertion)} \end{array}$$

where a and b are individual names, C is a concept description, and r is a role description. An example of an ABox is given in Figure 4. We us all-uppercase words to denote concrete individual names.

To assign a semantics to ABoxes, we have to extend interpretations to individual names: interpretations $\mathcal{I}$ are now required to map, additionally, every individual name a to a domain element $a^{\mathcal{I}} \in \Delta^{\mathcal{I}}$. Usually, the *unique name assumption (UNA)* is adopted, which requires that different individual names are mapped to distinct domain elements, i.e., $a \neq b$ implies $a^{\mathcal{I}} \neq b^{\mathcal{I}}$. The interpretation $\mathcal{I}$ *satisfies* the concept assertion $C(a)$ if $a^{\mathcal{I}} \in C^{\mathcal{I}}$, and it *satisfies* the role assertion $r(a,b)$ if $(a^{\mathcal{I}}, b^{\mathcal{I}}) \in r^{\mathcal{I}}$. An interpretation is a *model* of an ABox $\mathcal{A}$ if it satisfies all assertions in $\mathcal{A}$. Often, we are interested in models of an ABox $\mathcal{A}$ *w.r.t. a TBox* $\mathcal{T}$, i.e. common models of $\mathcal{A}$ and $\mathcal{T}$.

There is an obvious connection between ABoxes and nominals which provides a link between ABoxes and modal logic: if a concept language providing for nominals, conjunction, and existential restrictions is used, then we can simulate an ABox $\mathcal{A}$ using the

concept description

$$C_{\mathcal{A}} := \bigsqcap_{D(a)\in\mathcal{A}} \exists u.(a \sqcap D) \sqcap \bigsqcap_{r(a,b)\in\mathcal{A}} \exists u.(a \sqcap \exists r.b)$$

where u is a role name not used in $\mathcal{A}$, and we assume that, for each individual name, there exists a nominal of the same name.[3] This is a simulation in the sense that every model for $C_{\mathcal{A}}$ is a model for $\mathcal{A}$, and every model $\mathcal{I}$ for $\mathcal{A}$ can be extended to a model for $C_{\mathcal{A}}$ by setting $u^{\mathcal{I}} = \Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}}$. However, nominals are strictly more expressive than ABoxes. For example, this is reflected by the complexity of reasoning in $\mathcal{ALCI}$, the extension of $\mathcal{ALC}$ with inverse roles: while reasoning in $\mathcal{ALCI}$ with ABoxes but without TBoxes is PSPACE-complete, reasoning in $\mathcal{ALCI}$ extended with nominals is EXPTIME-complete.[4] The latter is due to the possibility of defining "spy-points" in $\mathcal{ALCI}$ with nominals (see Chapter 14), which is not possible using ABoxes.

3 STANDARD DESCRIPTION LOGIC INFERENCES

Reasoning has always been a major emphasis of description logic research. The main purpose of reasoning in DLs is to explicate knowledge that is contained only implicitly in a given concept description, TBox, or ABox. This inferencing capability can be used by applications to infer new knowledge when needed, and it helps knowledge engineers to construct and structure complex knowledge bases. In this section, we introduce the inference problems for description logics that have direct counterparts in modal logic. Because these inference problems have played an important rôle since the very beginnings of description logic, they are often referred to as "standard inference problems"—in contrast to the more recent "non-standard inference problems" that are discussed in Section 5. We also give a brief survey of the most important results and techniques concerning the decidability and computational complexity of the standard inference problems. In doing so, we concentrate on description logics that have close counterparts in modal logics and defer the treatment of logics that are less common from the modal logic perspective to Section 6. Our discussion of results and techniques will be brief as these or very similar issues are covered in more detail in other chapters of this handbook.

3.1 Terminological Reasoning

The inference problems introduced here operate on concept descriptions and TBoxes, without reference to ABoxes. The basic such inference problems are the following:

Satisfiability. A concept description C is *satisfiable* with respect to a TBox $\mathcal{T}$ if there exists a common model of C and $\mathcal{T}$.

Subsumption. A concept description C is *subsumed* by a concept description D with respect to a TBox $\mathcal{T}$ if $C^{\mathcal{I}} \subseteq D^{\mathcal{I}}$ for every model $\mathcal{I}$ of $\mathcal{T}$ (written $C \sqsubseteq_{\mathcal{T}} D$).

In both cases, we simply drop the reference "with respect to $\mathcal{T}$" (and the index $\mathcal{T}$ from $C \sqsubseteq_{\mathcal{T}} D$) if we are interested in reasoning w.r.t. the empty TBox. In this case, we also talk about reasoning *with concept descriptions.* Intuitively, satisfiability is important to

[3]The additional role can be omitted if the "$@_a$" operator of hybrid logic is used, c.f. Chapter 14.
[4]With "reasoning" we refer to ABox consistency, c.f. Section 3.2.

(automatically) verify whether a concept description makes sense from a logical perspective, i.e., whether it is contradictory in itself or to a given TBox. Satisfiability also plays an important rôle because many other inference problems can be reduced to it. Subsumption can be used to check whether a concept D is more general than a concept C, i.e., whether each instance of C also is an instance of D. For example, the concept name Parent is subsumed by the concept description $\mathsf{Man} \sqcup \mathsf{Woman}$ w.r.t. the TBox shown in Figure 3: by the semantics, every Parent is also a Man or a Woman. As we will discuss in more detail later, subsumption defines a hierarchy of the concept names occurring in a TBox w.r.t. their generality. There are some additional terminological inference problems such as the equivalence of concept descriptions: C and D are *equivalent* with respect to a TBox $\mathcal{T}$ (written $C \equiv_{\mathcal{T}} D$) iff $C^{\mathcal{I}} = D^{\mathcal{I}}$ for all models $\mathcal{I}$ of $\mathcal{T}$. We will not consider such additional inference problems in this chapter since they can clearly be reduced to subsumption and satisfiability in a trivial way.

There is a straightforward connection between satisfiability and subsumption: if a concept language provides for negation and conjunction, we can polynomially reduce subsumption to unsatisfiability: $C \sqsubseteq_{\mathcal{T}} D$ if and only $C \sqcap \neg D$ is unsatisfiable w.r.t. $\mathcal{T}$. We can also do the converse reduction if the concept language provides for (or can express) the bottom concept: C is satisfiable w.r.t. $\mathcal{T}$ if and only if $C \not\sqsubseteq_{\mathcal{T}} \bot$. Because of this close connection, many description logic systems concentrate on providing algorithms for solving satisfiability, and treat subsumption by means of the above reduction.[5] Another important group of reductions is concerned with reducing satisfiability with respect to TBoxes to satisfiability w.r.t. the empty TBox. Whether such a reduction can be done depends on the concept language and the chosen TBox formalism. Here we discuss the two most important cases.

Eliminating acyclic TBoxes. As already mentioned in Section 2.2, acyclic TBoxes merely define abbreviations for compound concept descriptions. This suggests the following reduction: to decide whether a concept description C is satisfiable w.r.t. the acyclic TBox $\mathcal{T}$, first expand $\mathcal{T}$ (c.f. Section 2.2), then replace all defined concepts in C according to their definition in the expansion of $\mathcal{T}$, and finally decide satisfiability of the resulting concept description without reference to a TBox. As observed by Nebel [128], this reduction may yield an exponential blowup even for the concept language $\mathcal{FL}_0$ that only provides for the concept constructors conjunction and value restriction. For example, expanding the following TBox of size $\mathcal{O}(n)$ yields a TBox of size 2^n:

$$
\begin{array}{rcl}
C_1 & \equiv & \forall r_1.C_0 \sqcap \forall r_2.C_0 \\
 & \vdots & \\
C_n & \equiv & \forall r_1.C_{n-1} \sqcap \forall r_2.C_{n-1}
\end{array}
$$

This exponential blowup can sometimes be avoided by devising satisfiability algorithms that explicitly take acyclic TBoxes into account. For example, satisfiability of $\mathcal{ALC}$ concept descriptions w.r.t. acyclic TBoxes is PSpace-complete, and without TBoxes this problem is of exactly the same complexity [142, 110]. However this is not always the case: in Sections 4 and 6, we will discuss DLs for which reasoning w.r.t. acyclic TBoxes is considerably more difficult than reasoning without them.

Eliminating GCIs. In several expressive description logics, it is possible to reduce satisfiability w.r.t. GCIs to satisfiability without reference to GCIs. Two examples are the

[5] An important exception are sub-Boolean DLs that do not provide for general negation; c.f. Section 4.

description logics $\mathcal{ALC}_{reg}$ and $\mathcal{SHOIQ}$. It is not difficult to prove that, in $\mathcal{ALC}_{reg}$, a concept description C is satisfiable w.r.t. $\mathcal{T}$ if, and only if, $C \sqcap \forall(r_1 \sqcup \cdots \sqcup r_k)^*.C_{\mathcal{T}}$ is satisfiable, where $r_1, \ldots, r_k$ are the role names used in C and $\mathcal{T}$, and $C_{\mathcal{T}}$ is defined at the end of Section 2.2. Similarly, it has been observed in [94] that, in $\mathcal{SHOIQ}$, a concept description C is satisfiable w.r.t. a TBox $\mathcal{T}$ and a role hierarchy $\mathcal{H}$[6] if and only if $C \sqcap \forall r.C_{\mathcal{T}}$ is satisfiable w.r.t. the role hierarchy $\mathcal{H} \cup \{r_1 \sqsubseteq r, \ldots, r_k \sqsubseteq r\}$, where $r_1, \ldots, r_k$ are the role names used in C and $\mathcal{T}$, and r is a transitive role not occurring in C and $\mathcal{T}$. Reductions like the ones sketched above are often called *internalizations* of TBoxes, and have first been proposed in [11]. However, implemented reasoning systems usually treat GCIs in an explicit way for efficiency reasons [90, 99].

We now give a brief survey of the results and techniques for terminological reasoning. The main driving force behind the research on DL reasoning is the following trade-off between expressivity and computational complexity: on the one hand, non-trivial applications require a high expressivity of the concept language and of the terminological and assertional formalism; on the other hand, applications need an implementation of DL inference algorithms in an actual knowledge representation system that exhibits an acceptable run-time behavior on "realistic" inputs, i.e. on inputs that stem from an application and have not been artificially crafted to make reasoning hard.

It is generally agreed upon that an implemented DL system should be based on algorithms that are sound, complete, and terminating, i.e., decidability of the relevant inference problems is indispensable. Fortunately, satisfiability and subsumption is indeed decidable for almost all possible combinations of concept language and TBox formalism that we have introduced up to this point, including $\mathcal{ALC}$ with cyclic TBoxes and fixpoint semantics [140], $\mathcal{ALC}_{\mathrm{reg}}$ with GCIs [54], and $\mathcal{SHOIQ}$ with GCIs [150].[7] However, decidability of reasoning is usually only a necessary, but not a sufficient condition for the usefulness of a description logic. Additionally, it is important that the computational complexity of reasoning is within acceptable bounds, and that there exist *practical* reasoning algorithms, i.e. algorithms that have the potential of being implemented in a system that behaves well on realistic inputs as demanded above.

The general opinion on the (worst-case) complexity that is acceptable has changed dramatically over time. Historically, the early times of DL research have been concentrating on identifying formalisms for which reasoning is tractable, i.e. can be performed in polynomial time.[8] Obviously, demanding tractability means that we cannot include all Boolean operators in the concept language, and thus are in the realm of sub-Boolean DLs. The complexity of satisfiability and subsumption in this family of DLs is laid out in detail in Section 4, ranging from tractable to ExpTime-complete depending on the choice of constructors and TBox formalism. Around 1990, the $\mathcal{KRIS}$ system showed that tableau algorithms for satisfiability and subsumption in $\mathcal{ALC}$ w.r.t. acyclic TBoxes, two PSpace-complete inference problems, can be implemented in a system with acceptable run-time behavior on realistic inputs [17]. A step towards even more expressive DLs has been made around 1997 by Ian Horrocks and his FaCT system, which originally implemented satisfiability and subsumption for an ExpTime-complete fragment of

[6] C is satisfiable w.r.t. $\mathcal{T}$ and $\mathcal{H}$ if there is a model $\mathcal{I}$ of C and $\mathcal{T}$ with $r^{\mathcal{I}} \subseteq s^{\mathcal{I}}$ for all $r \sqsubseteq s \in \mathcal{H}$.

[7] An exception is satisfiability of $\mathcal{SHOIQ}$-concepts w.r.t. TBoxes with least fixpoint semantics, which was shown to be undecidable by Bonatti [35].

[8] Curiously, it was found later that reasoning in the description logic supported by the very first description logic system KL-ONE is undecidable [141]—c.f. Section 5.

$\mathcal{SHOIQ}$ with GCIs. The complexity of most description logics extending $\mathcal{ALC}$ is between PSpace-complete and NExpTime-complete. Some important landmarks are the following:

- satisfiability of $\mathcal{ALC}$ concept descriptions without reference to TBoxes is PSpace-complete [142]; this also holds in the presence of acyclic TBoxes [110];
- satisfiability of $\mathcal{ALC}$ concept descriptions w.r.t. cyclic TBoxes or GCIs is ExpTime-complete; this holds for fixpoint semantics as well as for descriptive semantics [138, 140];
- satisfiability of $\mathcal{SHOIQ}$ concept descriptions w.r.t. GCIs is NExpTime-complete, with the lower bound applying to all extensions of $\mathcal{ALC}$ that provide for (qualifying or non-qualifying) number restrictions, inverse roles, and nominals [150].

All these bounds transfer to subsumption with the exception of the last one, where NExpTime-completeness of satisfiability flips to co-NExpTime-completeness of subsumption. It should be mentioned that the exact meaning of an "acceptable run-time behavior" of course also depends on the concrete application at hand. As argued e.g. in [51], there are applications that require "real" tractability and therefore research in tractable DLs is an ongoing endeavour [51, 46, 10]. Since our survey of the complexity of reasoning in DLs is by no means exhaustive, we refer the interested reader to [61] for more information on the complexity of DLs.

The issue of practicability is not only related to computational complexity, but also to the techniques that are used to obtain decision procedures for DL reasoning. A large number of such techniques have been proposed and investigated. For sub-Boolean DLs, so-called "structural algorithms" play the most important role, and we describe them in detail in Section 4. For $\mathcal{ALC}$ and its many extensions, the following approaches are most important: tableau algorithms [30], reduction techniques [54], automata-based approaches [122, 50], and resolution calculi [101, 100]. With respect to practicability, tableau algorithms are the most successful approach so far: they proved to be amenable to a number of powerful optimization techniques (see Chapter 4 and [92]), and highly-optimized implementations of tableau algorithms in DL systems have performed extraordinarily well in system comparisons. As a result, nowadays almost all state-of-the-art DL reasoners, such as FaCT and RACER [91, 79], are based on tableau algorithms.

From the perspective of modal logic, satisfiability of concept descriptions clearly corresponds to standard formula satisfiability, whereas a subsumption $C \sqsubseteq D$ corresponds to the validity of the implication $C \rightarrow D$. For this reason, the discussion of tableau- and resolution-based algorithms for modal logics provided in Chapter 4 of this handbook applies to description logics as well, and we omit further details.

3.2 Assertional Reasoning

The inference problems discussed in this section operate on knowledge bases, i.e. on pairs $(\mathcal{A}, \mathcal{T})$ with $\mathcal{A}$ an ABox and $\mathcal{T}$ a TBox. The fundamental inference problems are the following:

Consistency. An ABox $\mathcal{A}$ is *consistent* w.r.t. a TBox $\mathcal{T}$ if there exists a common model of $\mathcal{A}$ and $\mathcal{T}$.

Instance Checking. An individual name a in an ABox $\mathcal{A}$ is an *instance* of a concept description C w.r.t. a TBox $\mathcal{T}$ if $a^{\mathcal{I}} \in C^{\mathcal{I}}$ for all models $\mathcal{I}$ of $\mathcal{A}$ and $\mathcal{T}$ (denoted with $\mathcal{A} \models_{\mathcal{T}} C(a)$).

Consistency is the ABox-analogue of satisfiability, i.e., it can be used to check whether a given knowledge base is contradictory. The purpose of instance checking is also obvious: it is used to derive concept memberships of individuals that are not stated explicitly. For example, the individual DONALD in the ABox shown in Figure 4 is an instance of Father w.r.t. the TBox in Figure 3.

As in the previous section, there is a close connection between the two fundamental inference problems if certain Boolean constructors are available. First, consistency can be polynomially reduced to (non-)instance checking if the bottom concept is available: an ABox $\mathcal{A}$ is consistent w.r.t. a TBox $\mathcal{T}$ if and only if $\mathcal{A} \not\models_{\mathcal{T}} \bot(a)$ with a an arbitrary individual name. And second, we can do the converse reduction if full negation is available: $\mathcal{A} \models_{\mathcal{T}} C(a)$ if and only if $\mathcal{A} \cup \{\neg C(a)\}$ is inconsistent w.r.t. $\mathcal{T}$. It is sometimes also possible to eliminate acyclic TBoxes and GCIs as discussed in the previous section. In the presence of nominals, it is possible to polynomially reduce consistency (and thus also instance checking) to the satisfiability of concept descriptions using the simulation sketched at the end of Section 2.3.

The techniques used to devise decision procedures for consistency and instance checking are essentially the same as those employed for concept satisfiability and subsumption. In the case of tableau algorithms, there are two approaches for reasoning with ABoxes: first, ABox consistency can sometimes be reduced to concept satisfiability using the *pre-completion* technique described in [87]; and second, tableau algorithms can be extended to treat ABoxes in a direct way (see e.g. [86, 15, 77]). Regarding practicability, it should be noted that some optimization techniques fail or become significantly more complex in the presence of ABoxes.

Concerning the decidability and computational complexity of assertional reasoning, one should distinguish sub-Boolean DLs from $\mathcal{ALC}$ and its extensions. In the sub-Boolean case, there are some description logics for which instance checking is harder than concept subsumption (see Section 4.3). If all Boolean constructors are available, the complexity of instance checking coincides with the complexity of subsumption for all such description logics investigated so far. For example, instance checking in $\mathcal{ALC}$ ABoxes without reference to TBoxes is known to be PSPACE-complete [18], and instance checking in $\mathcal{ALC}$ ABoxes w.r.t. GCIs is EXPTIME-complete [54]—just as the corresponding cases of subsumption.

3.3 Compound Inference Problems

Some of the most important inference problems in DLs are of a compound nature in the sense that, in principle, they can be reduced to multiple invocations of the more basic inference problems mentioned above. However, when the goal is to achieve an efficient implementation, it is vital to consider compound inferences as first-class citizens [13]. Here we discuss the three most important such problems.

Classification. Given a TBox $\mathcal{T}$, compute the restriction of the subsumption relation "$\sqsubseteq_{\mathcal{T}}$" to the set of concept names used in $\mathcal{T}$.

Realization. Given an ABox $\mathcal{A}$, a TBox $\mathcal{T}$, and an individual name a, compute the set $R_{\mathcal{A},\mathcal{T}}(a)$ of those concept names A that are used in $\mathcal{T}$, satisfy $\mathcal{A} \models_{\mathcal{T}} A(a)$, and are

minimal with this property w.r.t. the subsumption relation "$\sqsubseteq_{\mathcal{T}}$".

Retrieval. Given an ABox $\mathcal{A}$, a TBox $\mathcal{T}$, and a concept C, compute the set $I_{\mathcal{A},\mathcal{T}}(C)$ of individual names a used in $\mathcal{A}$ and satisfying $\mathcal{A} \models_{\mathcal{T}} C(a)$.

Compound inferences are a very important interface to description logics reasoners and are offered by almost all systems. The purpose of classification is to construct a hierarchy of concept names w.r.t. their generality, with more general concepts higher up in the hierarchy: B is above A if and only if $A \sqsubseteq_{\mathcal{T}} B$. Such a hierarchy can then be presented to a knowledge engineer for browsing and structuring the TBox. Realization also facilitates browsing and understanding of the knowledge base, and is a precursor to certain operations on knowledge bases that presuppose knowledge of the concept memberships of individuals. The main use of retrieval is database-like querying of description logic knowledge bases: in some applications, it is natural to define ABoxes with a huge number of individual names, and to query such ABoxes like a database with deductive capabilities [78].

By definition, compound inferences can be reduced to more basic inference problems. For classification, we may simply check whether $A \sqsubseteq_{\mathcal{T}} B$ for all concept names A, B used in $\mathcal{T}$. In the case of realization, we can obviously just use multiple invocations of instance checking and subsumption. Similarly, multiple instance checks suffice to get a naïve implementation of retrieval. However, basic inferences such as subsumption and instance checking are potentially very costly, and thus it is vital for DL reasoners to replace these "brute force" methods of compound inferences by more subtle approaches.

To illustrate how compound inferences can be implemented in a more efficient way, we exemplarily consider classification. Here, the aim is to minimize the number of subsumption tests, of which the naïve approach performs n^2 many with n the number of concept names in $\mathcal{T}$. The common strategies for achieving this minimization are described and evaluated by Baader et al. in [13]. Although Baader et al. restrict themselves to acyclic TBoxes, the proposed strategies can also be used for cyclic ones. In general, two kinds of optimizations can be distinguished. Firstly, classification can be conceived as an abstract combinatorial problem on partial orders: compute a complete representation of a partial ordering by making as few as possible comparisons. This quite general problem is also considered in non-DL contexts, see e.g. [69]. Secondly, we can take into account the structure of concept descriptions to reveal obvious subsumption relationships and to control the order in which concepts are added to the hierarchy. In the following, we assume that the restriction of "$\sqsubseteq_{\mathcal{T}}$" to the concepts names of $\mathcal{T}$ is represented as a Hasse diagram, i.e. as a directed acyclic graph (DAG) such that

- nodes are sets of concept names that are pair-wise equivalent w.r.t. $\mathcal{T}$;
- two nodes S_1, S_2 are connected by an edge if every $A_2 \in S_2$ is a *direct subsumer* of every $A_1 \in S_1$, i.e., we have (i) $A_1 \sqsubseteq_{\mathcal{T}} A_2$ and (ii) $A_1 \sqsubseteq_{\mathcal{T}} B \sqsubseteq_{\mathcal{T}} A_2$ implies $B \equiv_{\mathcal{T}} A_1$ or $B \equiv_{\mathcal{T}} A_2$ for all concept names B in $\mathcal{T}$.

To this diagram, we henceforth refer as the *(concept) hierarchy*. We assume that the hierarchy always contains a top node whose label includes $\top$, and a bottom node whose label includes $\bot$.[9] In DL TBoxes originating from applications, the concept hierarchy is usually not too deep, i.e., the represented order has short chains and long antichains.

[9] In case of unsatisfiable TBoxes, the top node and bottom node coincide.

One way to compute the concept hierarchy with only few subsumption tests is to use an incremental algorithm [13]: we start with a hierarchy containing only $\top$ and $\bot$, and then repeatedly place additional concept names at the appropriate position in the (growing) hierarchy. The placing of a new concept name A consists of two phases: a *top search* phase computing the direct subsumers of A that are already contained in the hierarchy, and a *bottom search* phase computing the set of all concept names that are already contained in the hierarchy, and of which A is a direct subsumer. Obviously, knowledge of these two sets allows us to place A appropriately. Due to the transitivity of the subsumption relation, the top search phase is best implemented as a top down search, whereas a bottom up approach is appropriate for the bottom search phase. Additionally, failed tests can be propagated down the hierarchy in the top search phase: if $A \not\sqsubseteq_{\mathcal{T}} B$ and B' is below B in the hierarchy (implying $B' \sqsubseteq_{\mathcal{T}} B$), then it follows immediately that $A \not\sqsubseteq_{\mathcal{T}} B'$. Analogously to propagation in the top search phase, successful tests can be propagated up the hierarchy in the bottom search phase. Finally, it is possible to use information gained in the top search phase to speed up the bottom search phase, and vice versa (see [13] for details).

Using the structure of concepts, we can additionally avoid subsumption tests in a straightforward way: if we find a concept definition $A \equiv C$ with C a conjunction having as one of its conjuncts a concept name B, then $A \sqsubseteq_{\mathcal{T}} B$ holds trivially. In this case, B is a *told subsumer* of A. Of course, if B is a defined concept, it can have told subsumers as well, and these (and their told subsumers, etc.) can also be viewed as told subsumers of A. The information about the told subsumers can be propagated down the hierarchy before starting the top search phase. To take full advantage of this idea, it is advisable to classify concepts in *definition order*. This means that a concept is not classified until all of its told subsumers are classified.

These optimizations typically reduce the number of necessary subsumption tests to a small fraction of n^2 (see [13] for details). Most techniques sketched here can be used in the same or a slightly modified form if sets of GCIs are used instead of TBoxes. Of course, it is (at least) equally important to optimize the subsumption test itself. More on this issue can be found in Chapter 4.

4 SUB-BOOLEAN DESCRIPTION LOGICS

As mentioned in the introduction, the DLs used in the first DL systems did not allow for all Boolean operators. Usually, these DLs provided for conjunction, value-restriction, and number restriction, and some other special constructors, but existential restriction, disjunction and full negation were not available. In some of these formalisms, disjointness statements between concept names or atomic negation (i.e., negation restricted to concept names) were allowed.

This restriction to sub-Boolean logics was, on the one hand, due to the origins of DLs. These formalisms were not primarily seen as logics (where the inclusion of at least proposition logic is natural), but as knowledge representation formalisms in the spirit of semantic networks and frames, though equipped with a formal semantics. Graph-based formalisms like semantic networks usually favor a conjunctive point of view since conjunction corresponds to just drawing several things in the same picture, whereas expressing disjunction and negation would require special conventions (like drawing a box around the parts that are negated, as in conceptual graphs [147]), which easily

destroy the readability of such graphical representations.

On the other hand, the restriction to sub-Boolean DLs was motivated by the goal of designing representation formalisms with tractable (i.e., polynomial-time decidable) inference problems, which would be precluded by the presence of all Boolean operators. The first paper addressing the trade-off between expressiveness and tractability of reasoning in the context of DL was [109], where it was shown that a seemingly minor extension of the description language can make the subsumption problem intractable. This work triggered an extensive investigation of the borderline between tractability and intractability of reasoning in sub-Boolean DLs [127, 145, 63, 62, 40, 65].[10] In *Section 4.1*, we give a brief review of these results. We also sketch in more detail polynomial-time subsumption algorithms for the DL $\mathcal{FL}_0$ (which allows for conjunction and value restriction only) and some of its extensions. The results mentioned until now were all restricted to extensions of $\mathcal{FL}_0$. The reason was that until the late 1990ies, both conjunction and value restriction were assumed to be indispensable for a DL. For conjunction this indeed appears to be the case since one usually wants to require several properties simultaneously when defining a concept. In order to obtain more than just a fragment of propositional logic, one also needs at least one constructor involving roles. However, instead of value restrictions one could also use existential restrictions. In fact, there are large DL-based medical terminologies [134, 148] that employ existential restrictions rather than value restrictions. The complexity of reasoning in DLs extending $\mathcal{EL}$, which allows for conjunction, existential restriction, and the top-concept, is less well-investigated than for extensions of $\mathcal{FL}_0$. We will briefly review the results in [84], where the complexity of the satisfiability problem in all fragments of $\mathcal{ALC}$, including ones that do not extend $\mathcal{FL}_0$, is investigated. In addition, we sketch a polynomial-time subsumption algorithms for $\mathcal{EL}$.

All the complexity results mentioned until now are concerned with satisfiability and subsumption of concept descriptions. If one considers reasoning w.r.t. a TBox, then the complexity may increase drastically, even for acyclic TBoxes, which do not increase the expressive power. The first such result is due to Nebel [128], who showed that the subsumption problem w.r.t. acyclic TBoxes is coNP-complete for the DL $\mathcal{FL}_0$. Recall that subsumption of $\mathcal{FL}_0$ concept descriptions is polynomial. If one allows for cyclic TBoxes, then subsumption in $\mathcal{FL}_0$ becomes PSpace-complete, and in the presence of GCIs it becomes even ExpTime-complete. In contrast, the subsumption problem in $\mathcal{EL}$ remains polynomial in the presence of acyclic or cyclic TBoxes and GCIs. These results for reasoning w.r.t. TBoxes in sub-Boolean DLs will be described in more detail in *Section 4.2*.

Not only TBox reasoning, but also ABox reasoning, may be harder than reasoning with concept descriptions. *Section 4.3* gives an example, due to A. Schaerf [137], of a sub-Boolean DL where the instance problem is harder than the subsumption problem.

Finally, *Section 4.4* reviews bisimulation characterizations for various sub-Boolean DLs due to de Rijke and Kurtonina [105], which can be used to characterize the expressive power of these DLs.

[10] We have not included [64] in this list since the polynomiality results for subsumption claimed there turned out to be incorrect (see [66] for details).

Symbol	Syntax	$\mathcal{ALN}$	$\mathcal{ALE}$	$\mathcal{ALU}$	$\mathcal{ALUN}$	$\mathcal{ALEN}$	$\mathcal{ALC}$	$\mathcal{ALCN}$
$\mathcal{E}$	$\exists r.C$		x			x	x	x

$\mathcal{N}$	$(\leqslant n\, r), (\geqslant n\, r)$	x			x	x		x

Figure 5. The $\mathcal{AL}$ family of DLs.

4.1 Reasoning with concept descriptions in sub-Boolean DLs

Donini et al. [65] start their investigation of the complexity of sub-Boolean DLs with the DL $\mathcal{AL}$, whose concept descriptions are formed according to the following syntax rule:

$$C, D \longrightarrow A \mid \top \mid \bot \mid \neg A \mid C \sqcap D \mid \forall r.C \mid \exists r.\top$$

The difference to $\mathcal{ALC}$ is that the application of negation is restricted to concept names (atomic negation) and that in existential restrictions only the top concept may occur (restricted existential quantification).

In the following, we consider the extensions of $\mathcal{AL}$ by subsets of the following set of constructors: (full) existential restriction, number restrictions, and disjunction.[11] This yields the 7 different extensions of $\mathcal{AL}$ shown in Figure 5. Note that adding both existential restriction and disjunction to $\mathcal{AL}$ yields $\mathcal{ALC}$. This is due to the presence of atomic negation in $\mathcal{AL}$. In fact, by using de Morgan's law, the duality of the quantifiers, and the removal of double negation, any $\mathcal{ALC}$ concept description can be transformed into an equivalent one that employs only atomic negation.

Figure 6 gives a complete classification of the DLs belonging to the $\mathcal{AL}$ family regarding the worst-case complexity of subsumption and (un)satisfiability of concept descriptions. Except for the case of $\mathcal{ALEN}$, these results are shown in [65]. PSPACE-hardness of $\mathcal{ALEN}$ was shown by Hemaspaandra [84].

Before trying to explain some of these results, let us first point out that subsumption and unsatisfiability are in general not trivially interreducible in sub-Boolean DLs. We have seen that

$$\begin{aligned} C \text{ is unsatisfiable} \quad &\text{iff} \quad C \sqsubseteq \bot, \\ C \sqsubseteq D \quad &\text{iff} \quad \neg C \sqcap D \text{ is unsatisfiable.} \end{aligned}$$

Since $\bot$ is available in the DLs of the $\mathcal{AL}$ family, unsatisfiability can be reduced in this way to subsumption, and thus subsumption is at least as hard as unsatisfiability, and unsatisfiability is at least as easy as subsumption. However, for a DL strictly below $\mathcal{ALC}$, $\neg C \sqcap D$ usually does not belong to this DL even if C and D do. Nevertheless, the results summarized in Figure 6 show that, for the $\mathcal{AL}$ family, the complexities of unsatisfiability and of subsumption coincide. In general, this need not be the case. For example, the extension $\mathcal{ALNI}$ of $\mathcal{ALN}$ by inverse roles has a polynomial-time (un)satisfiability problem, but the subsumption problem is coNP-hard [66]. In very simple DLs such as $\mathcal{FL}_0$ and $\mathcal{EL}$, satisfiability is even trivial (in contrast to subsumption) since there are no unsatisfiable concepts We exemplarily discuss at least one DL for each of the complexity classes appearing in Figure 6. Satisfiability in intractable DLs is treated in Section 4.1 and subsumption in tractable DLs such as $\mathcal{FL}_0$ and $\mathcal{ALN}$ is discussed in Section 4.1.

[11] Donini et al. [65] actually consider a somewhat larger family of DLs, where also intersection of roles is available as a constructor.

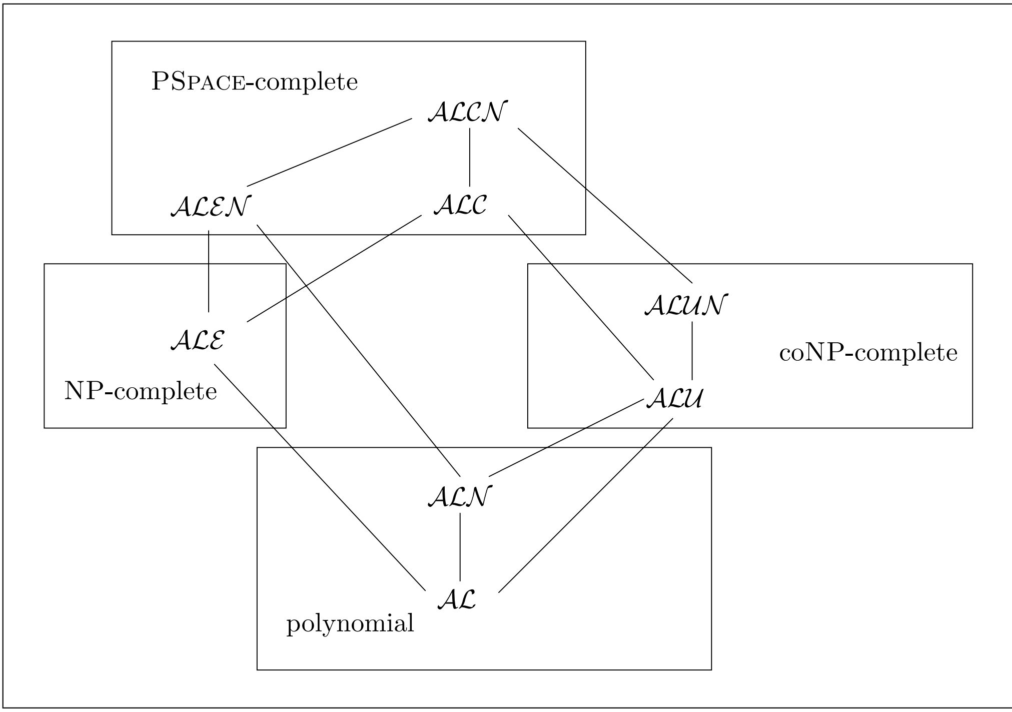

Figure 6. The complexity of unsatisfiability and subsumption for the $\mathcal{AL}$ family of DLs.

In Section 4.1 we review the results from [84] on satisfiability in other sub-Boolean DLs, and in Section 4.1 we sketch a polynomial-time subsumption algorithm for $\mathcal{EL}$ concept description.

(Un)satisfiability in $\mathcal{ALC}$, $\mathcal{ALU}$, and $\mathcal{ALE}$

One way of deciding satisfiability in $\mathcal{ALC}$ is to use a tableau algorithm, as described in more detail in Chapter 4 for the modal logic equivalent K_n of $\mathcal{ALC}$. This algorithm tries to generate a finite, tree-shaped model for a given input concept description C. This tree model is of depth linear in the size of C, but may still be exponentially large due to the branching in the tree model. There are two sources of complexity for this approach: first, the potentially exponential size of the model that must be generated, and second the non-deterministic treatment of disjunction when trying to generate the model. In order to stay within PSpace, one generates one branch of the tree at a time, whereas non-determinism is harmless since it is well-known that NPSpace = PSpace.

If we restrict this approach to $\mathcal{ALU}$, then it is easy to see that the tree models generated by a tableau-based algorithm are of polynomial size. Thus, to decide satisfiability within NP (and thus unsatisfiability within coNP) one can simply guess an interpretation of polynomial size, and check whether it is a model. NP-hardness is trivial since $\mathcal{ALU}$ contains full propositional logic.

In the case of $\mathcal{ALE}$, the model generated by a tableau-based algorithm may still be exponentially large, but the process of generating it is deterministic. In order to check

unsatisfiability within NP (and thus satisfiability within coNP), one can guess one path through the potential model, and then check whether it must satisfy contradictory constraints. To be more precise, instead of trying to generate successors for all existential restrictions, one non-deterministically chooses the ones that actually lead to a contradiction. Since the paths are linear in the size of the input description, this leads to an NP-algorithm for unsatisfiability.

Showing the lower complexity bound for $\mathcal{ALE}$ is less trivial than for $\mathcal{ALU}$. To show that unsatisfiability of concept descriptions in $\mathcal{ALE}$ is NP-complete, we sketch the reduction from set traversal given in [62]. An instance of the *set traversal problem* is given by a finite collection $\mathcal{M} = \{M_1, \ldots, M_m\}$ of finite sets of positive integers. A *set traversal* is a finite set of positive integers N such that $N \cap M_\ell$ is a singleton set for all $\ell, 1 \leq \ell \leq m$. NP-hardness of the existence of a set traversal is an immediate consequence of the fact that monotone ONE-IN-THREE 3SAT [73] is a special case of this problem.

Let $\mathcal{M} = \{M_1, \ldots, M_m\}$ be an instance of the set traversal problem, and assume without loss of generality that the numbers occurring in the sets are the ones from 1 to n for some positive integer n. We define the corresponding $\mathcal{ALE}$ concept description as

$$C_{\mathcal{M}} := C_1 \sqcap \ldots \sqcap C_n \sqcap D,$$

where

$$C_\ell := Q_{1,\ell}r.Q_{2,\ell}r.\cdots Q_{m,\ell}r.\ Q_{1,\ell}r.Q_{2,\ell}r.\cdots Q_{m,\ell}r.\ \top$$

such that

$$Q_{i,\ell} = \begin{cases} \exists & \text{if } \ell \in M_i, \\ \forall & \text{if } \ell \notin M_i, \end{cases}$$

and D is the nesting of $2m$ value restrictions followed by $\bot$, i.e.,

$$D := \underbrace{\forall r.\cdots\forall r.}_{2m \text{ times}} \bot.$$

As an example, consider the two instances

$$\mathcal{M} := \{\{1,3,5\}, \{2,4\}, \{4,5\}\} \qquad \text{and} \qquad \mathcal{M}' := \{\{1,3\}, \{2,4\}, \{4,5\}\}$$

of the set traversal problem. Then the corresponding $\mathcal{ALE}$ concept descriptions look as follows:

$$\begin{array}{ll}
C_1 = \exists\mathbf{r}.\forall r.\forall r.\ \exists\mathbf{r}.\forall r.\forall.r\ \top, & C_1' = \exists\mathbf{r}.\forall r.\forall r.\ \exists\mathbf{r}.\forall r.\forall.r\ \top, \\
C_2 = \forall r.\exists\mathbf{r}.\forall r.\ \forall r.\exists\mathbf{r}.\forall r.\ \top, & C_2' = \forall r.\exists\mathbf{r}.\forall r.\ \forall r.\exists\mathbf{r}.\forall r.\ \top, \\
C_3 = \exists\mathbf{r}.\forall r.\forall r.\ \exists\mathbf{r}.\forall r.\forall r.\ \top, & C_3' = \exists\mathbf{r}.\forall r.\forall r.\ \exists\mathbf{r}.\forall r.\forall r.\ \top, \\
C_4 = \forall r.\exists\mathbf{r}.\exists\mathbf{r}.\ \forall r.\exists\mathbf{r}.\exists\mathbf{r}.\ \top, & C_4' = \forall r.\exists\mathbf{r}.\exists\mathbf{r}.\ \forall r.\exists\mathbf{r}.\exists\mathbf{r}.\ \top, \\
C_5 = \exists\mathbf{r}.\forall r.\exists\mathbf{r}.\ \exists\mathbf{r}.\forall r.\exists\mathbf{r}.\ \top, & C_5' = \forall r.\forall r.\exists\mathbf{r}.\ \forall r.\forall r.\exists\mathbf{r}.\ \top, \\
D = \forall r.\forall r.\forall r.\ \forall r.\forall r.\forall r.\ \bot, & D' = \forall r.\forall r.\forall r.\ \forall r.\forall r.\forall r.\ \bot.
\end{array}$$

One can view the quantifier prefixes as a matrix, where the rows correspond to the elements of the sets, whereas the columns correspond to the sets (written twice). The existential quantifier indicates that the element belongs to the respective set. For example, the first existential quantifier in C_5 expresses that 5 belongs to the first set of $\mathcal{M}$, whereas the universal quantifier at the same position in C_5' says that 5 does not belong to the first set of $\mathcal{M}'$.

In [62], it is shown that $C_{\mathcal{M}}$ is unsatisfiable iff $\mathcal{M}$ has a set traversal. We illustrate the connection between unsatisfiability of $C_{\mathcal{M}}$ and the existence of a set traversal for $\mathcal{M}$ on our example. For $C_{\mathcal{M}}$ to be unsatisfiable, the conjunction of the concept descriptions C_i must enforce an r-path of length $2m$, which then clashes with the $\bot$ in D. The set $\{1,2,5\}$ is a set traversal for $\mathcal{M}'$. This implies that $C'_1 \sqcap C'_2 \sqcap C'_5$ enforces a path of length 6. In fact, C'_1 starts with an existential restriction, and C'_2 and C'_5 with value restrictions. Thus, there is an r-successor of the initial element that must satisfy the conjunction of the three concept description C''_1, C''_2, C''_5 that are respectively obtained from C'_1, C'_2, C'_5 by removing the first quantifier. Now C''_2 starts with an existential quantifier, and the other two with value restrictions. Thus, we can continue with the corresponding r-successor. In general, the properties of a set traversal ensure that each time we have one existential restriction, whereas all the others are value restrictions (and thus the remaining parts of the concept descriptions are propagated to the r-successor required by the existential restriction).

It remains to explain why we have to encode the sets twice. Again, we illustrate this on our example. It is easy to see that the collection $\mathcal{M} := \{\{1,3,5\}, \{2,4\}, \{4,5\}\}$ does not have a set traversal. Nevertheless, if we consider the simpler reduction concept $\widehat{C}_{\mathcal{M}} := \widehat{C}_1 \sqcap \widehat{C}_2 \sqcap \widehat{C}_3 \sqcap \widehat{C}_4 \sqcap \widehat{C}_5 \sqcap \widehat{D}$ where

$$\begin{aligned}
\widehat{C}_1 &= \exists\mathbf{r}.\forall r.\forall .r\ \top, \\
\widehat{C}_2 &= \forall r.\exists\mathbf{r}.\forall r.\ \top, \\
\widehat{C}_3 &= \exists\mathbf{r}.\forall r.\forall r.\ \top, \\
\widehat{C}_4 &= \forall r.\exists\mathbf{r}.\exists\mathbf{r}.\ \top, \\
\widehat{C}_5 &= \exists\mathbf{r}.\forall r.\exists\mathbf{r}.\ \top, \\
\widehat{D} &= \forall r.\forall r.\forall r.\ \bot,
\end{aligned}$$

then $\widehat{C}_{\mathcal{M}}$ is unsatisfiable. In fact, $\widehat{C}_4 \sqcap \widehat{C}_5$ enforce a path of length 3. The corresponding set $\{4,5\}$ is not a set traversal since its intersection with $M_3 = \{4,5\}$ is not a singleton. For the shorter reduction concept $\widehat{C}_{\mathcal{M}}$, the fact that $\widehat{C}_4$ and $\widehat{C}_5$ have an existential restriction in the same row is irrelevant. However, for the correct longer reduction concept $C_{\mathcal{M}}$ this means that, for one of the two, the remaining part is missing in the second round.

Subsumption in $\mathcal{FL}_0$ and $\mathcal{ALN}$

Subsumption in $\mathcal{ALN}$ can be decided in polynomial time using a *structural subsumption algorithm*, i.e., an algorithm that normalizes the descriptions to be tested for subsumption, and then compares the syntactic structure of the normal forms. For simplicity, we first explain the ideas underlying this approach for the small DL $\mathcal{FL}_0$, which allows for conjunction ($C \sqcap D$) and value restriction ($\forall r.C$) only. Subsequently, we show how the bottom concept ($\bot$), atomic negation ($\neg A$), and number restrictions ($\leqslant n\, r$ and $\geqslant n\, r$) can be handled.

An $\mathcal{FL}_0$ concept description is in *normal form* iff it is of the form

$$A_1 \sqcap \ldots \sqcap A_m \sqcap \forall r_1.C_1 \sqcap \ldots \sqcap \forall r_n.C_n,$$

where $A_1, \ldots, A_m$ are distinct concept names, $r_1, \ldots, r_n$ are *distinct* role names, and $C_1, \ldots, C_n$ are $\mathcal{FL}_0$ concept descriptions in normal form. It is easy to see that any description can be transformed into an equivalent one in normal form, using associativity,

commutativity and idempotence of $\sqcap$, and the fact that the descriptions $\forall r.(C \sqcap D)$ and $(\forall r.C) \sqcap (\forall r.D)$ are equivalent. Now, let

$$C \equiv A_1 \sqcap \ldots \sqcap A_m \sqcap \forall r_1.C_1 \sqcap \ldots \sqcap \forall r_n.C_n \text{ and } D \equiv B_1 \sqcap \ldots \sqcap B_k \sqcap \forall s_1.D_1 \sqcap \ldots \sqcap \forall s_\ell.D_\ell$$

respectively be the normal forms of the $\mathcal{FL}_0$ concept descriptions C and D. Then $C \sqsubseteq D$ iff the following two conditions hold:

1. for all $i, 1 \leq i \leq k$, there exists $j, 1 \leq j \leq m$ such that $B_i = A_j$.
2. For all $i, 1 \leq i \leq \ell$, there exists $j, 1 \leq j \leq n$ such that $s_i = r_j$ and $C_j \sqsubseteq D_i$.

It is easy to see that this characterization of subsumption is sound (i.e., the "if" direction of the equivalence holds) and complete (i.e., the "only-if" direction of the equivalence holds as well). This characterization yields an obvious recursive algorithm for computing subsumption. This algorithm can easily be shown to be of polynomial time complexity: in Condition 2, there is at most one subsumption test per role name occurring in C and D since all role names in $r_1, \ldots, r_n$ and all role names in $s_1, \ldots, s_\ell$ are distinct.

If we extend $\mathcal{FL}_0$ by language constructors that can express unsatisfiable concepts, then we must, on the one hand, change the definition of the normal form. On the other hand, the structural comparison of the normal forms must take into account that an unsatisfiable concept is subsumed by every concept. The simplest DL where this occurs is $\mathcal{FL}_\bot$, the extension of $\mathcal{FL}_0$ by the bottom concept $\bot$. An $\mathcal{FL}_\bot$ concept description is in *normal form* iff it is $\bot$ or of the form

$$A_1 \sqcap \ldots \sqcap A_m \sqcap \forall R_1.C_1 \sqcap \ldots \sqcap \forall R_n.C_n,$$

where $A_1, \ldots, A_m$ are distinct concept names different from $\bot$, $R_1, \ldots, R_n$ are distinct role names, and $C_1, \ldots, C_n$ are $\mathcal{FL}_\bot$ concept descriptions in normal form. Again, such a normal form can easily be computed. In principle, one just computes the $\mathcal{FL}_0$-normal form of the description (where $\bot$ is treated as an ordinary concept name): $B_1 \sqcap \ldots \sqcap B_k \sqcap \forall R_1.D_1 \sqcap \ldots \sqcap \forall R_n.D_n$. If one of the B_is is $\bot$, then replace the whole description by $\bot$. Otherwise, apply the same procedure recursively to the D_js. For example, the $\mathcal{FL}_0$-normal form of $\forall R.\forall R.B \sqcap A \sqcap \forall R.(A \sqcap \forall R.\bot)$ is $A \sqcap \forall R.(A \sqcap \forall R.(B \sqcap \bot))$, which yields the $\mathcal{FL}_\bot$-normal form $A \sqcap \forall R.(A \sqcap \forall R.\bot)$.

The structural subsumption algorithm for $\mathcal{FL}_\bot$ works just like the one for $\mathcal{FL}_0$, with the only difference that $\bot$ is subsumed by any description. For example, $\forall r.\forall r.B \sqcap A \sqcap \forall r.(A \sqcap \forall r.\bot) \sqsubseteq \forall r.\forall r.A \sqcap A \sqcap \forall r.A$ since the recursive comparison of their $\mathcal{FL}_\bot$-normal forms $A \sqcap \forall r.(A \sqcap \forall r.\bot)$ and $A \sqcap \forall r.(A \sqcap \forall r.A)$ finally leads to the comparison of $\bot$ and A.

The extension of $\mathcal{FL}_\bot$ by atomic negation (i.e., negation applied to concept names only) can be treated similarly. During the computation of the normal form, negated concept names are just treated like concept names. If, however, a name and its negation occur on the same level of the normal form, then $\bot$ is added, which can then be treated as described above. For example, $\forall r.\neg A \sqcap A \sqcap \forall r.(A \sqcap \forall r.B)$ is first transformed into $A \sqcap \forall r.(A \sqcap \neg A \sqcap \forall r.B)$, then into $A \sqcap \forall r.(\bot \sqcap A \sqcap \neg A \sqcap \forall r.B)$, and finally into $A \sqcap \forall r.\bot$. The structural comparison of the normal forms treats negated concept names just like concept names.

Finally, if we consider the language $\mathcal{ALN}$, the additional presence of number restrictions leads to a new type of conflict. On the one hand, as in the case of atomic negation,

number restrictions may be conflicting with each other (e.g., $\geqslant 2\, r$ and $\leqslant 1\, r$). On the other hand, at-least restrictions $\geqslant n\, r$ for $n \geq 1$ are in conflict with value restrictions $\forall r.\bot$ that prohibit role successors. When computing the normal form, one can again treat number restrictions like concept names, and then take care of the new types of conflicts by introducing $\bot$ and using it for normalization as described above. During the structural comparison of normal forms, one must also take into account inherent subsumption relationships between number restrictions (e.g., $\geqslant n\, r \sqsubseteq \geqslant m\, r$ iff $n \geq m$). A more detailed description of a structural subsumption algorithm working on a graph-like data structure for a DL extending $\mathcal{ALN}$ can be found in [40].

Satisfiability in other sub-Boolean DLs

Until now, we have only considered sub-Boolean DLs that extend $\mathcal{AL}$. Hemaspaandra [84] looks at all possible combinations of the constructors

$$\top,\ \ \bot,\ \ C \sqcap D,\ \ C \sqcup D,\ \ \neg A,\ \ \neg C,\ \ \forall r.C,\ \ \exists r.C,$$

and shows that there are only four possibilities for the complexity of the *satisfiability* problem:[12] P, NP-complete, coNP-complete, and PSPACE-complete:

- DLs that contain a complete basis for $\mathcal{ALC}$ have a PSPACE-complete satisfiability problem.
- DLs that contain a complete basis for propositional logic, but not for $\mathcal{ALC}$, have an NP-complete satisfiability problem.
- The DL $\mathcal{ALE}$ and its sublanguages where $\bot$, $\top$, or both are disallowed, have a coNP-complete satisfiability problem.
- The DL defined by the constructors $\bot$, $C \sqcap D$, $C \sqcup D$, $\forall r.C$, $\exists r.C$ has a PSPACE-complete satisfiability problem.
- All other DLs obtained as a combination of the above constructors have a polynomial satisfiability problem.

Subsumption in $\mathcal{EL}$

Recall that $\mathcal{EL}$ is defined by the constructors top concept ($\top$), conjunction ($C \sqcap D$), and existential restriction ($\exists r.C$). We show that subsumption of $\mathcal{EL}$ concept descriptions can be decided in polynomial time by reducing the subsumption problem to a combinatorial problem on trees. Any $\mathcal{EL}$ concept description C can be represented as a tree $\mathcal{G}_C$ whose edges are labeled with role names and whose nodes are labeled with sets of primitive concepts (where the empty set stands for $\top$). For example, the $\mathcal{EL}$ concept descriptions

$$\begin{aligned} C &:= P \sqcap \exists r.(\exists r.(P \sqcap Q) \sqcap \exists s.Q) \sqcap \exists r.(P \sqcap \exists s.P) \\ D &:= \exists r.(\exists r.P \sqcap \exists s.Q) \sqcap \exists r.P \end{aligned}$$

yield the $\mathcal{EL}$ description trees $\mathcal{G}_C$ and $\mathcal{G}_D$ depicted in Figure 7 (see [25] for a formal definition of the translation between $\mathcal{EL}$ concept descriptions and $\mathcal{EL}$ description trees).

Let C, D be $\mathcal{EL}$ concept descriptions. A *simulation* from $\mathcal{G}_D$ to $\mathcal{G}_C$ is a binary relation Z between the nodes of $\mathcal{G}_D$ and the nodes of $\mathcal{G}_C$ such that

[12] Unfortunately, the complexity of subsumption is not considered in [84].

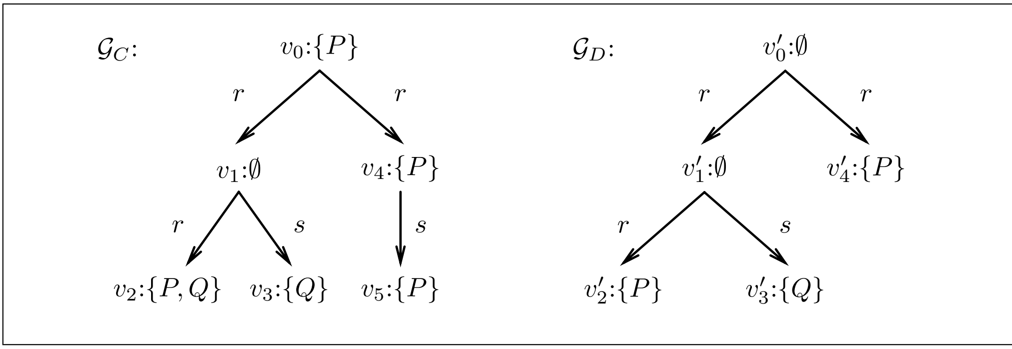

Figure 7. Two $\mathcal{EL}$ description trees.

1. $(v', v) \in Z$ implies that the label of v' is contained in the label of v;
2. $(v', v) \in Z$ implies that, for every r-successor u' of v' there is an r-successor u of v such that $(u', u) \in Z$.

Subsumption between $\mathcal{EL}$ concept descriptions corresponds to the existence of a simulation relation[13] between the corresponding trees: if v_0 is the root of $\mathcal{G}_C$ and v'_0 the root of $\mathcal{G}_D$, then we have

$$C \sqsubseteq D \quad \text{iff} \quad \text{there is a simulation } Z \text{ from } \mathcal{G}_D \text{ to } \mathcal{G}_C \text{ such that } (v'_0, v_0) \in Z.$$

In our example, we have $C \sqsubseteq D$ since the following relation Z is a simulation from $\mathcal{G}_D$ to $\mathcal{G}_C$:

$$Z := \{(v'_0, v_0),\ (v'_1, v_1),\ (v'_2, v_2),\ (v'_3, v_3),\ (v'_4, v_4)\}.$$

The definition of a simulation suggests the following top-down algorithm for constructing a simulation Z containing the tuple consisting of the roots (v'_0, v_0). First, put (v'_0, v_0) into Z and check whether the first property of a simulation (containment of labels) is satisfied for this tuple. If not, then stop with failure. Otherwise, try to extend Z by guessing pairs of successors of v'_0 and v_0, respectively, such that the second property of a simulation is satisfied for the pair (v'_0, v_0). Then continue the process with these new pairs. Since there are different ways of pairing off the successors, this algorithm is non-deterministic, and thus it does not yield a deterministic polynomial-time subsumption algorithm.

Fortunately, one can do better. One can compute the largest simulation between two trees (and actually also between two graphs with distinguished "root" nodes) by starting with all pairs of nodes, and then successively removing pairs that violate the first condition in the definition of a simulation or the second one (w.r.t. the current relation). It is easy to see that this procedure terminates after polynomially many steps with the largest simulation $\widehat{Z}$ from $\mathcal{G}_C$ to $\mathcal{G}_D$ (see [85] for a more efficient algorithm). We have $C \sqsubseteq D$ iff the pair consisting of the root nodes has not been removed, i.e., belongs to $\widehat{Z}$ (see [9] for more details).

[13] In [25], subsumption was actually characterized by the existence of a homomorphism, i.e., a simulation that is a total function. However, it is easy to see that, in case of *trees*, the existence of a simulation implies the existence of a homomorphism.

4.2 TBox reasoning in sub-Boolean DLs

As mentioned in Section 3, reasoning w.r.t. acyclic TBoxes can be reduced to reasoning on concept descriptions by expanding the definitions. Unfortunately, expansion may lead to an exponential blow-up of the descriptions. Is this due to the inherent complexity of reasoning with TBoxes, or can this exponential increase in the complexity be avoided? It turns out that the answer to this question depends on which sub-Boolean DL we consider.[14]

For the DL $\mathcal{FL}_0$, subsumption of concept descriptions is polynomial, whereas subsumption w.r.t. acyclic TBoxes is coNP-complete, subsumption w.r.t. cyclic TBoxes is PSPACE-complete, and subsumption w.r.t. GCIs in EXPTIME-complete. In contrast, for the DL $\mathcal{EL}$, subsumption remains polynomial even w.r.t. GCIs.

TBox reasoning in $\mathcal{FL}_0$

We start by describing an alternative approach for showing that subsumption of $\mathcal{FL}_0$ concept descriptions can be decided in polynomial time. In Section 4.1, the equivalence $\forall r.C \sqcap \forall r.D \equiv \forall r.(C \sqcap D)$ was used as a rewrite rule from left to right in order to compute the *structural subsumption normal form* of $\mathcal{FL}_0$ concept descriptions. If we use this rule in the opposite direction, we obtain a different normal form, which is called *concept-centered normal form* in [24], since it groups the concept descriptions w.r.t. concept names (and not w.r.t. role names, as the structural subsumption normal form does). Using this rule, any $\mathcal{FL}_0$ concept description can be transformed into an equivalent description that is a conjunction of descriptions of the form $\forall r_1. \cdots \forall r_m.A$ for $m \geq 0$ (not necessarily distinct) role names $r_1, \ldots, r_m$ and a concept name A. We abbreviate $\forall r_1. \cdots \forall r_m.A$ by $\forall r_1 \ldots r_m.A$, where $r_1 \ldots r_m$ is viewed as a word over the alphabet Σ of all role names. In addition, instead of $\forall w_1.A \sqcap \ldots \sqcap \forall w_\ell.A$ we write $\forall L.A$ where $L := \{w_1, \ldots, w_\ell\}$ is a finite set of words over Σ. The term $\forall \emptyset.A$ is considered to be equivalent to the top concept $\top$, which means that it can be added to a conjunction without changing the meaning of the concept. Using these abbreviations, any pair of $\mathcal{FL}_0$ concept descriptions C, D containing the concept names $A_1, \ldots, A_k$ can be rewritten as

$$C \equiv \forall U_1.A_1 \sqcap \ldots \sqcap \forall U_k.A_k \quad \text{and} \quad D \equiv \forall V_1.A_1 \sqcap \ldots \sqcap \forall V_k.A_k,$$

where U_i, V_i are finite sets of words over the alphabet of all role names. This normal form provides us with the following *characterization of subsumption* of $\mathcal{FL}_0$ concept descriptions [28]:

$$C \sqsubseteq D \quad \text{iff} \quad U_i \supseteq V_i \ \text{ for all } i, 1 \leq i \leq k.$$

Since the size of the concept-based normal forms is polynomial in the size of the original descriptions, and since the inclusion tests $U_i \supseteq V_i$ can also be realized in polynomial time, this yields a polynomial-time decision procedure for subsumption in $\mathcal{FL}_0$. In fact, as shown in [24], the structural subsumption algorithm for $\mathcal{FL}_0$ can be seen as a special implementation of these inclusion tests.

This characterization of subsumption via inclusion of finite sets of words can be extended to cyclic TBoxes with greatest fixpoint semantics as follows. A given TBox $\mathcal{T}$ can

[14] The same is true for propositionally closed DLs (see Section 6).

$$
\begin{array}{rcl}
A & \equiv & \forall r.A \sqcap \forall s.C \\
B & \equiv & \forall r.\forall s.C \\
C & \equiv & P \sqcap \forall s.C
\end{array}
$$

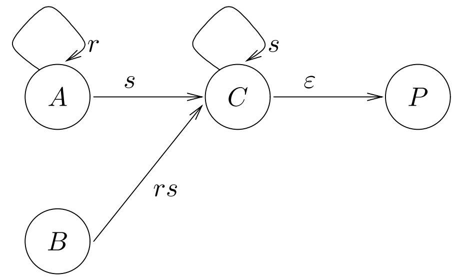

Figure 8. A cyclic $\mathcal{FL}_0$ TBox and the corresponding automaton.

be translated into a finite automaton[15] $\mathcal{A}_\mathcal{T}$ whose states are the concept names occurring in $\mathcal{T}$ and whose transitions are induced by the value restrictions occurring in $\mathcal{T}$ (see Fig. 8 for an example and [5] for the formal definition). For a defined concept A and a primitive concept P in $\mathcal{T}$, the language $L_{\mathcal{A}_\mathcal{T}}(A, P)$ is the set of all words labeling paths in $\mathcal{A}_\mathcal{T}$ from A to P. The languages $L_{\mathcal{A}_\mathcal{T}}(A, P)$ represent all the value restrictions that must be satisfied by instances of the concept A. With this intuition in mind, it should not be surprising that subsumption w.r.t. cyclic $\mathcal{FL}_0$ TBoxes can be characterized in terms of inclusion of regular languages represented by automata. Indeed, the following *characterizes subsumption w.r.t. greatest fixpoint semantics*:

$$A \sqsubseteq_{gfp,\mathcal{T}} B \quad \text{iff} \quad L_{\mathcal{A}_\mathcal{T}}(A, P) \supseteq L_{\mathcal{A}_\mathcal{T}}(B, P) \text{ for all primitive concepts } P.$$

In the example of Fig. 8, we have $L_{\mathcal{A}_\mathcal{T}}(A, P) = r^*ss^* \supset rss^* = L_{\mathcal{A}_\mathcal{T}}(B, P)$, and thus $A \sqsubseteq_\mathcal{T} B$, but not $B \sqsubseteq_\mathcal{T} A$.

Obviously, the languages $L_{\mathcal{A}_\mathcal{T}}(A, P)$ are regular, and any regular language can be obtained as such a language. Since inclusion of regular languages is a PSpace-complete problem [73], this shows that subsumption w.r.t. cyclic $\mathcal{FL}_0$ TBoxes with greatest fixpoint semantics is PSpace-complete [5]. The same complexity can be shown for subsumption in cyclic $\mathcal{FL}_0$ TBoxes interpreted with least fixpoint semantics or with descriptive semantics [5, 102]. In addition, the PSpace-completeness result can be extended to the DL $\mathcal{ALN}$ [106].

For an acyclic $\mathcal{FL}_0$ TBox $\mathcal{T}$, the automaton $\mathcal{A}_\mathcal{T}$ is acyclic as well. Since inclusion of languages accepted by acyclic finite automata is coNP-complete [73] and subsumption w.r.t. greatest fixpoint semantics coincides with subsumption w.r.t. descriptive semantics in the case of acyclic TBoxes, this proves Nebel's result that subsumption w.r.t. acyclic $\mathcal{FL}_0$-TBoxes is coNP-complete [128]. Thus, for $\mathcal{FL}_0$, even the presence of acyclic TBoxes increases the complexity of the subsumption problem.

Finally, ExpTime-hardness of subsumption in $\mathcal{FL}_0$ w.r.t. GCIs was shown in [10]. The ExpTime-upper bound follows from the fact that subsumption in $\mathcal{ALC}$ w.r.t. GCIs is in ExpTime [138].

[15] Strictly speaking, we obtain a finite automaton with word transitions, i.e., transitions that may be labeled by a word over Σ rather than a letter of Σ.

$$B \equiv P \sqcap \exists r.C,$$
$$C \equiv Q \sqcap \exists r.D, \qquad D \equiv P \sqcap \exists r.C,$$
$$A \equiv P \sqcap Q \sqcap \exists r.A', \quad A' \equiv Q \sqcap P \sqcap \exists r.D.$$

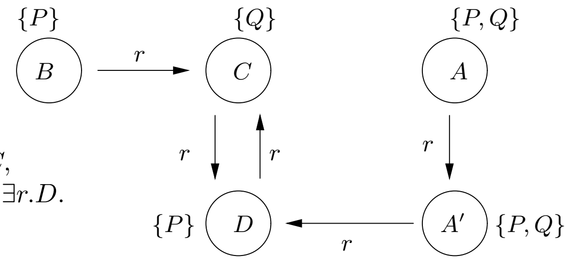

Figure 9. A normalized $\mathcal{EL}$ TBox and the corresponding description graph.

TBox reasoning in $\mathcal{EL}$

The approach for deciding subsumption between $\mathcal{EL}$ concept descriptions sketched in Section 4.1 can be extended to $\mathcal{EL}$ TBoxes [9]. In fact, one can show that any $\mathcal{EL}$ TBox can be transformed in polynomial time into an equivalent *normalized TBox* whose definitions are of the form

$$A \equiv P_1 \sqcap \ldots \sqcap P_m \sqcap \exists r_1.B_1 \sqcap \ldots \sqcap \exists r_\ell.B_\ell,$$

where $P_1, \ldots, P_m$ are primitive concepts, $r_1, \ldots, r_\ell$ roles, and $B_1, \ldots, B_\ell$ defined concepts. Any normalized $\mathcal{EL}$ TBox $\mathcal{T}$ can then be transformed into an $\mathcal{EL}$ *description graph* $\mathcal{G}_\mathcal{T}$ whose nodes are the defined concepts of $\mathcal{T}$. If A is a defined concept whose definition in $\mathcal{T}$ is of the normalized form shown above, then A has label $\{P_1, \ldots, P_m\}$, and is the source of the edges $(A, r_1, B_1), \ldots, (A, r_\ell, B_\ell)$ (see Figure 9 for an example).

Subsumption w.r.t. greatest fixpoint semantics corresponds to the existence of an appropriate simulation on $\mathcal{G}_\mathcal{T}$ [9]: if A, B are defined concepts in $\mathcal{T}$, then

$$A \sqsubseteq_{gfp,\mathcal{T}} B \quad \text{iff} \quad \text{there is a simulation } Z \text{ from } \mathcal{G}_\mathcal{T} \text{ to } \mathcal{G}_\mathcal{T} \text{ such } (B, A) \in Z.$$

Since the algorithm for computing the largest simulation sketched in Section 4.1 also works on graphs, this shows that subsumption w.r.t. $\mathcal{EL}$ TBoxes interpreted with greatest fixpoint semantics can be decided in polynomial time. In [9], the same result is also shown for descriptive and least fixpoint semantics. As a special case we have that subsumption w.r.t. acyclic $\mathcal{EL}$ TBoxes is polynomial.

In [46], it is shown that subsumption in $\mathcal{EL}$ remains polynomial even in the presence of GCIs, and in [10] this result is extended to the DL $\mathcal{EL}^{++}$, which extends $\mathcal{EL}$ by the bottom concept, nominals, a restricted form of concrete domains, and a restricted form of role-value maps.[16]

The polynomial-time subsumption algorithms for $\mathcal{EL}$ and $\mathcal{EL}^{++}$ actually classify the given set of GCIs $\mathcal{T}$, i.e., they simultaneously compute all subsumption relationships between the concept names occurring in $\mathcal{T}$. In the following, we sketch an algorithm for $\mathcal{EL}$. This algorithm proceeds in four steps:

1. Normalize the set of GCIs.

2. Translate the normalized set of GCIs into a graph.

[16] Concrete domains and role-value maps will be introduced in Section 6. Adding unrestricted concrete domains or role-value maps to $\mathcal{EL}$ with GCIs would cause undecidability of subsumption [10, 8].

3. Complete the graph using completion rules.

4. Read off the subsumption relationships from the normalized graph.

A set of $\mathcal{EL}$ GCIs is *normalized* iff it only contains GCIs of the following form:

$$A_1 \sqcap A_2 \sqsubseteq B, \quad A \sqsubseteq \exists r.B, \quad \exists r.A \sqsubseteq B,$$

where A, A_1, A_2, B are concept names or the top-concept $\top$. One can transform a given set of GCIs into a normalized one by applying normalization rules. Instead of describing these rules in the general case, we just illustrate them by an example:

$$\begin{array}{rl}
\exists r.A \sqcap \exists r.\exists s.A \sqsubseteq A \sqcap \exists r.\top & \rightsquigarrow \quad \exists r.A \sqsubseteq B_1, \quad B_1 \sqcap \exists r.\exists s.A \sqsubseteq A \sqcap \exists r.\top \\
\rightsquigarrow & \exists r.A \sqsubseteq B_1, \quad \exists r.\exists s.A \sqsubseteq B_2, \quad B_1 \sqcap B_2 \sqsubseteq A \sqcap \exists r.\top \\
\rightsquigarrow & \exists r.A \sqsubseteq B_1, \quad \exists s.A \sqsubseteq B_3, \quad \exists r.B_3 \sqsubseteq B_2, \quad B_1 \sqcap B_2 \sqsubseteq A \sqcap \exists r.\top \\
\rightsquigarrow & \exists r.A \sqsubseteq B_1, \quad \exists s.A \sqsubseteq B_3, \quad \exists r.B_3 \sqsubseteq B_2, \quad B_1 \sqcap B_2 \sqsubseteq A, \quad B_1 \sqcap B_2 \sqsubseteq \exists r.\top
\end{array}$$

For example, in the first normalization step we introduce the abbreviation B_1 for the description $\exists r.A$. One might think that one must make B_1 equivalent to $\exists r.A$, i.e., also add the GCI $B_1 \sqsubseteq \exists r.A$. However, it can be shown that adding just $\exists r.A \sqsubseteq B_1$ is sufficient to obtain a *subsumption-equivalent* set of GCIs, i.e., a set that induces the same subsumption relationships between the concept names occurring in the original set of GCIs. All normalization rules preserve equivalence in this sense, and if one uses an appropriate strategy (which basically defers the applications of the rule applied in the last step of our example to the end), then the normal form can be computed in linear time.

In the next step, we build the *classification graph* $G_\mathcal{T} = (V, V \times V, S, R)$ where

- V is the set of concept names (including $\top$) occurring in the normalized set of GCIs $\mathcal{T}$;
- S labels nodes with sets of concept names (again including $\top$);
- R labels edges with sets of role names.

The label sets are supposed to satisfy the following *invariants*:

- $B \in S(A)$ implies $A \sqsubseteq_\mathcal{T} B$, i.e., $S(A)$ contains only subsumers of A w.r.t. the set of GCIs $\mathcal{T}$.
- $r \in R(A, B)$ implies $A \sqsubseteq_\mathcal{T} \exists r.B$, i.e., $R(A, B)$ contains only roles r such that $\exists r.B$ subsumes A.

Initially, we set $S(A) := \{A, \top\}$ for all nodes $A \in V$, and $R(A, B) := \emptyset$ for all edges $(A, B) \in V \times V$. Obviously, the above invariants are satisfied by these initial label sets.

The labels of nodes and edges are then extended by applying the rules of Figure 10. Note that such a rule is only applied if it really extends a label set. It is easy to see that these rules preserve the above invariants. For example, consider the (most complicated) rule (R3). Obviously, $\exists r.B_1 \sqsubseteq A_1 \in \mathcal{T}$ implies $\exists r.B_1 \sqsubseteq_\mathcal{T} A_1$, and the assumption that the invariants are satisfied before applying the rule yields $B \sqsubseteq_\mathcal{T} B_1$ and $A \sqsubseteq_\mathcal{T} \exists r.B$. The subsumption relationship $B \sqsubseteq_\mathcal{T} B_1$ obviously implies $\exists r.B \sqsubseteq_\mathcal{T} \exists r.B_1$. By applying transitivity of the subsumption relation $\sqsubseteq_\mathcal{T}$, we thus obtain $A \sqsubseteq_\mathcal{T} A_1$.

The fact that subsumption in $\mathcal{EL}$ w.r.t. GCIs can be decided in polynomial time is an immediate consequence of the following statements:

(R1)	$A_1 \sqcap A_2 \sqsubseteq B \in \mathcal{T}$ and $A_1, A_2 \in S(A)$		then	add B to $S(A)$
(R2)	$A_1 \sqsubseteq \exists r.B \in \mathcal{T}$ and $A_1 \in S(A)$		then	add r to $R(A, B)$
(R3)	$\exists r.B_1 \sqsubseteq A_1 \in \mathcal{T}$ and $B_1 \in S(B), r \in S(A, B)$		then	add A_1 to $S(A)$

Figure 10. The completion rules for subsumption in $\mathcal{EL}$ w.r.t. GCIs.

1. Rule application terminates after a polynomial number of steps.

2. If no more rules are applicable, then $A \sqsubseteq_{\mathcal{T}} B$ iff $B \in S(A)$.

Regarding the first statement, note that the number of nodes is linear and the number of edges is quadratic in the size of $\mathcal{T}$. In addition, the size of the label sets is bounded by the number of concept names and role names, and each rule application extends at least one label. Regarding the equivalence in the second statement, the "if" direction follows from the fact that the above invariants are preserved under rule application. To show the "only-if" direction, assume that $B \notin S(A)$. Then the following interpretation $\mathcal{I}$ is a model of $\mathcal{T}$ in which $A \in A^{\mathcal{I}}$, but $A \notin B^{\mathcal{I}}$:

- $\Delta^{\mathcal{I}} := V$;
- $r^{\mathcal{I}} := \{(A', B') \mid r \in R(A', B')\}$ for all role names r;
- $B'^{\mathcal{I}} := \{A' \mid B' \in S(A')\}$ for all concept names A'.

More details can be found in [46, 10].

4.3 ABox reasoning in sub-Boolean DLs

In [67], the complexity of instance checking in DLs of the $\mathcal{AL}$ family is investigated. With one exception, the complexity[17] of instance checking coincides with the complexity of subsumption. This one exception is $\mathcal{ALE}$, where the subsumption problem is NP-complete, whereas instance checking is PSPACE-complete. In the following, we sketch the PSPACE-hardness proof given in [67]. It depends on the PSPACE-hardness proof of satisfiability in $\mathcal{ALC}$ given in [143], which works by a reduction[18] from Quantified Boolean Formulae (QBF), whose validity problem is known to be PSPACE-complete [73]. A given QBF φ is translated in polynomial time into an $\mathcal{ALC}$ concept description C_φ such that φ is valid iff C_φ is satisfiable. For the purpose of sketching the PSPACE-hardness proof from [67], it is not really necessary to know what a QBF is and how the reduction concept C_φ is defined in detail. The first important observation made in [67] is that C_φ is equivalent to a concept description of the form

$$D \sqcap \neg D_1 \sqcap \ldots \sqcap \neg D_n$$

[17] To be more precise, the "combined complexity" of $\mathcal{A} \models C(a)$, i.e., w.r.t. both the size of $\mathcal{A}$ and the size of C.

[18] Note that this reduction actually differs from the one usually employed in modal logic to show PSPACE-hardness of K [81].

where $D, D_1, \ldots, D_n$ are $\mathcal{ALE}$ concept descriptions whose size is polynomially related to the size of C_φ. Thus, it remains to be shown that satisfiability of concept descriptions of this form can be reduced in polynomial time to instance checking in $\mathcal{ALE}$.

Assume that $\mathcal{ALE}$ concept descriptions $D, D_1, \ldots, D_n$ are given. Let q be a new role and E_n a new concept name. We define $\mathcal{ALE}$ concept descriptions $E_0, \ldots, E_{n-1}$ as follows:

$$E_i := \exists q.(D_{i+1} \sqcap E_{i+1}) \quad \text{for } i = 0, \ldots, n-1.$$

The ABox $\mathcal{A}$ is defined as

$$\mathcal{A} \;:=\; \{\, q(a,a),\ q(a,b),\quad D_1(a),\ \ldots,\ D_n(a),\quad E_1(b),\ \ldots,\ E_n(b),\quad D(b)\,\}$$

In [67], it is shown that

$$D \sqcap \neg D_1 \sqcap \ldots \sqcap \neg D_n \text{ is satisfiable} \quad \text{iff} \quad \mathcal{A} \not\models E_0(a).$$

In fact, assume that $\mathcal{A} \not\models E_0(a)$. Then there is a model $\mathcal{I}$ of $\mathcal{A}$ such that

$$a^{\mathcal{I}} \in (\neg E_0)^{\mathcal{I}} = (\forall q.(\neg D_1 \sqcup \neg E_1))^{\mathcal{I}}.$$

Thus $(a^{\mathcal{I}}, a^{\mathcal{I}}) \in q^{\mathcal{I}}, a^{\mathcal{I}} \in D_1^{\mathcal{I}}$ and $(a^{\mathcal{I}}, b^{\mathcal{I}}) \in q^{\mathcal{I}}, b^{\mathcal{I}} \in E_1$ imply that $a^{\mathcal{I}} \in (\neg E_1)^{\mathcal{I}}$ and $b^{\mathcal{I}} \in (\neg D_1)^{\mathcal{I}}$. We can now apply the same argument to $a^{\mathcal{I}} \in (\neg E_1)^{\mathcal{I}} = (\forall q.(\neg D_2 \sqcup \neg E_2))^{\mathcal{I}}$, etc. In the end, we obtain that $b^{\mathcal{I}} \in (\neg D_i)^{\mathcal{I}}$ for $i = 1, \ldots, n$, and since we also have $b^{\mathcal{I}} \in D^{\mathcal{I}}$ this shows that $D \sqcap \neg D_1 \sqcap \ldots \sqcap \neg D_n$ is satisfiable.

Conversely, it is easy to see that a model of $D \sqcap \neg D_1 \sqcap \ldots \sqcap \neg D_n$ can be used to construct a model of $\mathcal{A}$ in which a does not belong to E_0.

4.4 Bi-simulation characterizations of sub-Boolean DLs

As noted before, concept descriptions of the $\mathcal{AL}$ family (and also of many other DLs) can be translated into first-order formulae with one free variable. Thus, any such DL $\mathcal{L}$ yields a fragment $FO_{\mathcal{L}}$ of first-order predicate logic, which consists of those formulae with one free variable that are equivalent to the first-order translation of an $\mathcal{L}$ concept description. These fragments can be used to compare the *expressive power*[19] of DLs.

We say that a DL $\mathcal{L}_2$ is *strictly more expressive* than a DL $\mathcal{L}_1$ ($\mathcal{L}_1 \prec \mathcal{L}_2$) iff $FO_{\mathcal{L}_1} \subset FO_{\mathcal{L}_2}$, i.e., every first-order translation of an $\mathcal{L}_1$ concept description is equivalent to the first-order translation of an $\mathcal{L}_2$ concept description, and there is an $\mathcal{L}_2$ concept description whose translation is not equivalent to any translation of an $\mathcal{L}_1$ concept description.

Usually, the inclusion between two fragments $FO_{\mathcal{L}_1}$ and $FO_{\mathcal{L}_2}$ is relatively easy to show. However, how can one show that such an inclusion is strict? One way of doing this is to use an appropriate bisimulation characterization of the first-order fragments. For example, it is well-know that the fragment $FO_{\mathcal{ALC}}$ consists of those first-order formulae that are preserved under bisimulation (see Chapter 1). This can be used to show that $\mathcal{ALC} \prec \mathcal{ALCN}$ by giving an example of an $\mathcal{ALCN}$ concept description that is not preserved under bisimulation (see [105]).

In [105], the bisimulation characterization of the first-order fragment corresponding to $\mathcal{ALC}$ is adapted to various sub-Boolean DLs, and then used to compare their expressive power. Here, we only sketch the characterization of $FO_{\mathcal{AL}}$.

[19]The definition of the expressive power of DLs obtained this way is used in [105]; it is weaker than the one defined in [4] since it does not allow one to extend the vocabulary.

First, we must introduce some notation. If X, Y are subsets of a set Δ, and R is a binary relation on Δ, then we define

$$\begin{array}{lll} X\,R^{\uparrow}\,Y & \text{iff} & \text{for all } d \in X \text{ there is } e \in Y \text{ such that } (d,e) \in R, \\ X\,R^{\downarrow}\,Y & \text{iff} & \text{for all } e \in Y \text{ there is } d \in X \text{ such that } (d,e) \in R. \end{array}$$

In order to explain the intuition underlying this definition from a DL point of view, assume that r is a role, C, D are concept descriptions, and $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ is an interpretation, and define $R := r^{\mathcal{I}}$, $X := C^{\mathcal{I}}$, and $Y := D^{\mathcal{I}}$. Then $X\,R^{\uparrow}\,Y$ means that $C^{\mathcal{I}} \subseteq (\exists r.D)^{\mathcal{I}}$, and $X\,R^{\downarrow}\,Y$ means that $D^{\mathcal{I}} \subseteq (\exists r^{-}.C)^{\mathcal{I}}$.

Let $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ and $\mathcal{J} = (\Delta^{\mathcal{J}}, \cdot^{\mathcal{J}})$ be two interpretations. An *$\mathcal{AL}$-simulation* between $\mathcal{I}$ and $\mathcal{J}$ is a non-empty relation $Z \subseteq 2^{\Delta^{\mathcal{I}}} \times \Delta^{\mathcal{J}}$ such that the following three conditions are satisfied:

1. If $(X_1, d_2) \in Z$, then $X_1 \subseteq A^{\mathcal{I}}$ implies $d_2 \in A^{\mathcal{J}}$ and $X_1 \subseteq (\neg A)^{\mathcal{I}}$ implies $d_2 \in (\neg A)^{\mathcal{J}}$ for all concept names A.

2. For every role name r, if $(X_1, d_2) \in Z$ and $X_1\,(r^{\mathcal{I}})^{\uparrow}\,Y_1$, then there is an $e_2 \in \Delta^{\mathcal{J}}$ such that $(d_2, e_2) \in r^{\mathcal{I}}$.

3. For every role name r, if $(X_1, d_2) \in Z$ and $(d_2, e_2) \in r^{\mathcal{J}}$, then there is an $Y_1 \subseteq \Delta^{\mathcal{I}}$ such that $X_1\,(r^{\mathcal{I}})^{\downarrow}\,Y_1$ and $(Y_1, e_2) \in Z$.

Intuitively, the fact that $\mathcal{AL}$-simulations are binary relations between *subsets* of $\Delta^{\mathcal{I}}$ and $\Delta^{\mathcal{J}}$ makes sure that disjunction (which is not available in $\mathcal{AL}$) is not preserved. The first clause of the definition ensures that concept names and negated concept names (but not full negation) are preserved. The second clause ensures preservation of restricted existential restrictions $\exists r.\top$, but not of full existential restrictions $\exists r.C$ (since we do not require $(Y_1, e_2) \in Z$). The third clause ensures that value restrictions are preserved.

The first order formula $\alpha(x)$ is *preserved under $\mathcal{AL}$-simulations* iff for all interpretations $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ and $\mathcal{J} = (\Delta^{\mathcal{J}}, \cdot^{\mathcal{J}})$ and all $\mathcal{AL}$-simulations Z between $\mathcal{I}$ and $\mathcal{J}$, we have:

$$(X, d_2) \in Z \text{ and } \mathcal{I} \models \alpha(d_1) \text{ for all } d_1 \in X \quad \text{implies} \quad \mathcal{I} \models \alpha(d_2).$$

In [105], it is shown that $FO_{\mathcal{AL}}$ consists of those first-order formulae that are preserved under $\mathcal{AL}$-simulations.

This result can be used to show that $\mathcal{ALU}$ is strictly more expressive than $\mathcal{AL}$. In fact, the formula $A(x) \vee B(x)$ obtained by translating the $\mathcal{ALU}$ concept description $A \sqcup B$ into first-order logic is not preserved under $\mathcal{AL}$-simulations. To see this, let $\mathcal{I}$ be the interpretation consisting of two elements d_1, e_1, where d_1 belongs to A and e_1 belongs to B, and let $\mathcal{J}$ be the interpretation consisting of the element d_2, which belongs neither to A nor to B. It is easy to see that $Z := \{(\{d_1, e_1\}, d_2)\}$ is an $\mathcal{AL}$-simulation between $\mathcal{I}$ and $\mathcal{J}$. However, $(\{d_1, e_1\}, d_2) \in Z$ and both d_1 and e_1 satisfy $A(x) \vee B(x)$, but d_2 does *not* satisfy $A(x) \vee B(x)$.

5 NON-STANDARD INFERENCES

After motivating the need for non-standard inferences in DLs and illustrating some of them by examples, we give formal definitions of the most important non-standard inferences considered until now, and review the existing results.

5.1 Motivation

All DL systems provide their users with standard inference services like computing the subsumption hierarchy, testing ABox consistency, and instance checking. These inferences are not only useful when working with “finished” knowledge bases, they can also support the knowledge engineer while building a knowledge base, by pointing out inconsistencies and unwanted consequences. They can help the knowledge engineer to check whether a concept definition makes sense, but they provide no support for actually coming up with a first version of the definition. The non-standard inferences introduced in this section can be used to overcome this deficit, basically by providing two ways of re-using “old” knowledge when defining new one: (i) constructing concepts by generalizing from examples, and (ii) constructing concepts by modifying “similar” ones.

The first approach was introduced as *bottom-up construction* of description logic knowledge bases in [20, 25]. Instead of defining the relevant concepts of an application domain from scratch, this methodology allows the user to give typical examples of individuals belonging to the concept to be defined. These individuals are then generalized to a concept by first computing the most specific concept (msc) of each individual (i.e., the least concept description w.r.t. subsumption in the available description language that has this individual as an instance), and then computing the least common subsumer (lcs) of these concepts (i.e., the least concept description w.r.t. subsumption in the available description language that subsumes all these concepts). The knowledge engineer can then use the computed concept as a starting point for the concept definition. As a simple example, assume that the knowledge engineer has already defined the concept of a man and a woman as

$$\mathsf{Man} \equiv \mathsf{Human} \sqcap \mathsf{Male} \quad \text{and} \quad \mathsf{Woman} \equiv \mathsf{Human} \sqcap \mathsf{Female},$$

and now wants to define the concept of a parent, but does not know how to do this within the available DL (which we assume to be $\mathcal{EL}$ in this example). However, the available ABox

$$\begin{array}{lll} \mathsf{Man}(\mathsf{JACK}), & \mathsf{child}(\mathsf{JACK}, \mathsf{CAROLINE}), & \mathsf{Woman}(\mathsf{CAROLINE}), \\ \mathsf{Woman}(\mathsf{JACKIE}), & \mathsf{child}(\mathsf{JACKIE}, \mathsf{JOHN}), & \mathsf{Man}(\mathsf{JOHN}), \end{array}$$

contains the individuals JACK and JACKIE, of whom the knowledge engineer knows that they are parents. The most specific concepts of JACK and JACKIE in the given ABox are

$$\mathsf{Man} \sqcap \exists \mathsf{child}.\mathsf{Woman} \quad \text{and} \quad \mathsf{Woman} \sqcap \exists \mathsf{child}.\mathsf{Man},$$

respectively, and the least common subsumer (in $\mathcal{EL}$) of these two concepts w.r.t. the definitions of Man and Woman is

$$\mathsf{Human} \sqcap \exists \mathsf{child}.\mathsf{Human},$$

which looks like a good starting point for a definition of parent.

In contrast to standard inferences like subsumption and instance checking, the output of the non-standard inferences we have mentioned until now (computing the msc and the lcs) is a concept description rather than a yes/no answer. In such a setting, it is important that the returned descriptions are as readable and comprehensible as possible. Unfortunately, the descriptions that are produced by the known algorithms for computing

the lcs and the msc do not satisfy this requirement. The reason is that – like most algorithms for the standard inference problems – these algorithms work on expanded concept descriptions, i.e., concept descriptions that do not contain names defined in the underlying TBox. Consequently, the descriptions that the algorithms produce also do not use defined concepts, which makes them in many cases large and hard to read and comprehend.[20] This problem can be overcome by *rewriting* the resulting concept w.r.t. the given TBox. Informally, the problem of rewriting a concept given a terminology can be stated as follows: given an acyclic TBox $\mathcal{T}$ and a concept description C that does not contain concept names defined in $\mathcal{T}$, can this description be rewritten into an equivalent shorter description E by using (some of) the names defined in $\mathcal{T}$? For example, w.r.t. the TBox in Figure 3, the concept description

$$\mathsf{Person} \sqcap \forall \mathsf{child}.\mathsf{Female} \sqcap \exists \mathsf{child}.\top \sqcap \forall \mathsf{child}.\mathsf{Person}$$

can be rewritten to the equivalent concept $\mathsf{Parent} \sqcap \forall \mathsf{child}.\mathsf{Woman}$.

Rewriting w.r.t. a TBox is just one instance of a more general rewriting framework, which will be introduced below. Another instance of this framework is *approximation*, where one tries to express a concept description C_1 defined in one DL $\mathcal{L}_1$ by a concept description C_2 expressed in another DL $\mathcal{L}_2$. If $\mathcal{L}_1$ is strictly more expressive than $\mathcal{L}_2$, then it is not always possible to find a concept description C_2 that is equivalent to C_1. In this case, one can try to approximate C_1 by an $\mathcal{L}_2$ concept description that is as "close" as possible to C_1, for example by trying to find an $\mathcal{L}_2$ concept description that subsumes C_1 and is minimal w.r.t. subsumption. One possible application for such an inference is translating knowledge bases from the language employed by one system into the language employed by another system.

In order to apply the second approach of constructing concepts by modifying existing ones, one must first find the right candidates for modification. One way of doing this is to give a partial description of the concept to be defined as a concept pattern (i.e., a concept description containing variables standing for concept descriptions), and then look for concept descriptions that match this pattern. For example, the pattern

$$\mathsf{Man} \sqcap \exists \mathsf{child}.(\mathsf{Man} \sqcap X) \sqcap \exists \mathsf{spouse}.(\mathsf{Woman} \sqcap X)$$

looks for descriptions of classes of men whose wives and sons share some characteristic. An example of a concept description *matching* this pattern is $\mathsf{Man} \sqcap \exists \mathsf{child}.(\mathsf{Man} \sqcap \mathsf{Tall}) \sqcap \exists \mathsf{spouse}.(\mathsf{Woman} \sqcap \mathsf{Tall})$.

Unification is a generalization of matching where both concepts may contain variables. The main motivation for introducing unification in DLs was to avoid redundancies in knowledge bases that are built by several knowledge engineers over a long time period. In this setting, it frequently happens that the same (intuitive) concept is introduced several times, often with slightly differing descriptions. Testing for equivalence of concepts is not always sufficient to find out whether, for a given concept description, there already exists another concept description in the knowledge base describing the same notion. As an example, lets us ask whether the following two $\mathcal{FL}_0$ concept descriptions might denote

[20] In the above example, this means that the definitions of Man and Woman are expanded before applying the lcs algorithm. If Human also had a definition, then it would also be expanded, and instead of the concept description containing Human shown above, the algorithm would return its expanded version.

the same (intuitive) concept:

$$\forall \mathsf{child}.\forall \mathsf{child}.\mathsf{Rich} \sqcap \forall \mathsf{child}.\mathsf{Rmr} \quad \text{and} \quad \mathsf{Acr} \sqcap \forall \mathsf{child}.\mathsf{Acr} \sqcap \forall \mathsf{child}.\forall \mathsf{spouse}.\mathsf{Rich}.$$

The answer is yes, since replacing the concept name Rmr by the description $\mathsf{Rich} \sqcap \forall \mathsf{spouse}.\mathsf{Rich}$ and Acr by $\forall \mathsf{child}.\mathsf{Rich}$ yields the descriptions

$$\begin{array}{l}\forall \mathsf{child}.\forall \mathsf{child}.\mathsf{Rich} \sqcap \forall \mathsf{child}.(\mathsf{Rich} \sqcap \forall \mathsf{spouse}.\mathsf{Rich}),\\ \forall \mathsf{child}.\mathsf{Rich} \sqcap \forall \mathsf{child}.\forall \mathsf{child}.\mathsf{Rich} \sqcap \forall \mathsf{child}.\forall \mathsf{spouse}.\mathsf{Rich},\end{array}$$

which are obviously equivalent. Thus, under the assumption that Rmr stands for "Rich and married rich" and Acr for "All children are rich", we can conclude that both descriptions are meant to express the concept "All grandchildren are rich and all children are rich and married rich". This connection between the two description can be found by a unification algorithm if we declare Rmr and Acr to be variables. Of course, unifiability does not necessarily mean that the concept descriptions are meant to represent the same concept. Unifiability only suggests that there is a possible connection: the final decision must be taken by the knowledge engineer.

5.2 Least common subsumers and most specific concepts

Intuitively, the least common subsumer of a given collection of concept descriptions is a description that represents the properties that all the elements of the collection have in common. More formally, it is the most specific concept description that subsumes the given descriptions. What this most specific description looks like, whether it really captures the intuition of representing the properties common to the input descriptions, and whether it exists at all strongly depends on the DL under consideration.

Let $\mathcal{L}$ be a DL. A concept description E of $\mathcal{L}$ is a *least common subsumer* (lcs) of the concept descriptions $C_1, \ldots, C_n$ in $\mathcal{L}$ ($lcs_{\mathcal{L}}(C_1, \ldots, C_n)$ for short) iff it satisfies

1. $C_i \sqsubseteq E$ for all $i = 1, \ldots, n$, and
2. E is the least $\mathcal{L}$ concept description with this property, i.e., if E' is an $\mathcal{L}$ concept description satisfying $C_i \sqsubseteq E'$ for all $i = 1, \ldots, n$, then $E \sqsubseteq E'$.

As an easy consequence of this definition, the lcs is unique up to equivalence, which justifies talking about *the* lcs. In addition, the n-ary lcs as defined above can be reduced to the binary lcs (the case where $n = 2$). Indeed, it is easy to see that $lcs_{\mathcal{L}}(C_1, \ldots, C_n) \equiv lcs_{\mathcal{L}}(C_1, \ldots, lcs_{\mathcal{L}}(C_{n-1}, C_n) \cdots)$. Thus, it is enough to devise algorithms for computing the binary lcs.

It should be noted, however, that the lcs need not always exist. This can have different reasons: (a) there may not exist a concept description in $\mathcal{L}$ satisfying (i) of the definition (i.e., subsuming $C_1, \ldots, C_n$); (b) there may be several subsumption incomparable minimal concept descriptions satisfying (i) of the definition; (c) there may be an infinite chain of more and more specific descriptions satisfying (i) of the definition. Obviously, (a) cannot occur for DLs containing the top concept. It is easy to see that, for DLs allowing for conjunction of descriptions, (b) cannot occur. An example for a DL exhibiting behavior (c) can be found in [6], where the lcs is defined w.r.t. a cyclic TBox.

It is also clear that in DLs allowing for disjunction, the lcs of $C_1, \ldots, C_n$ is their disjunction $C_1 \sqcup \ldots \sqcup C_n$. In this case, the lcs is not really of interest. Instead of

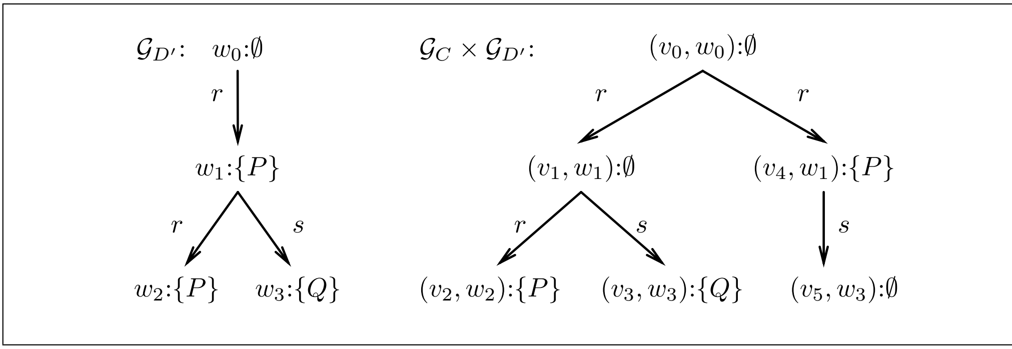

Figure 11. The product of $\mathcal{EL}$ description trees.

extracting properties common to $C_1, \ldots, C_n$, it just gives their disjunction, which does not provide us with new information. Thus, it only makes sense to look at the lcs in sub-Boolean DLs.

For DLs whose expressive power lies between $\mathcal{FL}_0$ and $\mathcal{ALN}$, one can use the characterization of subsumption via finite languages over the alphabet of the role names (see Subsection 4.2) to compute the lcs. Recall that any pair of $\mathcal{FL}_0$ concept descriptions C, D containing the concept names $A_1, \ldots, A_k$ can be written as

$$C \equiv \forall U_1.A_1 \sqcap \ldots \sqcap \forall U_k.A_k \quad \text{and} \quad D \equiv \forall V_1.A_1 \sqcap \ldots \sqcap \forall V_k.A_k,$$

where U_i, V_i are finite sets of words over the alphabet of all role names, and that $C \sqsubseteq D$ iff $U_i \supseteq V_i$ for $i = 1, \ldots, k$. As an easy consequence of this characterization we obtain that the lcs E of C, D is of the form

$$E \equiv \forall (U_1 \cap V_1).A_1 \sqcap \ldots \sqcap \forall (U_k \cap V_k).A_k.$$

Using the language-based characterization of subsumption in $\mathcal{ALN}$ [106], this approach for computing the lcs by language intersection can be extended to $\mathcal{ALN}$ [20], but this involves the use of certain infinite regular languages.

For DLs with existential restrictions, the characterization of subsumption via the existence of certain simulation relations between description trees (see Subsection 4.2) implies that the lcs corresponds to the product of the description trees [25]. The *product* $\mathcal{G}_C \times \mathcal{G}_D$ of two $\mathcal{EL}$ description trees $\mathcal{G}_C$ and $\mathcal{G}_D$ is defined by induction on the depth of the trees. Its root is the pair (v_0, w_0) consisting of the roots of $\mathcal{G}_C$ and $\mathcal{G}_D$, and the label of (v_0, w_0) is the intersection of the labels of v_0 and w_0. For each r-successor v of v_0 in $\mathcal{G}_C$ and w of w_0 in $\mathcal{G}_D$, we obtain an r-successor (v, w) of (v_0, w_0) in $\mathcal{G}_C \times \mathcal{G}_D$ that is the root of the product of the subtree of $\mathcal{G}_C$ with root v and the subtree of $\mathcal{G}_D$ with root w.

As an example, the product of the description tree $\mathcal{G}_C$ shown in Figure 7 and the description tree $\mathcal{G}_{D'}$ shown in Figure 11 is depicted on the right-hand side of Figure 11. Thus, the lcs in $\mathcal{EL}$ of the concept descriptions

$$C := P \sqcap \exists r.(\exists r.(P \sqcap Q) \sqcap \exists s.Q) \sqcap \exists r.(P \sqcap \exists s.P) \quad \text{and} \quad D' := \exists r.(P \sqcap \exists r.P \sqcap \exists s.Q)$$

is $lcs_{\mathcal{EL}}(C, D') \equiv \exists r.(\exists r.P \sqcap \exists s.Q) \sqcap \exists r.(P \sqcap \exists s.\top)$.

This approach of computing the lcs as a product of description trees can be extended to $\mathcal{ALE}$ [25] and to $\mathcal{ALEN}$ [108]. The main difference is that the concept descriptions must be normalized appropriately before building the description trees.

Now, we come to the formal definition of the most specific concept. Let $\mathcal{L}$ be a DL. The $\mathcal{L}$ concept description E is the *most specific concept* (msc) in $\mathcal{L}$ of the individual a in the $\mathcal{L}$ ABox $\mathcal{A}$ ($msc_{\mathcal{L}}(a)$ for short) iff

1. $\mathcal{A} \models E(a)$, and
2. E is the least concept satisfying (i), i.e., if E' is an $\mathcal{L}$ concept description satisfying $\mathcal{A} \models E'(a)$ then $E \sqsubseteq E'$.

As with the lcs, the msc is unique up to equivalence, if it exists. In contrast to the lcs, which usually exists for standard DLs, the msc does not always exist in $\mathcal{EL}$, $\mathcal{ALN}$, and $\mathcal{ALE}$. This is due to the presence of so-called role cycles in the ABox. For example, w.r.t. the ABox

$$\{\mathsf{loves}(\mathsf{NARCIS}, \mathsf{NARCIS}),\ \mathsf{Vain}(\mathsf{NARCIS})\},$$

the individual NARCIS does not have an msc in $\mathcal{EL}$. In fact, assume that E is the msc of NARCIS. Then E has a finite role depth, i.e., a finite maximal number of nestings of existential restrictions. If this role depth is smaller than n, then E is not subsumed by the $\mathcal{EL}$ concept description

$$E' := \underbrace{\exists \mathsf{loves}. \cdots \exists \mathsf{loves}.}_{n \text{ times}} \mathsf{Vain},$$

in spite of the fact that NARCIS is an instance of E'. The same example works for $\mathcal{ALE}$, and a similar one can be given for $\mathcal{ALN}$ [20].

One way to overcome this problem is to allow for cyclic TBoxes interpreted with greatest fixpoint semantics. In the above example, the defined concept $\mathsf{Narcis} \equiv \mathsf{Vain} \sqcap \exists \mathsf{loves}.\mathsf{Narcis}$ is then an msc of the individual NARCIS. In order to employ this approach in the bottom-up construction of DL knowledge bases, one must allow these knowledge bases to contain cyclic definitions. Thus, also the subsumption problem and the problem of computing the lcs must be solved w.r.t. cyclic definitions interpreted with greatest fixpoint semantics. In [106, 20], this is done for $\mathcal{ALN}$, and in [9, 7] for $\mathcal{EL}$. The appropriate treatment of cyclic TBoxes in $\mathcal{ALE}$ is still an open problem.

Another possibility is to approximate the msc by restricting the attention to concept descriptions whose role depth is bounded by a fixed number k [53, 107].

5.3 *Matching and unification*

Concept patterns are concept descriptions in which *concept variables* (usually denoted by X, Y, etc.) may occur in place of concept names. The main difference between concept names and concept variables is that the latter can be replaced by concept descriptions when applying a substitution.

For example, $D := P \sqcap X \sqcap \forall r.(Y \sqcap \forall r.X)$ is a concept pattern containing the concept variables X and Y. By applying the substitution $\sigma := \{X \mapsto Q,\ Y \mapsto \forall r.P\}$ to it, we obtain the concept description

$$\sigma(D) = P \sqcap Q \sqcap \forall r.(\forall r.P \sqcap \forall r.Q).$$

Let $\mathcal{L}$ be a DL. An $\mathcal{L}$ *unification problem* is of the form

$$C_1 \equiv^? D_1, \; \ldots, \; C_n \equiv^? D_n,$$

where $C_1, \ldots, D_n$ are $\mathcal{L}$ concept patterns. A *unifier* of this problem is a substitution σ such that $\sigma(C_i) \equiv \sigma(D_i)$ for $i = 1, \ldots, n$.

For unification, the only results available until now are for the small DL $\mathcal{FL}_0$ and its extension $\mathcal{FL}_{reg}$ by the role constructors union, composition, and reflexive-transitive closure. In [28], it is shown that deciding unifiability of $\mathcal{FL}_0$-patterns is an ExpTime-complete problem, and in [22] this result is extended to $\mathcal{FL}_{reg}$ and it's extension with $\bot$. In the following, we sketch how the results for unification in $\mathcal{FL}_0$ can be obtained. As shown in [28], we can without loss of generality restrict the attention to unification problems consisting of a single equation $C \equiv^? D$. Using the language-based normal form of $\mathcal{FL}_0$ concept descriptions, we can write the patterns C, D in the form

$$\begin{aligned} C &\equiv \forall S_{0,1}.A_1 \sqcap \ldots \sqcap \forall S_{0,k}.A_k \sqcap \forall S_1.X_1 \sqcap \ldots \sqcap \forall S_n.X_n, \\ D &\equiv \forall T_{0,1}.A_1 \sqcap \ldots \sqcap \forall T_{0,k}.A_k \sqcap \forall T_1.X_1 \sqcap \ldots \sqcap \forall T_n.X_n, \end{aligned}$$

where $A_1, \ldots, A_k$ are the concept names and $X_1, \ldots, X_n$ the concept variables occurring in C, D, and $S_{0,i}, S_j, T_{0,i}, T_j$ $(i = 1, \ldots, k, j = 1, \ldots, n)$ are finite sets of words over the alphabet of all role names. In [28], it is shown that $C \equiv^? D$ has a unifier iff for all $i = 1, \ldots, k$, the *linear language equation*

$$S_{0,i} \cup S_1 X_{1,i} \cup \cdots \cup S_n X_{n,i} = T_{0,i} \cup T_1 X_{1,i} \cup \cdots \cup T_n X_{n,i}$$

has a solution, i.e., we can substitute the variables $X_{j,i}$ by finite languages such that the equation holds. Note that this is not a system of k equations that must be solved simultaneously: since they do not share variables, each of these equations can be solved separately.

Let us illustrate the connection between $\mathcal{FL}_0$ unification problems and linear language equations by a simple example. The normal forms of the concept patterns

$$C := \forall r.(A_1 \sqcap \forall r.A_2) \sqcap \forall r.\forall s.X_1 \quad \text{and} \quad D := \forall r.\forall s.(\forall s.A_1 \sqcap \forall r.A_2) \sqcap \forall r.X_1 \sqcap \forall r.\forall r.A_2$$

are

$$C \equiv \forall\{r\}.A_1 \sqcap \forall\{rr\}.A_2 \sqcap \forall\{rs\}.X_1 \quad \text{and} \quad D \equiv \forall\{rss\}.A_1 \sqcap \forall\{rsr, rr\}.A_2 \sqcap \forall\{r\}.X_1.$$

Thus, the unification problem $C \equiv^? D$ leads to the two linear language equations

$$\begin{aligned} \{r\} \cup \{rs\}X_{1,1} &= \{rss\} \cup \{r\}X_{1,1}, \\ \{rr\} \cup \{rs\}X_{1,2} &= \{rsr, rr\} \cup \{r\}X_{1,2}. \end{aligned}$$

The first equation (the one for A_1) has $X_{1,1} = \{\varepsilon, s\}$ as a solution, and the second (the one for A_2) has $X_{1,2} = \{r\}$ as a solution. These two solutions yield the following unifier of $C \equiv^? D$:

$$\{X_1 \mapsto A_1 \sqcap \forall s.A_1 \sqcap \forall r.A_2\}.$$

By an exponential time reduction to the emptiness problem of top-down automata on finite trees it is shown in [28] that solvability of linear language equations of the form introduced above can be decided in exponential time. ExpTime-hardness is shown by

a reduction from the intersection emptiness problem for deterministic top-down tree automata. This shows that solvability of $\mathcal{FL}_0$ unification problems is an ExpTime-complete problem. In [22], these results are extended to $\mathcal{FL}_{reg}$. Basically, instead of linear language equations over finite sets, one obtains linear language equations over regular sets, and uses automata working on infinite trees to solve them.

An extension of these results to more expressive DLs, such as $\mathcal{ALC}$, appears to be very hard. This is supported by the fact that research on unification in modal logics has also not yet produced results on unification in K. In modal logic, unification can be seen as a special case of testing for the admissibility of an inference rule (see Chapter 8 for more details and references). The rule

$$\frac{\alpha_1(x_1,\ldots,x_n),\ldots,\alpha_m(x_1,\ldots,x_n)}{\beta(x_1,\ldots,x_n)}$$

is called *admissible* in a logic $\mathcal{L}$ iff every substitution of the x_i by formulae making $\alpha_1,\ldots,\alpha_m$ valid also makes β valid. If $\mathcal{L}$ is consistent, then the rule $\alpha(x_1,\ldots,x_n)/\bot$ is admissible iff $\alpha(x_1,\ldots,x_n) \equiv^? \top$ is not unifiable. If the logic is propositionally closed, then all unification problems can be brought into this form. Consequently, decidability of the admissible inference rule problem (e.g., in $\mathsf{K4}$, Grz) implies decidability of the unification problem.

Kracht also shows in Chapter 8 that admissibility of inference rules can be reduced to unification if every unification problem has a computable finite complete set of unifiers (see [32] for the relevant definitions from unification theory). Using Ghilardi's results that unification in $\mathsf{K4}$, $\mathsf{S4}$, and intuitionistic logic is finitary in this sense [76, 75], this shows that admissibility of inference rules is decidable for intuitionistic logic. It should be noted however, that these result consider only elementary unification, i.e., unification without free constants. In the DL setting introduced above, this means that they do not allow for concept names in concept descriptions (only concept variables). Also note that unification in $\mathcal{FL}_0$ is not finitary [2]. For the modal logic K, decidability of both admissibility of inference rules and unification are open problems (and generally assumed to be very hard).

Matching can be seen as a special case of unification where the left-hand sides of the unification problem are concept descriptions, i.e., the concept descriptions C_i in $C_i \equiv^? D_i$ do not contain variables. For DLs that are propositionally closed, unification can be reduced to matching. Indeed, it is easy to see that the equation $C \equiv^? D$ has the same solutions as $\top \equiv^? (C \sqcap D) \sqcup (\neg C \sqcap \neg D)$. Thus, for $\mathcal{ALC}$, matching is as hard as unification. For sub-Boolean DLs, matching can be significantly easier than unification (see below).

In [39], a different notion of matching, called *matching modulo subsumption*, was introduced.[21] In this setting, a matching problem is of the form $C \sqsubseteq^? D$ where C is a concept description and D a concept pattern. A *matcher* is then a substitution σ such that $C \sqsubseteq \sigma(D)$. Since $C \sqsubseteq \sigma(D)$ iff $C \sqcap \sigma(D) \equiv C$, and $C \sqcap \sigma(D) = \sigma(C) \sqcap \sigma(D) = \sigma(C \sqcap D)$, this matching problem modulo subsumption can be reduced to the following matching problem modulo equivalence: $C \equiv^? C \sqcap D$.

However, in many cases, matching modulo subsumption is simpler than matching modulo equivalence since it can be reduced to the subsumption problem. This is the case

[21] In the following, we call matching problems of the form $C \equiv^? D$ matching problems *modulo equivalence* to distinguish them from matching problems modulo subsumption.

for DLs that allow for $\top$ and where all constructors are *monotonic*, i.e., replacing their arguments by larger ones w.r.t. subsumption yields a larger description. An example of a monotonic constructor is conjunction: if $C \sqsubseteq C'$ and $D \sqsubseteq D'$, then $C \sqcap D \sqsubseteq C' \sqcap D'$. Other examples are value and existential restrictions as well as disjunction. For such a DL, $C \sqsubseteq^? D$ has a matcher iff the substitution $\sigma_\top$ that replaces all variables by $\top$ is a matcher, i.e., if $C \sqsubseteq \sigma_\top(D)$. In fact, monotonicity of the constructors implies that $\sigma(D) \sqsubseteq \sigma_\top(D)$ holds for all substitutions σ, and thus whenever there is a matcher σ, then $\sigma_\top$ is also a matcher. Also note that matching cannot be simpler than subsumption since the matching problem $C \sqsubseteq^? D$ where D does not contain variables has a solution iff $C \sqsubseteq D$.

In the context of matching modulo subsumption, one is, however, usually not interested in arbitrary solution, and in particular not in the trivial largest one $\sigma_\top$, but rather in *minimal* ones, i.e., in matchers σ of $C \sqsubseteq^? D$ such that there does not exist another substitution δ such that $C \sqsubseteq \delta(D) \sqsubset \sigma(D)$ (see [39] for a motivation). Computing minimal matcher may again be harder than simply testing whether the trivial solution candidate $\sigma_\top$ is indeed a matcher.

In [28], the language-based approach for unification is used to show that solvability of matching problems modulo equivalence (and thus also modulo subsumption) in $\mathcal{FL}_0$ can be decided in polynomial time, and that minimal matchers of matching problems modulo subsumption are unique up to equivalence and can be computed in polynomial time. In [23], this result is extended to $\mathcal{ALN}$.[22] Matching in $\mathcal{EL}$ and $\mathcal{ALE}$ is considered in [21]. For both DLs, matching modulo equivalence is NP-complete. As explained above, the complexity of matching modulo subsumption coincides with the complexity of the subsumption problem, i.e., it is polynomial for $\mathcal{EL}$ and NP-complete for $\mathcal{ALE}$. In the following, we consider the complexity of matching modulo equivalence in $\mathcal{EL}$ and $\mathcal{ALE}$ in some more detail. NP-hardness of matching in $\mathcal{ALE}$ is an immediate consequence of NP-hardness of subsumption in $\mathcal{ALE}$.

NP*-hardness of matching modulo equivalence in* $\mathcal{EL}$ is shown in [21] by a reduction from SAT. Let $\phi = \varphi_1 \wedge \cdots \wedge \varphi_m$ be a propositional formula in conjunctive normal form and let $\{p_1, \ldots, p_n\}$ be the propositional variables of this problem. For these variables, we introduce the concept variables $\{X_1, \ldots, X_n, \overline{X}_1, \ldots, \overline{X}_n\}$. Furthermore, we need concept names A and B as well as role names $r_1, \ldots, r_n$ and $s_1, \ldots, s_m$. First, we specify a matching problem $C_n \equiv^? D_n$ that encodes the truth values of the n propositional variables:

$$\begin{array}{lcl} C_n & := & \exists r_1.A \sqcap \exists r_1.B \sqcap \ldots \sqcap \exists r_n.A \sqcap \exists r_n.B \\ D_n & := & \exists r_1.X_1 \sqcap \exists r_1.\overline{X}_1 \sqcap \ldots \sqcap \exists r_n.X_n \sqcap \exists r_n.\overline{X}_n. \end{array}$$

The matchers of this problem are exactly the substitutions that replace X_i by A and $\overline{X}_i$ by B (corresponding to $p_i = \mathsf{true}$), or vice versa (corresponding to $p_i = \mathsf{false}$).

In order to encode ϕ, we introduce a concept pattern D_{φ_i} for each clause φ_i. For example, if $\varphi_i = p_1 \vee \neg p_2 \vee p_3 \vee \neg p_4$, then $D_{\varphi_i} := X_1 \sqcap \overline{X}_2 \sqcap X_3 \sqcap \overline{X}_4 \sqcap B$. The whole formula is then represented by the matching problem $C_\phi \equiv^? D_\phi$, where

$$C_\phi := \exists s_1.(A \sqcap B) \sqcap \ldots \sqcap \exists s_m.(A \sqcap B) \quad \text{and} \quad D_\phi := \exists s_1.D_{\varphi_1} \sqcap \ldots \sqcap \exists s_m.D_{\varphi_m}.$$

This matching problem ensures that, among all the variables in D_{φ_i}, at least one must be replaced by A. This corresponds to the fact that, within one clause φ_i, there must

[22] In the presence of atomic negation one defines patterns such atomic negation may not be applied to variables, and thus atomic negation does not destroy the monotonicity property introduced above.

$$C := \mathsf{W} \sqcap \exists \mathsf{c}.(\mathsf{W} \sqcap \exists \mathsf{c}.(\mathsf{W} \sqcap \mathsf{D}) \sqcap \exists \mathsf{c}.(\mathsf{W} \sqcap \mathsf{P})) \sqcap \exists \mathsf{c}.(\mathsf{W} \sqcap \mathsf{D} \sqcap \exists \mathsf{c}.(\mathsf{W} \sqcap \mathsf{P}))$$

$$D := \mathsf{W} \sqcap \exists \mathsf{c}.(X \sqcap \exists \mathsf{c}.(\mathsf{W} \sqcap Y)) \sqcap \exists \mathsf{c}.(X \sqcap Y)$$

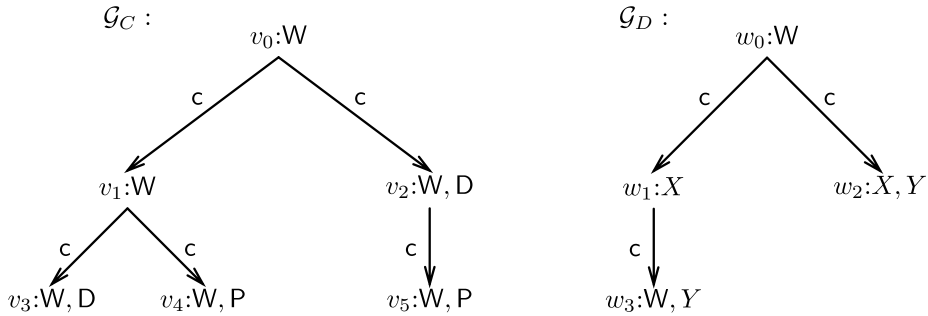

Figure 12. An $\mathcal{EL}$ concept description and an $\mathcal{EL}$ concept pattern, and the corresponding description trees.

be at least one literal that evaluates to true. Note that we need the concept B in D_{φ_i} to cover the case where all variables in D_{φ_i} are substituted with A. If we combine the two matching problems introduced above into a single problem $C_n \sqcap C_\phi \equiv^? D_n \sqcap D_\phi$, then it is easy to verify that ϕ is satisfiable iff this matching problem is solvable.

Membership in NP *for matching modulo equivalence in $\mathcal{EL}$ and $\mathcal{ALE}$* is an easy consequence of the following two (non-trivial) facts [21]. If an $\mathcal{EL}$ or $\mathcal{ALE}$ matching problem modulo equivalence has a matcher, then it has one of size polynomially bounded by the size of the problem. Furthermore, this matcher uses only concept and role names already contained in the matching problem. Thus, one can simply guess a substitution satisfying the given size bound, and then test (in P for $\mathcal{EL}$ and in NP for $\mathcal{ALE}$) whether it is a matcher.

Of course, this NP-algorithm for testing solvability of a matching problem does not yield a practical algorithm for actually computing matchers. A more practical *algorithm that computes all minimal matchers* of $\mathcal{EL}$ and $\mathcal{ALE}$ matching problems *modulo subsumption* is based on the characterization of subsumption through the existence of a homomorphism (i.e., a simulation relation that is a function) between the corresponding description trees [25]. As an example, consider the $\mathcal{EL}$ matching problem $C \sqsubseteq^? D$ for the concept description C and the concept pattern D depicted in Figure 12. Readers not liking such abstract examples may read W as Woman, D as Doctor, P as Professor, and c as child. Thus, the pattern describes concepts consisting of women that have (i) a child satisfying some property X and having a female child satisfying some property Y, and (ii) a child satisfying both X and Y.

When considering homomorphisms between the description trees of a concept pattern and a concept description, we simply ignore the concept variables, i.e., the inclusion condition between the labels does not take variables into account. In our example, there are six homomorphisms from $\mathcal{G}_D$ into $\mathcal{G}_C$. We consider the ones mapping w_i onto v_i for $i = 0, 1, 2$, and w_3 onto v_3 or w_3 onto v_4, which we denote by h_1 and h_2, respectively.

The matching algorithm described in [21] tries to construct substitutions τ such that $C \sqsubseteq \tau(D)$, i.e., there is a homomorphism from $\mathcal{G}_{\tau(D)}$ into $\mathcal{G}_C$. This is achieved by first computing all homomorphisms from $\mathcal{G}_D$ into $\mathcal{G}_C$. Assume that the node w in $\mathcal{G}_D$, whose label contains X, is mapped onto the note v of $\mathcal{G}_C$. The idea is then to substitute X with the concept description corresponding to the subtree of $\mathcal{G}_C$ starting with the node v. We will denote this description by C_v in the following. The remaining problem is that a variable X may occur more than once in D, and thus nodes containing X may be mapped to several nodes in $\mathcal{G}_C$. Thus, we cannot simply define $\tau(X)$ as $C_{h(w)}$ where w is such that X occurs in the label of w. Since there may exist several nodes w with this property, we take the least common subsumer of the corresponding parts of C. The reason for taking the *least* common subsumer is that we want to compute minimal matchers.

In our example, the homomorphism h_1 yields the substitution τ_1:

$$\tau_1(X) := \mathit{lcs}(C_{v_1}, C_{v_2}) \equiv \mathsf{W} \sqcap \exists \mathsf{c}.(\mathsf{W} \sqcap \mathsf{P}), \qquad \tau_1(Y) := \mathit{lcs}(C_{v_2}, C_{v_3}) \equiv \mathsf{W} \sqcap \mathsf{D},$$

whereas h_2 yields the substitution τ_2:

$$\tau_2(X) := \mathit{lcs}(C_{v_1}, C_{v_2}) \equiv \mathsf{W} \sqcap \exists \mathsf{c}.(\mathsf{W} \sqcap \mathsf{P}), \qquad \tau_2(Y) := \mathit{lcs}(C_{v_2}, C_{v_4}) \equiv \mathsf{W}.$$

The algorithm is guaranteed to compute all minimal matchers, but may also compute some non-minimal ones, which must be removed in a post-processing step. In our example, the substitution τ_1 is a minimal matcher, but τ_2 is not minimal. In general, a given matching problem modulo subsumption may have exponentially many inequivalent minimal matchers, and the size of these minimal matchers may also be exponential in the size of the matching problem [21].

5.4 Rewriting and approximation

In [26], a very general framework for rewriting in DLs is introduced, which has several interesting instances. In order to introduce this framework, we fix a set N_R of role names and a set N_P of primitive concept names. Now, let $\mathcal{L}_s$, $\mathcal{L}_d$, and $\mathcal{L}_t$ be three DLs (the source-, destination, and TBox-DL, respectively). A *rewriting problem* is given by

- an $\mathcal{L}_t$ TBox $\mathcal{T}$ containing only role names from N_R and primitive concepts from N_P; the set of defined concepts occurring in $\mathcal{T}$ is denoted by N_D;
- an $\mathcal{L}_s$ concept description C using only the names from N_R and N_P;
- a binary relation ρ between $\mathcal{L}_s$ concept descriptions and $\mathcal{L}_d$ concept descriptions.

An $\mathcal{L}_d$ *rewriting of* C *using* $\mathcal{T}$ is an $\mathcal{L}_d$ concept description E built using role names from N_R and concept names from $N_P \cup N_D$ such that $C \rho E$. Given an appropriate ordering $\preceq$ on $\mathcal{L}_d$ concept descriptions, a rewriting E is called $\preceq$-*minimal* iff there does not exist a rewriting E' such that $E' \prec E$.

To illustrate the use of this general framework by examples, we consider two of its instances in more detail: the *minimal rewriting problem* and the *approximation problem.*

Minimal rewriting

This is the instance of the framework where (i) all three DLs are the same language $\mathcal{L}$; (ii) the TBox $\mathcal{T}$ is acyclic; (iii) the binary relation ρ corresponds to equivalence w.r.t. the TBox; and (iv) $\mathcal{L}$ concept descriptions are ordered by size, i.e., $E \preceq E'$ iff $|E| \leq |E'|$. The size $|E|$ of a concept description E is defined to be the number of occurrences of concept and role names in E.

In order to determine the complexity of the minimal rewriting problem, Baader et al. [26] first analyse the *decision problem* induced by this optimization problem for a given DL $\mathcal{L}$: given an $\mathcal{L}$ concept description C, an acyclic $\mathcal{L}$ TBox $\mathcal{T}$, and a nonnegative integer κ, does there exist an $\mathcal{L}$ rewriting E of C using $\mathcal{T}$ such that $|E| \leq \kappa$? Since this decision problem can obviously be reduced to the problem of computing a minimal rewriting of C using $\mathcal{T}$, hardness results for the decision problem carry over to the optimization problem.

For $\mathcal{ALC}$, this decision problem is PSPACE-hard since the PSPACE-complete subsumption problem can be reduced to it. Indeed, let C, D be two $\mathcal{ALC}$ concept descriptions, and A, P_1, P_2 three different concept names not occurring in C, D. Then $C \sqsubseteq D$ iff there exists a minimal rewriting of size 1 of the $\mathcal{ALC}$ concept description $P_1 \sqcap P_2 \sqcap C$ using the TBox $\mathcal{T} := \{A \equiv P_1 \sqcap P_2 \sqcap C \sqcap D\}$ [26]. The two concept names P_1 and P_2 are introduced to ensure that the size of the concept description to be rewritten is strictly larger than the size of A.

However, subsumption is not the only source of complexity for the minimal rewriting problem. In fact, even for the small DL $\mathcal{FL}_0$, for which subsumption of concept descriptions and w.r.t. expanded TBoxes is polynomial, the rewriting problem (using an expanded TBox) is NP-hard. This is shown in [26] by a reduction from the set cover problem.

For an arbitrary DL $\mathcal{L}$, the minimal rewriting decision problem can obviously be decided by a non-deterministic polynomial time algorithm that uses an oracle for subsumption. This algorithm just guesses an $\mathcal{L}$ concept description over the available vocabulary and of size at most κ, and then checks whether this description is equivalent to the input description modulo the TBox. For $\mathcal{ALC}$, this shows that the minimal rewriting decision problem is PSPACE-complete. It can also be used to show that the problem is NP-complete for $\mathcal{FL}_0$ (see [26] for details).

Let us now come to the problem of actually *computing minimal rewritings*. The hardness results mentioned above imply that computing one minimal rewriting is already a hard problem. In addition, the following simple example shows that the number of minimal rewritings of a concept description C using a TBox $\mathcal{T}$ can be exponential in the size of C and $\mathcal{T}$.

For a nonnegative integer n, let $C_n := P_1 \sqcap \ldots \sqcap P_n$ and $\mathcal{T}_n := \{A_i \equiv P_i \mid 1 \leq i \leq n\}$. For each vector $\mathbf{i} = (i_1, \ldots, i_n) \in \{0,1\}^n$, we define

$$E_{\mathbf{i}} := \bigsqcap_{1 \leq j \leq n, i_j = 0} P_j \sqcap \bigsqcap_{1 \leq j \leq n, i_j = 1} A_j.$$

Obviously, for all $\mathbf{i} \in \{0,1\}^n$, $E_{\mathbf{i}}$ is a rewriting of C_n of size $|E_{\mathbf{i}}| = n = |C_n|$. Furthermore, it is easy to see that there does not exist a smaller rewriting of C_n using $\mathcal{T}_n$. Hence, there exists an exponential number of different minimal rewritings of C_n using $\mathcal{T}_n$.

A *naïve algorithm* for computing one minimal rewriting would enumerate all concept descriptions E of size $k = 1$, then $k = 2$, etc., until a rewriting E_0 of C using $\mathcal{T}$ is

encountered. By construction, this rewriting is minimal, and since C is a rewriting of itself, one need not consider sizes larger than $|C|$. If one is interested in computing all minimal rewritings, it remains to enumerate all concept descriptions of size $|E_0|$, and test for each of them whether they are equivalent to C modulo $\mathcal{T}$. Obviously, this algorithm is not practical.

The main ideas underlying the more practical algorithm described in [26] is the following. For a given input description C, one splits the computation of rewritings into two steps:

- Compute an *extension* C^* of C. Such an extension is obtained from C by conjoining defined concepts at some positions of C while making sure that $C \equiv_{\mathcal{T}} C^*$ holds.
- Compute a *reduction* $\widehat{C}$ of C^*. Such a reduction is obtained from C^* by removing certain parts of C^* while making sure that $C^* \equiv_{\mathcal{T}} \widehat{C}$ holds.

The exact definitions of the right notions of extension and reduction depend, of course, on the DL under consideration. In [26], these definitions are given for $\mathcal{ALE}$. It is shown that the algorithm obtained this way computes only writings of the input description, and that all minimal rewritings are among the computed rewritings. In addition, [26] describes a more efficient heuristic algorithm that is not guaranteed to find *minimal* rewritings, but behaves quite well in practice. Basically, this algorithm uses a greedy strategy in the extension step, i.e., it conjoins as many defined concepts as possible to each position of C.

Approximation

This is the instance of the framework where (i) $\mathcal{T}$ is empty, and thus $\mathcal{L}_t$ is irrelevant; (ii) both ρ and $\preceq$ are the subsumption relation $\sqsubseteq$. In this case, we talk about approximation rather than rewriting. Given two DLs $\mathcal{L}_s$ and $\mathcal{L}_d$, an $\mathcal{L}_d$ *approximation* of an $\mathcal{L}_s$ concept description C is thus an $\mathcal{L}_d$ concept description D such that $C \sqsubseteq D$ and D is minimal (w.r.t. subsumption) with this property.

The case where $\mathcal{L}_s = \mathcal{ALC}$ and $\mathcal{L}_d = \mathcal{ALE}$ is investigated in [48]. Recall that the only difference between $\mathcal{ALC}$ and $\mathcal{ALE}$ is that disjunction is disallowed in $\mathcal{ALE}$ concept descriptions.[23] If C_1, C_2 are $\mathcal{ALE}$ concept descriptions, then it is easy to see that the approximation of the $\mathcal{ALC}$ concept description $C_1 \sqcup C_2$ by an $\mathcal{ALE}$ concept description is $lcs_{\mathcal{ALE}}(C_1, C_2)$. This suggests the following approach for approximating an $\mathcal{ALC}$ concept description C by an $\mathcal{ALE}$ concept description: just replace every disjunction in C by an application of the lcs operation. The following example demonstrates that this approach is too naïve: let $C := (\forall r.B \sqcup (\exists r.B \sqcap \forall r.A)) \sqcap \exists r.A$. If we replace the disjunction by an lcs operation and then compute the lcs, we obtain the $\mathcal{ALE}$ concept description

$$lcs_{\mathcal{ALE}}(\forall r.B, (\exists r.B \sqcap \forall r.A)) \sqcap \exists r.A \equiv \top \sqcap \exists r.A \equiv \exists r.A.$$

However, this concept description is too general. It is easy to see that $C \sqsubseteq \exists r.(A \sqcap B) \sqsubset \exists r.A$. In fact, $\exists r.(A \sqcap B)$ is the correct approximation.

In order to overcome this problem, the $\mathcal{ALC}$ concept description has to be transformed into an appropriate normal form. Basically, this normal form is obtained by distributing

[23] Here we assume without loss of generality that all $\mathcal{ALC}$ concept descriptions are in negation normal form where negation occurs only in front of concept names.

conjunctions over disjunctions, and by applying the rule $\forall r.C \sqcap \forall r.D \to \forall r.(C \sqcap D)$. For the example from above, the normal form is

$$C \equiv (\forall r.B \sqcap \exists r.A) \sqcup (\exists r.B \sqcap \forall r.A \sqcap \exists r.A),$$

and $lcs_{\mathcal{ALE}}(\forall r.B \sqcap \exists r.A, \exists r.B \sqcap \forall r.A \sqcap \exists r.A) = \exists r.(A \sqcap B)$.

However, even for $\mathcal{ALC}$ concept descriptions in this normal form, one cannot simply replace disjunction by the lcs operation to obtain their $\mathcal{ALE}$ approximation. Consider the $\mathcal{ALC}$ concept description $C' = \exists r.A \sqcap \exists r.B \sqcap \forall r.(\neg A \sqcup \neg B)$. If we simply replace the disjunction by the lcs, then we obtain $\exists r.A \sqcap \exists r.B \sqcap \forall r.\top \equiv \exists r.A \sqcap \exists r.B$. However, C' is also subsumed by the more specific $\mathcal{ALE}$ concept description $\exists r.(A \sqcap \neg B) \sqcap \exists r.(B \sqcap \neg A)$. This problem can be overcome by also propagating value restrictions onto existential restrictions. An approximation algorithms based on these ideas is described in [48]. It is shown that every $\mathcal{ALC}$ concept description has an $\mathcal{ALE}$ approximation, and this approximation is unique up to equivalence, i.e., there is always a least approximation. However, the size of the approximation may grow exponentially with the size of the input description. The algorithm for computing the approximation given in [48] runs in doubly-exponential time, and it is not clear whether this time bound can be improved. In [47], these results are extended to the approximation of $\mathcal{ALCN}$ concepts descriptions by $\mathcal{ALEN}$ concept descriptions.

6 NON-STANDARD EXPRESSIVITY

As discussed in Section 2, many expressive means of description logics have a counterpart in modal logic. In this section, we discuss two expressive means that are important for DLs, but lack a direct modal counterpart: concrete domains and role value maps.

6.1 Concrete Domains

The purpose of concrete domains is to enable the definition of concept descriptions with reference to concrete qualities of real-world objects such as their age, weight, temperature, and spatial extension. For example, we may define a teenager as a human whose age is between 10 and 19, or formulate a GCI stating that the age of a child is always smaller than the age of its parents. Representing concrete qualities and constraints of this form is necessary in almost all applications of description logics, such as reasoning about the semantic web [19] and about conceptual database models [114]. For this reason, even early DL systems such as MESON [68] and CLASSIC [44] addressed the issue of representing concrete qualities. However, these early approaches were of a rather ad hoc nature. The first approach that was fully (and formally) integrated with a description logic was presented by Baader and Hanschke [14], who proposed to extend the description logic $\mathcal{ALC}$ with so-called concrete domains.

Definitions

A *concrete domain* $\mathcal{D}$ is a pair $(\Delta^{\mathcal{D}}, \Phi^{\mathcal{D}})$ consisting of a non-empty set $\Delta^{\mathcal{D}}$ and a collection $\Phi^{\mathcal{D}}$ of *predicates names* such that each predicate $P \in \Phi^{\mathcal{D}}$ is equipped with an arity n and a fixed extension $P^{\mathcal{D}} \subseteq (\Delta^{\mathcal{D}})^n$. Slightly abusing notation, we will sometimes refer to the set $\Delta^{\mathcal{D}}$ as the concrete domain. In contrast, the domain $\Delta^{\mathcal{I}}$ of interpretations $\mathcal{I}$ will

be called the *abstract domain.* For many application areas, the most interesting concrete domains are numerical ones. A typical numerical concrete domain is $\mathsf{Q} = (\mathbb{Q}, \Phi^{\mathsf{Q}})$, where $\mathbb{Q}$ denotes the rational numbers, and Φ^{Q} is comprised of the following predicates:

- unary predicates P_q for each $P \in \{<, \leq, =, \neq, \geq, >\}$ and each $q \in \mathbb{Q}$ with $(P_q)^{\mathsf{Q}} = \{q' \in \mathbb{Q} \mid q' \; P \; q\}$;
- binary predicates $<, \leq, =, \neq, \geq, >$ with the obvious extensions;
- a ternary predicate $+$ with $(+)^{\mathsf{Q}} = \{(q, q', q'') \in \mathbb{Q}^3 \mid q + q' = q''\}$.

By integrating a concrete domain $\mathcal{D}$ into $\mathcal{ALC}$, we obtain the basic description logic with concrete domains $\mathcal{ALC}(\mathcal{D})$. More precisely, $\mathcal{ALC}(\mathcal{D})$ is obtained from $\mathcal{ALC}$ by augmenting it with

- *abstract features*: a new sort of roles that is interpreted as a partial function from $\Delta^{\mathcal{I}}$ to $\Delta^{\mathcal{I}}$; abstract features can be used inside value restrictions and existential restrictions;
- *concrete features*: a new sort of roles that is interpreted as a partial function from the abstract domain $\Delta^{\mathcal{I}}$ into the concrete domain $\Delta^{\mathcal{D}}$; concrete features can *not* be used inside value restrictions and existential restrictions;
- a new concept constructor $P(u_1, \ldots, u_n)$, where $P \in \Phi^{\mathcal{D}}$ is a predicate of arity n, and each u_i is an expression $f_1 \circ \cdots \circ f_k \circ g$ with $f_1, \ldots, f_k$ $(k \geq 0)$ abstract features and g a concrete feature. In the following, such expressions will be called *concrete paths.* The semantics of the new constructor is

$$P(u_1, \ldots, u_n)^{\mathcal{I}} := \{d \in \Delta^{\mathcal{I}} \mid \exists x_1, \ldots, x_n \in \Delta^{\mathcal{D}} : u_i^{\mathcal{I}}(d) = x_i \text{ for } 1 \leq i \leq n \text{ and } (x_1, \ldots, x_n) \in P^{\mathcal{D}}\},$$

  where the interpretation $u^{\mathcal{I}}$ of a concrete path $u = f_1 \circ \cdots \circ f_k \circ g$ is defined as the partial function that maps $d \in \Delta^{\mathcal{I}}$ to $g^{\mathcal{I}}(f_k^{\mathcal{I}} \cdots (f_1^{\mathcal{I}}(d)) \cdots)$.

Using the concrete domain Q, the teenagers mentioned above can now be defined as

$$\mathsf{Teenager} \equiv \mathsf{Human} \sqcap >_9(\mathsf{age}) \sqcap <_{20}(\mathsf{age})$$

where age is a concrete feature. Similarly, the constraint saying that the age of children is smaller than the age of their parents can be formulated as

$$\top \sqsubseteq <(\mathsf{age}, \mathsf{mother} \circ \mathsf{age}) \sqcap <(\mathsf{age}, \mathsf{father} \circ \mathsf{age}),$$

where mother and father are abstract features.

There is a slight difference between the logic $\mathcal{ALC}(\mathcal{D})$ as defined here and the original version introduced in [14]: Baader and Hanschke's variant uses only a single type of feature whose interpretation is a partial function from $\Delta^{\mathcal{I}}$ to $\Delta^{\mathcal{I}} \cup \Delta^{\mathcal{D}}$. Thus, this type of feature combines our abstract and concrete features into one sort. In the literature, both versions of $\mathcal{ALC}(\mathcal{D})$ are considered. All results discussed in this section hold for both versions. Also note that the assumption that $\mathcal{ALC}$ is extended with only *one* concrete domain can be made without loss of generality, as it is shown in [14] that multiple concrete domains can be combined into a single one. In the world of modal logic, the closest relatives to DLs with concrete domains are linear temporal logics with constraints, see for example [33, 60].

Basic Results

When considering a description logic that is equipped with concrete domains, it is most desirable to obtain decidability results and complexity bounds that do not depend on a particular concrete domain, but rather apply to a class of concrete domains that is as large as possible. The first (decidability) result in this spirit was given by Baader and Hanschke in their original paper. Their result concerns the satisfiability of $\mathcal{ALC}(\mathcal{D})$ concept descriptions, where the concrete domain $\mathcal{D}$ is only required to satisfy some weak conditions. These conditions are derived from the fact that any satisfiability algorithm not committing itself to a particular concrete domain must call some concrete domain reasoner as a subprocedure via a well-defined interface. This observation leads to the notion of *admissibility*.

Let $\mathcal{D}$ be a concrete domain and V a countably infinite set of variables. A $\mathcal{D}$-*conjunction* is a predicate conjunction of the form

$$c = \bigwedge_{i<k} P_i(x_0^{(i)}, \dots, x_{n_i}^{(i)})$$

where $P_i \in \Phi^{\mathcal{D}}$ is an n_i-ary predicate for each $i < k$ and the $x_j^{(i)}$ are variables from V. A $\mathcal{D}$-conjunction c is *satisfiable* iff there exists a function δ mapping the variables in c to elements of $\Delta^{\mathcal{D}}$ such that $(\delta(x_0^{(i)}), \dots, \delta(x_{n_i}^{(i)})) \in P_i^{\mathcal{D}}$ for each $i < k$. We say that the concrete domain $\mathcal{D}$ is *admissible* iff

1. its set of predicates is closed under negation[24] and contains a name $\top_{\mathcal{D}}$ for $\Delta^{\mathcal{D}}$, and

2. the satisfiability of $\mathcal{D}$-conjunctions is decidable.

We refer to the satisfiability of $\mathcal{D}$-conjunctions as $\mathcal{D}$-*satisfiability*. Property 1 of admissibility has to be satisfied since $\mathcal{ALC}(\mathcal{D})$ provides for negation: for example, the concept description $C := {=}(g_1, g_1)) \sqcap {=}(g_2, g_2) \sqcap \neg{<}(g_1, g_2)$ is such that $d \in C^{\mathcal{I}}$ implies $g_1^{\mathcal{I}}(d) \geq g_2^{\mathcal{I}}(d)$ without explicitly using the "$\geq$" predicate,[25] and such information must be conveyed to the concrete domain reasoner. Note that the concrete domain Q presented above can easily be extended to satisfy Property 1 of admissibility: simply add predicates $\top_{\mathsf{Q}}$, $\bot_{\mathsf{Q}}$, and $\overline{+}$ (i.e., the negation of "+") with the obvious extensions. Let Q^a denote the extended version of Q. By using a reduction to linear programming, it is straightforward to show that Q^a-satisfiability is decidable in polynomial time [115], and thus Q^a is admissible.

The basic decidability result for $\mathcal{ALC}(\mathcal{D})$ given by Baader and Hanschke states that satisfiability (and thus also subsumption) of $\mathcal{ALC}(\mathcal{D})$-concept descriptions is decidable if $\mathcal{D}$ is admissible [14]. The complexity of this problem has been analyzed by Lutz [113], who proved PSpace-completeness under the assumption that $\mathcal{D}$ is admissible and $\mathcal{D}$-satisfiability is in PSpace. Thus if $\mathcal{D}$-satisfiability is in PSpace, then adding concrete domains to $\mathcal{ALC}$ does not increase the complexity of reasoning. Since Q^a-satisfiability is a polynomial time problem, we obtain PSpace-completeness for the instance $\mathcal{ALC}(\mathsf{Q}^a)$ of $\mathcal{ALC}(\mathcal{D})$. A discussion of the complexity of $\mathcal{D}$-satisfiability for a variety of numerical, temporal, and spatial concrete domains can be found in [115, 112].

---

[24] i.e., for each $P \in \Phi^{\mathcal{D}}$ of arity n, we find a $\overline{P} \in \Phi^{\mathcal{D}}$ with $\overline{P}^{\mathcal{D}} = (\Delta^{\mathcal{D}})^n \setminus P^{\mathcal{D}}$.

[25] The first two conjuncts are needed to ensure that $g_1^{\mathcal{I}}(d)$ and $g_2^{\mathcal{I}}(d)$ are actually defined.

When TBoxes are admitted, the complexity of reasoning increases drastically. We first consider acyclic TBoxes. As discussed in Section 2.2, satisfiability and subsumption w.r.t. acyclic TBoxes can be reduced to satisfiability w.r.t. the empty TBox using expansion. Thus, we obtain decidability of $\mathcal{ALC}(\mathcal{D})$ reasoning w.r.t. acyclic TBoxes if $\mathcal{D}$ is admissible. Since expansion is worst-case exponential, we also obtain an ExpSpace upper bound if $\mathcal{D}$-satisfiability is in PSpace. In the case of $\mathcal{ALC}$ without concrete domains, this upper bound can be improved to a PSpace one. Quite surprisingly, we can only push down the ExpSpace upper bound to a NExpTime one in the case of $\mathcal{ALC}(\mathcal{D})$: as proved in [117], there exists a concrete domain $\mathcal{D}$ such that $\mathcal{D}$-satisfiability is in PTime and satisfiability in $\mathcal{ALC}(\mathcal{D})$ w.r.t. acyclic TBoxes is NExpTime-hard. A matching upper bound states that satisfiability in $\mathcal{ALC}(\mathcal{D})$ w.r.t. acyclic TBoxes is in NExpTime if $\mathcal{D}$ is admissible and $\mathcal{D}$-satisfiability is in NP [117]. For subsumption, this yields analogous co-NExpTime bounds.

The jump in complexity from PSpace-complete to NExpTime-complete that is induced by adding acyclic TBoxes to $\mathcal{ALC}(\mathcal{D})$ is due to the fact that this addition increases the succinctness of $\mathcal{ALC}(\mathcal{D})$ (but not the expressivity). The NExpTime lower bound has been proved by reduction of a NExpTime-complete variant of the Post Correspondence Problem (PCP). As we cannot describe the reduction in full detail here, we sketch only how it makes use of the succinctness of acyclic TBoxes. The key observation is that it is possible to devise an acyclic TBox of size $O(k)$ that enforces models (of the concept name L_0) to contain a binary tree of depth k such that left successors are reachable via the abstract feature ℓ and right successors are reachable via the abstract feature r:

$$L_0 \equiv \exists \ell.L_1 \sqcap \exists r.L_1, \quad \ldots, \quad L_{k-1} \equiv \exists \ell.L_k \sqcap \exists r.L_k.$$

Without TBoxes, such a tree can only be enforced with a concept of length exponential in k. For the reduction, we add concept definitions expressing that the (exponentially many) leaves of the tree are connected via a chain of concrete domain predicates. For example, if we augment the above TBox with the following concept definitions and consider models of the conjunction $L_0 \sqcap C_0$, then we enforce that each leaf has a smaller number stored in the concrete feature g than all leaves that are to the right of it:

$$\begin{array}{rcl} C_0 & \equiv & <(\ell r^{k-1} g, r\ell^{k-1} g) \sqcap \forall \ell.C_1 \sqcap \forall r.C_1, \\ & \vdots & \\ C_{k-2} & \equiv & <(\ell r g, r \ell g) \sqcap \forall \ell.C_{k-1} \sqcap \forall r.C_{k-1}, \\ C_{k-1} & \equiv & <(\ell g, r g). \end{array}$$

Intuitively, the exponentially long chain of concrete domain predicates connecting the leaves can now be used to simulate the exponentially time-bounded computation of a Turing machine, or to talk about the concatenation of words in a PCP.

We now consider reasoning in $\mathcal{ALC}(\mathcal{D})$ with respect to GCIs, starting with a closely related result: let $\mathcal{ALC}^+(\mathcal{D})$ be the extension of $\mathcal{ALC}(\mathcal{D})$ with a transitive closure operator on roles and abstract features. Baader and Hanschke [16] prove that reasoning in $\mathcal{ALC}^+(\mathsf{R})$ w.r.t. the empty TBox is undecidable, where R is the concrete domain of real numbers with predicates based on Tarski algebra [149]. Their proof can easily be adapted to reasoning in $\mathcal{ALC}(\mathsf{R})$ w.r.t. GCIs, which is thus also undecidable. This adaptation is performed in [117], where a more general result is obtained: satisfiability (and thus also subsumption) in $\mathcal{ALC}(\mathcal{D})$ w.r.t. GCIs is undecidable if the concrete domain $\mathcal{D}$ satisfies

$\mathbb{N} \subseteq \Delta^{\mathcal{D}}$, and $\Phi^{\mathcal{D}}$ provides for a unary predicate for equality with 0, a binary equality predicate, and a binary predicate for incrementation. Thus, reasoning in $\mathcal{ALC}(\mathsf{Q})$ w.r.t. GCIs is undecidable since, in Q, incrementation can be expressed using the predicates "$=_1$" and "$+$". There are two ways for overcoming this rather disappointing result: either use a less powerful concrete domain constructor or very carefully choose the concrete domain.

The first approach was adopted, among others, by Möller et al. [80] and by Horrocks and Sattler [95, 130]. The imposed restriction on the concrete domain constructor usually is to allow only concrete features inside the concrete domain constructor instead of concrete paths of arbitrary length. In the following, the variant of $\mathcal{ALC}(\mathcal{D})$ obtained by this restriction will be called *path-free*. A particular form of path-freeness is to admit only unary predicates as proposed in [95]: in this case, reasoning in $\mathcal{ALC}(\mathcal{D})$ can be reduced to reasoning in path-free $\mathcal{ALC}(\mathcal{D})$ by replacing each concept description $P(f_1 \circ \cdots \circ f_k \circ g)$ with the equivalent path-free one $\exists f_1.\exists f_2. \cdots .\exists f_k.P(g)$. In [78] and [130], it is shown that reasoning in $\mathcal{SHN}(\mathcal{D})$ and $\mathcal{SHOQ}(\mathcal{D})$, the extensions of two expressive fragments of $\mathcal{SHOIQ}$ by concrete domains, is decidable w.r.t. GCIs if path-freeness is assumed and the concrete domain $\mathcal{D}$ is admissible. A more general result has been obtained in Section 5.3 of [27], where it is shown that any description logic $\mathcal{L}$ such that (i) satisfiability in $\mathcal{L}$ w.r.t. GCIs is decidable and (ii) $\mathcal{L}$'s class of interpretations is closed under disjoint unions (see [27] for details) can be extended with the path-free variant of the concrete domain constructor without losing decidability—provided that the concrete domain is admissible. Indeed, the "harmlessness" of the path-free concrete domain constructor is not very surprising since dropping concrete paths deprives concrete domains of most of their expressive power. For this reason, the complexity of reasoning w.r.t. GCIs in a DL incorporating path-free concrete domains is often not harder than the corresponding problem without concrete domains (if it dominates the complexity of $\mathcal{D}$-satisfiability). For example, in Section 2.4.1 of [112], it is shown that satisfiability in path-free $\mathcal{ALC}(\mathcal{D})$ w.r.t. GCIs is ExpTime-complete if $\mathcal{D}$ is admissible and $\mathcal{D}$-satisfiability is in ExpTime.

The second approach to overcome undecidability of $\mathcal{ALC}(\mathcal{D})$ with GCIs is to keep the original version of the concrete domain constructor and identify concrete domains that do not destroy decidability of reasoning if combined with GCIs. The first positive result following this route was established in [116], where a concrete domain C (for *c*omparison) is considered that is based on the rational numbers $\mathbb{Q} = \Delta^{\mathsf{C}}$, and provides for the binary predicates $<, \leq, =, \neq, \geq$, and $>$. It is shown that satisfiability (and thus also subsumption) in $\mathcal{ALC}(\mathsf{C})$ w.r.t. GCIs is ExpTime-complete, and that an analogous result holds for an interval-based temporal concrete domain. In [111], these results are further improved: first, the concrete domain C is extended to C^+, which additionally admits unary predicates $=_q$ for each $q \in \mathbb{Q}$; and second, the description logic is extended from $\mathcal{ALC}(\mathcal{D})$ to $\mathcal{SHIQ}(\mathcal{D})$, i.e. $\mathcal{SHOIQ}$ without nominals, but with the concrete domain C^+. For this extended logic, an ExpTime result analogous to the one stated above is established. A more general result is proved in [120], where a property of concrete domains is identified that is sufficient for decidability of $\mathcal{ALC}(\mathcal{D})$ with GCIs: a concrete domain $\mathcal{D}$ is called *ω-admissible* if it satisfies all of the following:

- $\mathcal{D}$ has only binary predicates;
- $\mathcal{D}$ has compactness: an infinite $\mathcal{D}$-conjunction is satisfiable if and only if every finite sub-conjunction is satisfiable;

- $\mathcal{D}$ has the patchwork property, which is defined as follows. A $\mathcal{D}$-conjunction c is *complete* iff, for all variables x, y occurring in c, c contains exactly one conjunct $P(x, y)$ and exactly one conjunct $P(y, x)$. Then, $\mathcal{D}$ has the *patchwork property* if the union of two satisfiable and complete $\mathcal{D}$-conjunctions that agree w.r.t. the conjuncts $P(x, y)$ and $P(y, x)$ w.r.t. all shared variables x, y is satisfiable.

The concrete domain C and the temporal concrete domain based on time intervals considered in [116] are ω-admissible. Additionally, it is shown in [120] that a spatial concrete domain based on the topological RCC8 relations is also ω-admissible, and therefore the corresponding incarnation of $\mathcal{ALC}(\mathcal{D})$ is decidable with GCIs. The result in [120] for DLs with ω-admissible concrete domains is established using a tableau algorithm and does not yield tight upper complexity bounds.

Roles in the Concrete Domain Constructor

The reader may wonder why the concrete domain constructor is introduced along with abstract features, instead of admitting normal roles in concrete paths. Indeed, this variant of concrete domains has also been considered by Hanschke [82]: a *concrete role path* is an expression $r_1 \circ \cdots \circ r_k \circ g$ with $r_1, \ldots, r_k$ roles and g a concrete feature. Then we may extend $\mathcal{ALC}$ with the concept constructors $\forall R_1, \ldots, R_k.P$ and $\exists R_1, \ldots, R_k.P$, where $R_1, \ldots, R_k$ are concrete role paths and $P \in \Phi^{\mathcal{D}}$ is a predicate of arity k. The semantics of these constructors is as follows:

$$\begin{array}{rcl}
(\forall R_1, \ldots, R_k.P)^{\mathcal{I}} & := & \{d \in \Delta^{\mathcal{I}} \mid \forall x_1, \ldots, x_k \in \Delta^{\mathcal{D}} : \\
& & \qquad (d, x_i) \in R_i^{\mathcal{I}} \text{ for } 1 \leq i \leq k \text{ implies } (x_1, \ldots, x_k) \in P^{\mathcal{D}}\} \\
(\exists R_1, \ldots, R_k.P)^{\mathcal{I}} & := & \{d \in \Delta^{\mathcal{I}} \mid \exists x_1, \ldots, x_k \in \Delta^{\mathcal{D}} : \\
& & \qquad (d, x_i) \in R_i^{\mathcal{I}} \text{ for } 1 \leq i \leq k \text{ and } (x_1, \ldots, x_k) \in P^{\mathcal{D}}\}
\end{array}$$

where the interpretation $R^{\mathcal{I}}$ of concrete role paths R is defined in the obvious way through relational composition.[26] The resulting DL is called $\mathcal{ALCP}(\mathcal{D})$. Reasoning with $\mathcal{ALCP}(\mathcal{D})$ concept descriptions has been proved to be decidable in [82]. When investigating the complexity of $\mathcal{ALCP}(\mathcal{D})$, it becomes clear that the restriction to abstract features inside the concrete domain constructor has computational advantages: it is shown in [117] that there exists a concrete domain $\mathcal{D}$ such that $\mathcal{D}$-satisfiability is in PTime and satisfiability of $\mathcal{ALCP}(\mathcal{D})$ concept descriptions is NExpTime-hard. Again, a matching upper bound is obtained for the case where $\mathcal{D}$-satisfiability is in NP. This should be contrasted with the PSpace-completeness of satisfiability of concept descriptions in $\mathcal{ALC}(\mathcal{D})$.

We have seen that both the generalized concrete domain constructor and acyclic TBoxes are seemingly moderate extension of $\mathcal{ALC}(\mathcal{D})$ that make reasoning considerably harder. Other such extensions include inverse roles, role conjunction, nominals, and a concrete domain *role* constructor [117, 118]. Thus, the PSpace upper bound of $\mathcal{ALC}(\mathcal{D})$ is not robust w.r.t. extensions of the language.

Uniqueness Constraints and Functional Dependencies

Uniqueness constraints (sometimes also called *identification constraints* and *keys*) and functional dependencies play an important role in the database area, and are also useful

[26] In $\mathcal{ALC}(\mathcal{D})$ with only functional roles inside the concrete domain constructor, the universal version of this constructor can be defined in terms of the existential one (see e.g. [113]).

in connection with concrete domains [118, 119].[27] Say, for example, that there exists a concrete feature socnum associating humans with their social security number. Then, if a human is American, this person should be *uniquely* identified by this number: no other instance of the concept name American should have the same value of the concrete feature socnum. This corresponds to a uniqueness constraint. As another example, we may want to enforce that all books having the same ISBN number share the same title. This is a functional dependency, i.e. the value of the ISBN number determines the title in a functional way. It is not a uniqueness constraint since different books may have the same ISBN number (say, two different copies of the "Handbook of Modal Logic").

In the following, we concentrate on uniqueness constraints. A *key box* is a finite set of *uniqueness constraints* ($u_1, \dots, u_n$ keyfor C), where $u_1, \dots, u_n$ are concrete paths and C is a concept description. An interpretation $\mathcal{I}$ *satisfies* ($u_1, \dots, u_n$ keyfor C) if, for all $d, e \in C^{\mathcal{I}}$,

$$u_i^{\mathcal{I}}(d) = u_i^{\mathcal{I}}(e) \text{ for } 1 \leq i \leq n \quad \text{implies} \quad d = e,$$

and it is a *model* of a key box $\mathcal{K}$ if it satisfies all uniqueness constraints in $\mathcal{K}$. In the presence of key boxes, we are interested in the satisfiability of a concept description w.r.t. a TBox and a key box, i.e. in joint models of all three components (and similarly for subsumption).

It is interesting to note that there is a close relationship between nominals and key boxes. For example, if used together with the uniqueness constraint (g keyfor $\top$), the $\mathcal{ALC}(\mathsf{Q})$ concept description $\exists g.{=_q}$ behaves similar to a nominal for each $q \in \mathbb{Q}$: it is interpreted by a set of cardinality at most one. Key boxes are strong enough to render reasoning in $\mathcal{ALC}(\mathcal{D})$ undecidable [118]: satisfiability of $\mathcal{ALC}(\mathcal{D})$ concept descriptions w.r.t. key boxes is undecidable (even without TBoxes) if the concrete domain $\mathcal{D}$ satisfies $\mathbb{N} \subseteq \Delta^{\mathcal{D}}$ and $\Phi^{\mathcal{D}}$ provides a unary predicate for equality with 0, a binary equality predicate, and a binary predicate for incrementation. Note that this result is similar to the undecidability of satisfiability in $\mathcal{ALC}(\mathcal{D})$ w.r.t. GCIs.

Decidability can be regained by allowing only Boolean combinations of concept names inside uniqueness constraints. Key boxes satisfying this property are called *Boolean*. Even w.r.t. Boolean key boxes, reasoning is much harder than reasoning without key boxes: there exists a concrete domain $\mathcal{D}$ such that $\mathcal{D}$-satisfiability is in PTime and satisfiability of $\mathcal{ALC}(\mathcal{D})$ concept descriptions w.r.t. Boolean key boxes is NExpTime-hard [118]. This high complexity cannot even be reduced if paths are restricted to length one inside $\mathcal{ALC}(\mathcal{D})$ concept descriptions and key boxes (*path-freeness*). The matching upper bound relies on a modified notion of admissibility, called *key-admissibility*. Roughly spoken, a concrete domain is key-admissible if it is admissible and provides for a binary equality predicate. The original definition given in [118] is slightly more general, but too complex to be repeated here. In [118] it is shown that satisfiability of $\mathcal{ALC}(\mathcal{D})$ concept descriptions w.r.t. Boolean key boxes is in NExpTime if $\mathcal{D}$ is key-admissible and $\mathcal{D}$-satisfiability is in NP. In the same work, also a more powerful DL with concrete domains, $\mathcal{SHOQ}(\mathcal{D})$, is extended with key boxes, and a decidability result for the path-free case is established (where $\mathcal{D}$ is required to be key-admissible, but key boxes are not expected to be Boolean).

In the case of functional dependencies, quite similar results can be established. We refer to [119] for more details.

[27] They can also be used in description logics without concrete domains, c.f. [41, 49, 103, 151].

Aggregation

Aggregation is a useful mechanism available in many expressive conceptual modelling formalisms such as database schema languages and query languages. The use of aggregation in the context of concrete domains has been proposed in [31]. As an example, consider the following description of a process and its subprocesses:

$$\mathsf{Process} \sqcap >_0(\mathsf{duration}) \sqcap \forall \mathsf{subproc}.(\mathsf{Process} \sqcap >_0(\mathsf{duration})).$$

The aggregation function "sum" is needed if we want to express that the duration of the mother process is identical to the sum of the durations of its subprocesses (of which there may be arbitrarily many).

A *concrete domain with aggregation* is a concrete domain that, additionally, provides for a set of aggregation functions $\mathsf{agg}(\mathcal{D})$, where each $\Gamma \in \mathsf{agg}(\mathcal{D})$ is associated with a partial function $\Gamma^{\mathcal{D}}$ from the set of finite multisets over $\Delta^{\mathcal{D}}$ into $\Delta^{\mathcal{D}}$. To distinguish concrete domains with aggregation from those without, we denote the former with Σ. Typical aggregation functions are min, max, sum, count, and $\mathsf{average}$. The set of $\mathcal{ALC}(\Sigma)$ concept descriptions is now defined in the same way as $\mathcal{ALC}(\mathcal{D})$ concept descriptions, except that *aggregated features* may be be used in place of concrete features, where an aggregated feature is an expression $\Gamma(r \circ g)$ with r a role, g a concrete feature, and Γ an aggregation function from Σ. The semantics of aggregated features is defined via multisets: for each interpretation $\mathcal{I}$ and each $d \in \Delta^{\mathcal{I}}$ such that the set $\{e \mid (d,e) \in r^{\mathcal{I}}\}$ is finite, we use $M_d^{r \circ g}$ to denote the multiset that, for each $z \in \Delta^{\mathcal{D}}$, contains z exactly $|\{e \mid (d,e) \in r^{\mathcal{I}} \text{ and } g^{\mathcal{I}}(e) = z\}|$ times. The semantics of aggregated features is now defined as follows:

$$(\Gamma(r \circ g))^{\mathcal{I}}(d) := \begin{cases} \Gamma^{\Sigma}(M_d^{r \circ g}) & \text{if } \{e \mid (d,e) \in r^{\mathcal{I}}\} \text{ is finite} \\ \text{undefined} & \text{otherwise.} \end{cases}$$

Returning to the initial example, we can now express the fact that the duration of the mother process is identical to the sum of the durations of all its subprocesses by writing $=(\mathsf{duration}, \mathsf{sum}(\mathsf{subproc} \circ \mathsf{duration}))$. The investigations performed by Baader and Sattler [31] reveal that the expressive power provided by aggregation functions is hard to tame in order to obtain a decidable formalism: for concrete domains with aggregation Σ where (i) $\mathbb{N} \subseteq \Delta^{\Sigma}$, (ii) Φ^{Σ} contains a (unary) predicate for equality with 1 and a (binary) equality predicate, and (iii) $\mathsf{agg}(\Sigma)$ contains min, max, and sum, satisfiability of $\mathcal{ALC}(\Sigma)$ concept descriptions is undecidable. This lower bound applies even if we admit only conjunction, the $\forall r.C$ constructor, and the concrete domain constructor, but drop all other concept constructors. Rather strong measures have to be taken to regain decidability: either, we have to drop the $\forall r.C$ constructor from the language, thus obtaining a sub-Boolean DL, or we have to confine ourselves to "well-behaved" aggregation functions such as min and max of which there exist only very few. More details can be found in [31].

6.2 Role Value Maps

Role value maps are a family of concept constructors that were available in the first description logic system, KL-ONE [45], and have since then been considered in several variations. The original and most powerful variant of role value maps has later been

found to cause undecidability, even if used with quite weak (sub-Boolean) description logics such as the one available in the KL-ONE system.

To define role value maps, we must introduce the notion of a *path*, i.e., a composition $r_1 \circ \cdots \circ r_n$ of role names. If R and S are paths, then the expression $(R \subseteq S)$ is a *containment role value map* and $(R = S)$ is an *equality role value map*. To extend $\mathcal{ALC}$ with role value maps, we admit them as additional concept constructors. The resulting description logic is denoted $\mathcal{ALC}^{\mathsf{rvm}}$. The semantics of the additional concept constructors is as follows:

$$\begin{array}{lcl} (R \subseteq S)^{\mathcal{I}} & = & \{d \in \Delta^{\mathcal{I}} \mid \forall e.(d,e) \in R^{\mathcal{I}} \text{ implies } (d,e) \in S^{\mathcal{I}}\}, \\ (R = S)^{\mathcal{I}} & = & \{e \in \Delta^{\mathcal{I}} \mid \forall e.(d,e) \in R^{\mathcal{I}} \text{ iff } (d,e) \in S^{\mathcal{I}}\}, \end{array}$$

where the interpretation $R^{\mathcal{I}}$ of paths R is defined in the obvious way through relational composition. For example, the concept description $\mathsf{Person} \sqcap (\mathsf{child} \circ \mathsf{friend} \subseteq \mathsf{knows})$ describes persons knowing all the friends of their children.

Though there appears to be no direct modal counterpart to role value maps as a concept constructor, there is a connection to *modal reduction principles* as discussed in Chapter 7. Modal reduction principles (MRPs) are axioms of the form $Mp \rightarrow Np$, where M and N are sequences of modal operators $\Box_i$ and $\Diamond_j$ [152]. We call an MRP *box-only* if M and N are non-empty sequences of box operators. There is a close correspondence between normal modal logics axiomatized by box-only MRPs and $\mathcal{ALC}^{\mathsf{rvm}}$: it follows from Sahlqvist's completeness theorem that normal modal logics axiomatized by a box-only MRP $\varphi = \Box_{i_1} \cdots \Box_{i_n} p \rightarrow \Box_{j_1} \cdots \Box j_m p$ are characterized by the class of frames that validates φ; moreover, it is a routine task to show that the same class of frames is determined by all models of the GCI $\top \sqsubseteq (r_{i_1} \circ \cdots \circ r_{i_n} \subseteq s_{j_1} \circ \cdots \circ s_{j_m})$. There is also a close connection between role value maps and so-called grammar logics [58], which will be discussed in more detail below.

Undecidability

Reasoning in the first description logic system KL-ONE was initially believed to be in PTIME. However, in 1989 Schmidt-Schauß was able to show that it is undecidable, identifying role value maps as the main culprit [141]. More precisely, Schmidt-Schauß proves that, even in the description logic $\mathcal{FL}_0^{\mathsf{rvm}}$ providing only for the constructors conjunction, value restriction, and role value maps, subsumption w.r.t. the empty TBox is undecidable.

The proof of Schmidt-Schauß uses a reduction of the word problem for groups. We present here a slight variation that reduces the word problem for semigroups [36].[28] For simplicity, we first show undecidability of $\mathcal{FL}_0^{\mathsf{rvm}}$ w.r.t. GCIs, and then eliminate the GCIs from the reduction. A finitely presented semigroup S is given in the form of defining identities $s_1 = t_1, \ldots, s_m = t_m$, where the s_i and t_i are words over some finite alphabet Σ. Then the word problem is to decide, given S and words s and t, whether $s = t$ holds in S, i.e., whether the identity $s = t$ can be derived from the defining identities of S and the usual axioms for semigroups. For the reduction, we view the symbols $r_1, \ldots, r_n$ of Σ

[28] The reduction of Schmidt-Schauß yields a slightly stronger result since it applies also to the case where we have only equality role value maps, but no containment role value maps.

as role names and construct a set of GCIs $\mathcal{T}_S$ and a concept description $D_{s,t}$ as follows:

$$\begin{array}{rcl} \mathcal{T}_S & := & \{\top \sqsubseteq (s_1 = t_1) \sqcap \cdots \sqcap (s_m = t_m)\} \\ D_{s,t} & := & (s = t) \end{array}$$

Then it is not hard to show that $\top \sqsubseteq_{\mathcal{T}_S} D_{s,t}$ if and only if $s = t$ can be derived from the defining identities of S. This yields undecidability of subsumption in $\mathcal{FL}_0^{\mathsf{rvm}}$ w.r.t. GCIs. To get rid of GCIs, we can internalize them (c.f. Section 3.1). More precisely, the subsumption $\top \sqsubseteq_{\mathcal{T}_S} D_{s,t}$ holds if and only if $C_S \sqsubseteq D_{s,t}$, where C_S is defines as follows:

$$C_S \quad := \quad \bigsqcap_{r \in \Sigma} \big((r \subseteq u) \sqcap (u \circ u \subseteq u)\big) \sqcap \forall u.((s_1 = t_1) \sqcap \cdots \sqcap (s_m = t_m))$$

where u is a role name that does not occur in Σ. It follows that subsumption in $\mathcal{FL}_0^{\mathsf{rvm}}$ is undecidable also without GCIs.

There is a related result in modal logic that should be mentioned: Shehtman proved in 1982 that there exists a set Γ of box-only modal reduction principles such that, in the normal modal logic axiomatized by Γ, satisfiability is undecidable [146]. By what was said above about the connection between MRPs and role value maps, and since GCIs can be internalized in $\mathcal{ALC}^{\mathsf{rvm}}$ similar to what was done above in the case of $\mathcal{FL}_0^{\mathsf{rvm}}$, it is obvious that this gives a proof of undecidability of reasoning in $\mathcal{ALC}^{\mathsf{rvm}}$ without TBoxes and GCIs.

To avoid undecidability, two approaches have been considered: first, role value maps have been weakened into feature agreements and feature disagreements, which have a similar semantics but are restricted to paths comprised only of functional roles; and second, the original role value maps have been used for paths of a syntactically restricted form. In the next section, we describe the first approach. Syntactic restrictions on paths are discussed subsequently in Section 6.2.

Feature Agreements

A *feature path* is a composition $f_1 \circ \cdots \circ f_n$ of abstract features as introduced in Section 6.1. If u and v are feature paths, then the expression $(u = v)$ is a *feature agreement*, and $(u \neq v)$ is a *feature disagreement*. The description logic $\mathcal{ALCF}$ is obtained from $\mathcal{ALC}^{\mathsf{rvm}}$ by replacing role value maps with feature (dis)agreements. The semantics of the new concept constructors is:

$$\begin{array}{rcl} (u = v)^{\mathcal{I}} & = & \{d \in \Delta^{\mathcal{I}} \mid \exists e.(d,e) \in u^{\mathcal{I}} \text{ and } (d,e) \in v^{\mathcal{I}}\} \\ (u \neq v)^{\mathcal{I}} & = & \{d \in \Delta^{\mathcal{I}} \mid \exists e, e'.(d,e) \in u^{\mathcal{I}}, (d,e') \in v^{\mathcal{I}}, \text{ and } e \neq e'\} \end{array}$$

In the literature, feature agreements are sometimes called the *same-as* constructor, e.g. in their incarnation in the Classic system [44]. The restriction of role value maps to feature paths has an impairing effect on the usefulness of feature (dis)agreements. For example, the concept description

$$\mathsf{Person} \sqcap (\mathsf{child} \circ \mathsf{friend} \subseteq \mathsf{knows})$$

cannot be expressed in $\mathcal{ALCF}$ since child and knows should not be forced to be functional. However, feature (dis)agreements can still be usefully employed, as illustrated by the following concept definition:

$$\mathsf{ParentsMarried} \equiv (\mathsf{mother} \circ \mathsf{married\text{-}to} = \mathsf{father})$$

The main advantage of feature agreements over role value maps lies in their computational properties. Indeed, Hollunder and Nutt [89] show that satisfiability (and thus also subsumption) of $\mathcal{ALCF}$ concept descriptions is decidable and PSPACE-complete (see also [113]).

When further expressive means are added to $\mathcal{ALCF}$, the computational complexity often gets dramatically worse. In this respect, feature (dis)agreements resemble concrete domains: the PSPACE upper bound of the basic description logic with feature (dis)agreements $\mathcal{ALCF}$ is rather fragile w.r.t. extensions of the language. An important example for this behaviour are TBoxes. As shown in [110], satisfiability in $\mathcal{ALCF}$ w.r.t. acyclic TBoxes is NEXPTIME-complete. The result is established by reduction of a NEXPTIME-complete variant of the domino problem, and exploits the succinctness gained by introducing acyclic TBoxes similar to what is discussed in Section 6.1 in the context of concrete domains. When cyclic TBoxes or GCIs are admitted, satisfiability and subsumption in $\mathcal{ALCF}$ even become undecidable [11], which can be shown by a reduction of the word problem for groups. Other extensions of $\mathcal{ALCF}$ that make reasoning harder include intersection of roles, inverse roles, and transitive closure of functional roles. In the first case, satisfiability of concept descriptions becomes NEXPTIME-complete, while it is undecidable in the latter two cases [11, 112].

Restricted Paths in Role Value Maps

In this section, we consider syntactic restrictions on paths inside role value maps. There are some quite drastic restrictions that are easily seen to regain decidability of reasoning in $\mathcal{ALC}^{\mathsf{rvm}}$:

- Only allow paths of length one. In this case, reasoning in $\mathcal{ALC}^{\mathsf{rvm}}$ can be reduced to reasoning in $\mathcal{ALC}^{\neg,\cap,\cup}$, the extension of $\mathcal{ALC}$ with Boolean role constructors: simply replace $(r = s)$ with $(r \subseteq s) \sqcap (s \subseteq r)$, and $(r \subseteq s)$ with $\forall(r \cap \neg s).\bot$. Since satisfiability and subsumption in $\mathcal{ALC}^{\neg,\cap,\cup}$ w.r.t. GCIs is known to be decidable [122, 121], so is the restricted version of $\mathcal{ALC}^{\mathsf{rvm}}$. Note that there is also a close connection to role hierarchies: a role inclusion $r \sqsubseteq s$ as used in a role hierarchy can be simulated using the concept equation $\top \equiv (r \subseteq s)$ in $\mathcal{ALC}^{\mathsf{rvm}}$.

- Only admit role value maps of the form $(r \circ r \subseteq r)$. Clearly, we obtain a localized variant of transitive roles. It is straightforward to adapt the standard techniques for dealing with (globally) transitive roles [135, 94] to show that, in this variant of $\mathcal{ALC}^{\mathsf{rvm}}$, satisfiability and subsumption w.r.t. GCIs are decidable. It appears to be an open problem whether admitting single-role role value maps of the form $(r^n \subseteq r^m)$, with $n, m \in \mathbb{N}$ and r^n denoting the n-fold composition of r, yields a decidable variant of $\mathcal{ALC}^{\mathsf{rvm}}$.

More powerful decidable fragments of $\mathcal{ALC}^{\mathsf{rvm}}$ can be obtained by restricting paths in a less strict way. This is done by Horrocks and Sattler [96] in their work on complex role inclusion axioms (RIAs), and in the closely related area of grammar logics [58, 34, 59]. In both cases, role value maps are *not* considered to be concept constructors, but rather they are *global*, similar to the role inclusions in a role hierarchy, i.e., the role value map must hold for every element of the interpretation domain. In the following, we consider $\mathcal{ALC}$ concept descriptions and assume the presence of a *role box*, i.e. a finite set of role value maps $(R \subseteq S)$. An interpretation $\mathcal{I}$ is a *model* of a role box $\mathcal{R}$ if it satisfies $R^{\mathcal{I}} \subseteq S^{\mathcal{I}}$

for all $(R \subseteq S) \in \mathcal{R}$. In this setting, we are interested in satisfiability and subsumption w.r.t. TBoxes/GCIs and role boxes, i.e., in common models of all three inputs.

Translated to this terminology, the idea of grammar logic is to view a role value map $(r_1 \circ \cdots \circ r_k \subseteq s_1 \circ \cdots \circ s_\ell)$ as a production rule $s_1 \cdots s_\ell \to r_1 \cdots r_k$, and a role box as a formal grammar [58]. Here, the mapping from role names to terminal and non-terminal symbols is arbitrary, but fixed. From the description logic perspective, the most relevant results from grammar logic are the following. First, Demri shows that satisfiability and subsumption of $\mathcal{ALC}$ concept descriptions is ExpTime-complete if only role boxes corresponding to left-linear or right-linear grammars are admitted [59]. In role boxes of this form, we can express properties such as "the enemies of my friends are my enemies":

$$(\mathsf{friend} \circ \mathsf{enemy} \subseteq \mathsf{enemy}).$$

Note that this result captures the case where paths are required to be of length at most one, but not the case $(r \circ r \subseteq r)$. Second, Baldoni et al. show that satisfiability of $\mathcal{ALC}$ concept descriptions is undecidable if role boxes corresponding to context-free grammars are admitted [34]. This result was later strengthened by Demri to linear grammars [59].

Horrocks and Sattler consider the extension of $\mathcal{SHIQ}$ with global role value maps of the form $(r \subseteq s)$, $(r \circ s \subseteq r)$, and $(s \circ r \subseteq r)$, where r, s is a role name or the inverse of a role name [96]. For example, the statement about enemies of friends from above can be strengthened by additionally saying that the friends of my enemies are my enemies:

$$\begin{array}{lcl}(\mathsf{friend} \circ \mathsf{enemy} & \subseteq & \mathsf{enemy}) \\ (\mathsf{enemy} \circ \mathsf{friend} & \subseteq & \mathsf{enemy}).\end{array}$$

Note that this role box does not correspond to a left-linear or right-linear grammar. Role value maps of this form are of particular interest since they allow to describe the propagation of properties, e.g. along part-whole relations: "the owner of a whole is the owner of all parts" can be written as $(\mathsf{part\text{-}of} \circ \mathsf{owner} \subseteq \mathsf{owner})$. Let us call Horrocks and Sattler's variant of role value maps *HS-RVMs*. Horrocks and Sattler obtain the following results: first, reasoning in the extension of $\mathcal{SHIQ}$ with HS-RVMs is undecidable in the general case. An inspection of the proof shows that undecidability already arises in $\mathcal{ALC}$ extended with inverse roles, number restrictions of the form $(\leqslant 1\ r)$, GCIs, and HS-RVMs. Decidability of plain $\mathcal{ALC}$ extended with HS-RVMs (and possibly GCIs) appears to be an open problem. Second, satisfiability and subsumption in $\mathcal{SHIQ}$ w.r.t. GCIs and role boxes becomes decidable if we admit only HS-RVMs and *acyclic* role boxes. Acyclicity of role boxes is defined similar to the TBox case: a role r *directly affects* a role s if $r \neq s$ and there is an HS-RVM with (i) r appearing on the left-hand side (possibly inside a composition) and s appearing on the right-hand side, or (ii) the inverse of r appearing on the left-hand side and the inverse of s appearing on the right-hand side. *Affects* is the transitive closure of "directly affects". Then a role box is acyclic if no role affects itself. Observe that the above example about friends and enemies is acyclic.

There are several other restrictions of paths that can be considered. An interesting example is to admit only role value maps $(R \subseteq S)$ with R and S paths of equal length. This restriction has been investigated by Molitor [126], but the decidability status of $\mathcal{ALC}^{\mathsf{rvm}}$ under this restriction is, as of now, unknown.

ACKNOWLEDGEMENTS

We are grateful to Silvio Ghilardi and Andrey Bovykin for useful remarks on earlier versions of this article.

This chapter provides a modern overview of the field of hybrid logic. Hybrid logics are extensions of standard modal logics, involving symbols that name individual states in models. The first results that are nowadays considered as part of the field date back to the early work of Arthur Prior in 1951. Since then, hybrid logic has gone through a number of revivals and reinventions. Nowaways, it is a field of research in its own right, with a wealth of results, techniques, and applications.

Our main aim, in this chapter, is to provide a coherent picture of the current state of affairs in the field of hybrid logic. Rather than a comprehensive summary, we will try to give the reader a taste for the type of results and techniques that we consider hallmarks of the field. In some cases, we will only state results, with pointers to relevant literature, while in other cases we will provide full proofs.

In Section 1, we give an intuitive introduction to hybrid logics, with examples of the extra expressive power offered by the hybrid operators. This section also contains the basic definitions of syntax and semantics that are used throughout the chapter. In Section 2 we provide a short history of the field, discussing the work of Prior in the 50s, of the Sofia School in the 80s, and the work on very expressive hybrid languages in the 90s. Sections 3 and 4 form the core of

the chapter. They contain the most important techniques and results in the field, with respect to completeness, expressive power, frame definability, interpolation and complexity. In Section 5 we briefly present proof systems for hybrid languages (sequents, natural deduction, tableaux, and resolution), and we discuss some issues concerning the development of automated provers based on them. In Section 6 we comment on connections with related areas (some of which are discussed in detail in other chapters of this handbook). Section 7 finishes the chapter with a summary and general perspectives.

1 WHAT ARE HYBRID LOGICS?

In their simplest form, hybrid languages are modal languages that have special symbols to name individual states in models. These new symbols, which are called *nominals*, enter the stage gracefully: we simply add a new sort of atomic symbols $\mathsf{NOM} = \{i, j, k, \ldots\}$ disjoint from the set PROP of propositional variables and let them combine freely in formulas. For example, if i is a nominal and p and q are propositional variables, then

$$\Diamond(i \wedge p) \wedge \Diamond(i \wedge q) \to \Diamond(p \wedge q), \tag{1}$$

is a well formed formula. Now for the important twist: since nominals name individual states in the model, they denote *singleton sets*. In other words, they are true at a unique point in the model. Once this step has been taken, the whole landscape changes. For example, (1) becomes a validity: let $\mathcal{M}$ be a model, m a state in the domain of $\mathcal{M}$, and suppose $\mathcal{M}, m \models \Diamond(i \wedge p) \wedge \Diamond(i \wedge q)$. Then some successor state m' of m satisfies $i \wedge p$, and some successor state m'' of m satisfies $i \wedge q$. Since i is a nominal, it is true at a unique point in $\mathcal{M}$. Hence $m' = m''$ and we have $\mathcal{M}, m \models \Diamond(p \wedge q)$. Note that (1) could be falsified if i were an ordinary propositional variable.

When we realize the potential that nominals have, an interesting idea suggests itself: to introduce, for each nominal i, an operator $@_i$ that allows us to jump to the point named by i. The formula $@_i\varphi$ (read "at i, φ") moves the point of evaluation to the state named by i and evaluates φ there. These operators satisfy many nice logical properties. For a start, each $@_i$ is a normal modal operator: it satisfies the distributivity axiom $(@_i(\varphi \to \psi) \to (@_i\varphi \to @_i\psi))$ and the necessitation rule (if φ is valid, then $@_i\varphi$ is also valid). Moreover, it is self-dual: $@_i\varphi$ is equivalent to $\neg @_i \neg\varphi$. In an intuitive sense, the $@_i$ operators provide a bridge between semantics and syntax by internalizing the satisfaction relation '$\models$' into the logical language:

$$\mathcal{M}, w \models \varphi \;\text{ iff }\; \mathcal{M} \models @_i\varphi, \;\text{where } i \text{ is a nominal naming } w.$$

For this reason, these operators are usually called *satisfaction operators*.

Aiming to make full use of the flexibility provided by direct reference to specific points in the model naturally leads to further enrichment of the language. One possibility would be to have not only names for individual states but also variables ranging over states, with corresponding quantifiers. We would then be able to write formulas like

$$\forall y. \Diamond y. \tag{2}$$

The first-order translation of this formula is $\forall y. \exists z.(R(x, z) \wedge z = y)$ or, simply, $\forall y. R(x, y)$, forcing the current state to be related to all states in the domain. The $\forall$ quantifier is very expressive. As discussed in [32], even the basic modal language extended with state variables and this universal quantifier is undecidable. Moreover, $\forall$ and $@$ together give us already full first-order

expressive power (cf. Section 3.2). Nevertheless, the $\forall$ quantifier is historically important. The earliest treatments are probably those of [117, 118, 46].

The $\forall$ quantifier is very "classical." If we think modally, and remember that evaluation of modal formulas takes place *at a given point*, a different kind of binder suggests itself. The $\downarrow$ binder binds variables to points but, unlike $\forall$, it binds to the *current* point. In essence, it enables us to create a name for the here-and-now, and refer to it later in the formula. For example, the formula

$$\downarrow y.\Diamond y \tag{3}$$

is true at a state m iff m is related to itself. The intuitive reading of (3) is quite straightforward: the formula says "call the current state y and check that y is reachable." The difference between $\forall$ and $\downarrow$ is subtle, but important. $\forall$ is *global*, in the sense that formulas containing $\forall$ are not preserved under generated submodels [32]. On the other hand, $\downarrow$ is intrinsically local and, as we will show in Theorems 16 and 18, it can be characterized in terms of the operation of taking generated submodels.

Like $\forall$, the $\downarrow$ binder has been invented independently on several occasions. For example, in [122], $\downarrow$ is introduced as part of an investigation into temporal semantics and temporal databases, [131] uses it to aid reasoning about automata, it is related to the freeze operator in [88], and [52] employs it as part of his treatment of indexicality. However, none of the systems just mentioned allows the free syntactic interplay of variables with the underlying propositional logic; that is, they make use of $\downarrow$, but in languages that are not fully hybrid. The earliest paper to introduce it into a fully hybrid language seems to be [77].

Note that satisfaction operators work in perfect coordination with $\downarrow$. Whereas $\downarrow$ "stores" the current point of evaluation (by binding a variable to it), the satisfaction operators enable us to "retrieve" stored information by shifting the point of evaluation in the model. By using the "storing and retrieving" intuition it is easy to define complex properties. For example, Kamp's temporal *until* operator U (with semantics: $U(\varphi, \psi)$ is true at a state m if there is a future state m' where φ holds, such that ψ holds in all states between m and m') can be defined as follows:

$$U(\varphi, \psi) := \downarrow x.\Diamond\downarrow y.(\varphi \wedge @_x\Box(\Diamond y \rightarrow \psi)).$$

Let us see how this work. First, we name the current state x using $\downarrow$, and use the $\Diamond$ operator to find a suitable successor state, which we call y, where φ holds. Without the @ operator we would be stuck in that successor state, but we can use @ to go back to x and demand that in all successors of x having y as a successor, ψ holds.

Summarizing the above discussion, we can say that the term *hybrid logic* refers to a family of extensions of the basic hybrid language with devices that, in one way or another, allow for explicit reference to individual states of the Kripke model. But, why are hybrid logics called *hybrid*?

One explanation comes from the work of Arthur Prior in the 1950s. As we will discuss more in detail in Section 2, Prior was interested in the relation between what McTaggart called the A-series and B-series of time [109]. Following McTaggart's analysis of time in terms of the A-series of past, present and future and the B-series of earlier and later, Prior discusses two logical systems: the I-calculus aims to capture the properties of the B-series and takes variables ranging over instants as primitive, while the T-calculus examines tenses and takes variables ranging over propositions. In [117, Chapter V.6], Prior proposes a way to develop the I-calculus *inside* the T-calculus, and for this he allows instant-variables to be used together with propositional variables. He will call this step "the third grade of tense-logical involvement" in [118, Chapter XI], where instant-variables are treated as representing (special) propositions. From this perspective, the

terms hybrid applies to the "confusion" of terms (the variables over instants) with formulas (the propositional variables).

There is another sense in which hybrid logics are hybrid, namely that, both in terms of expressive power and in terms of the techniques used to analyze them, hybrid languages lie in between the basic modal language and first-order logic. While having a distinctly modal flavor, hybrid logics enjoy features which are of a clear first-order nature. As we discussed above, the more expressive hybrid languages include binders and variables over elements of the domain, traditional hallmarks of first-order languages, while nominals are nothing else than first-order constants. The nominals and satisfaction operators also introduce a restricted form of equality: a state m in a model can satisfy a nominal i if and only if it is equal to the denotation of i, and a model $\mathcal{M}$ satisfies $@_i j$ if and only if the denotations of i and j coincide. In other words, nominals introduce equality between the point of evaluation and a named state, while satisfaction operators enable us to express equality between named states. Concerning first-order techniques which can be used for hybrid languages, we will see in Section 3.1 for example, that nominals can be used as 'witnesses' in a classical Henkin-style completeness proof for hybrid languages, and classical first-order notions like potential isomorphisms are useful for characterizing the expressive power of hybrid languages. In Section 3.3, we will see a very general interpolation result, the proof of which relies on the fact that shared nominals can be "bound away" using $\downarrow$, in the same way that shared constants can be replaced by existentially quantified variables in first-order logic.

For a more detailed introduction, including further intuitive examples using the different hybrid languages, the reader is referred to [26]. The Hybrid Logic Web Pages [3] provides additional information and a broad on-line bibliography. We now move on to the basic definitions of syntax and semantics that will be used through the chapter.

1.1 Basic Definitions

The simplest hybrid language is $\mathcal{H}$, which extends the basic modal language with nominals only. Further extensions will be named by listing the additional operators. The most expressive system we will discuss in detail is $\mathcal{H}(\mathsf{E}, @, \downarrow)$, with the existential modality E, @-operators, and the $\downarrow$ binder (when considering languages containing the $\downarrow$ binder, it is implicitly understood that the language also contains state variables). At various points, we will briefly mention other hybrid languages as well (e.g., hybrid extensions of temporal and dynamic logics).

The following two definitions give the syntax and semantics of $\mathcal{H}(\mathsf{E}, @, \downarrow)$. The corresponding definitions for sublanguages of $\mathcal{H}(\mathsf{E}, @, \downarrow)$ can be obtained by leaving out irrelevant clauses.

DEFINITION 1. Let $\mathsf{REL} = \{R_1, R_2, \ldots\}$ (the *relational symbols*), $\mathsf{PROP} = \{p_1, p_2, \ldots\}$ (the *propositional variables*), $\mathsf{NOM} = \{i_1, i_2, \ldots\}$ (the *nominals*), and $\mathsf{SVAR} = \{x_1, x_2, \ldots\}$ (the *state variables*) be pairwise disjoint, countably infinite sets of symbols. By a *state symbol*, we will mean any element of $\mathsf{NOM} \cup \mathsf{SVAR}$. The well-formed formulas of the hybrid language $\mathcal{H}(\mathsf{E}, @, \downarrow)$ in the signature $\langle \mathsf{REL}, \mathsf{PROP}, \mathsf{NOM}, \mathsf{SVAR} \rangle$ are given by the following recursive definition:

$$\mathsf{FORMS} \;::=\; \top \mid p \mid s \mid \neg\varphi \mid \varphi_1 \wedge \varphi_2 \mid \langle R \rangle \varphi \mid \mathsf{E}\varphi \mid @_s\varphi \mid \downarrow x.\varphi,$$

where $p \in \mathsf{PROP}$, $s \in \mathsf{NOM} \cup \mathsf{SVAR}$, $x \in \mathsf{SVAR}$, $R \in \mathsf{REL}$ and $\varphi, \varphi_1, \varphi_2 \in \mathsf{FORMS}$.

Given a set of formulas $\Gamma \subseteq \mathsf{FORMS}$, we will use $\mathsf{PROP}(\Gamma)$, $\mathsf{NOM}(\Gamma)$ and $\mathsf{SVAR}(\Gamma)$ to denote, respectively, the set of propositional variables, nominals, and state variables occurring in formulas in Γ. Also, for φ a formula, $\mathsf{SF}(\varphi)$ will be the set of subformulas of φ.

Note that the above syntax is simply that of ordinary (multi-modal) propositional modal logic extended with clauses for the state symbols and for $\mathsf{E}\varphi$, $@_s\varphi$ and $\downarrow x_j.\varphi$. Also, note that, like propositional variables, nominals and state variables can be used as atomic formulas. The difference between nominals and state variables is analogous to the difference between constants and variables in first-order logic: nominals cannot be bound by $\downarrow$, and their interpretation is specified by the model, whereas state variables are interpreted by assignment functions, and they can be bound by the $\downarrow$-binder.

The notions of *free* and *bound* state variable are defined as in first-order logic, with $\downarrow$ as the only binding operator. Similarly, other syntactic notions (such as *substitution*, and a state symbol t being *substitutable for* x *in* φ) are defined as in first-order logic. A *sentence* is a formula containing no free state variables. Furthermore, a formula is *pure* if it contains no propositional variables, and *nominal-free* if it contains no nominals.

In the remainder of the chapter we will assume fixed a signature $\langle \mathsf{REL}, \mathsf{PROP}, \mathsf{NOM}, \mathsf{SVAR} \rangle$. Now for the semantics.

DEFINITION 2. A (hybrid) *model* $\mathcal{M}$ is a triple $\mathcal{M} = \langle M, (R^{\mathcal{M}})_{R\in\mathsf{REL}}, V \rangle$ such that M is a non-empty set, each $R^{\mathcal{M}}$ is a binary relation on M, and $V : \mathsf{PROP} \cup \mathsf{NOM} \to \wp(M)$ is such that for all nominals $i \in \mathsf{NOM}$, $V(i)$ is a singleton subset of M. We usually write M (roman letters) for the domain of a model $\mathcal{M}$, and call the elements of M *states*, *worlds* or *points*. Each $R^{\mathcal{M}}$ is an *accessibility relation*, and V is the *valuation*. A *frame* is defined in the usual way: as a model without a valuation. If $\mathcal{F} = \langle M, (R^{\mathcal{F}})_{R\in\mathsf{REL}} \rangle$ is a frame and V is a valuation on M, then $\mathcal{M} = \langle \mathcal{F}, V \rangle$ is the model $\langle M, (R^{\mathcal{F}})_{R\in\mathsf{REL}}, V \rangle$. In this case we, say that $\mathcal{M}$ *is based on* $\mathcal{F}$, and that $\mathcal{F}$ *is the underlying frame of* $\mathcal{M}$.

An *assignment* g for $\mathcal{M}$ is a mapping $g : \mathsf{SVAR} \to M$. Given an assignment $g : \mathsf{SVAR} \to M$, a state variable $x \in \mathsf{SVAR}$, and a state $m \in M$, we define g^x_m (an x*-variant of* g) by letting $g^x_m(x) = m$ and $g^x_m(y) = g(y)$ for all $y \neq x$.

Let $\mathcal{M} = \langle M, (R^{\mathcal{M}})_{R\in\mathsf{REL}}, V \rangle$ be a model, $m \in M$, and g an assignment for $\mathcal{M}$. For any state symbol $s \in \mathsf{NOM} \cup \mathsf{SVAR}$, let $[s]^{\mathcal{M},g}$ be the state denoted by s (i.e., for $i \in \mathsf{NOM}$, $[i]^{\mathcal{M},g}$ is the unique $m \in M$ such that $V(i) = \{m\}$, and for $x \in \mathsf{SVAR}$, $[x]^{\mathcal{M},g} = g(x)$). Then the *satisfaction relation* is defined as follows:

$$
\begin{array}{lll}
\mathcal{M}, g, m \models \top & & \\
\mathcal{M}, g, m \models p & \text{iff} & m \in V(p) \quad \text{for } p \in \mathsf{PROP} \\
\mathcal{M}, g, m \models s & \text{iff} & m = [s]^{\mathcal{M},g} \quad \text{for } s \in \mathsf{NOM} \cup \mathsf{SVAR} \\
\mathcal{M}, g, m \models \neg\varphi & \text{iff} & \mathcal{M}, g, m \not\models \varphi \\
\mathcal{M}, g, m \models \varphi_1 \wedge \varphi_2 & \text{iff} & \mathcal{M}, g, m \models \varphi_1 \text{ and } \mathcal{M}, g, m \models \varphi_2 \\
\mathcal{M}, g, m \models \langle R \rangle\varphi & \text{iff} & \text{there is a state } m' \text{ such that } R^{\mathcal{M}}(m, m') \text{ and } \mathcal{M}, g, m' \models \varphi \\
\mathcal{M}, g, m \models \mathsf{E}\varphi & \text{iff} & \text{there is a state } m' \in M \text{ such that } \mathcal{M}, g, m' \models \varphi \\
\mathcal{M}, g, m \models @_s\varphi & \text{iff} & \mathcal{M}, g, [s]^{\mathcal{M},g} \models \varphi \quad \text{for } s \in \mathsf{NOM} \cup \mathsf{SVAR} \\
\mathcal{M}, g, m \models \downarrow x.\varphi & \text{iff} & \mathcal{M}, g^x_m, m \models \varphi.
\end{array}
$$

The first six clauses in the definition of the satisfaction relation are similar to the ones for the basic modal language, except that they are relativized to an additional assignment function. Recall that nominals and state variables can be used as atomic formulas, in which case they act as propositional variables that are true at a unique state. The $\downarrow$ binder binds state variables to the state where evaluation is being performed (the *current world*), and $@_s$ shifts evaluation to the state named by s. As in first-order logic, if φ is a *sentence* (i.e., a formula with no free state variables), the truth of φ at a state in a model does not depend on the assignment. Hence, in this case we will write $\mathcal{M}, m \models \varphi$ instead of $\mathcal{M}, g, m \models \varphi$.

A formula φ is said to be *globally true* in a model $\mathcal{M}$ under an assignment g (notation: $\mathcal{M}, g \models \varphi$), if $\mathcal{M}, g, m \models \varphi$ for all $m \in M$. A formula φ is *satisfiable* if there is a model $\mathcal{M}$, an assignment g on $\mathcal{M}$, and a world $m \in M$ such that $\mathcal{M}, g, m \models \varphi$. A formula φ is *valid* (notation: $\models \varphi$) if for all models $\mathcal{M}$ and assignments g, $\mathcal{M}, g \models \varphi$. A formula φ is a *local consequence* of a set of formulas Σ if for all models $\mathcal{M}$, assignments g, and points $m \in M$, $\mathcal{M}, g, m \models \Sigma$ implies $\mathcal{M}, g, m \models \varphi$. A formula φ is a *global consequence* of a set of formulas Σ if for all models $\mathcal{M}$ and assignments g, $\mathcal{M}, g \models \Sigma$ implies $\mathcal{M}, g \models \varphi$. We denote local consequence by $\Sigma \models^{loc} \varphi$ and global consequence by $\Sigma \models^{glo} \varphi$. As in ordinary propositional modal logic, local consequence is strictly stronger than global consequence.

Definitions 1 and 2 specify the syntax and semantics of the most expressive hybrid language we are going to discuss in detail, $\mathcal{H}(\mathsf{E}, @, \downarrow)$. Two important fragments of this language are $\mathcal{H}(@, \downarrow)$, which is obtained by dropping the clauses for the existential modality E, and $\mathcal{H}(@)$, which is obtained by dropping in addition the state variables and the $\downarrow$-binder. In other words, $\mathcal{H}(@)$ is simply the extension of the basic modal language with nominals and satisfaction operators. The languages $\mathcal{H}(@)$ and $\mathcal{H}(@, \downarrow)$ will receive most attention in this chapter.

2 HISTORY

In this section we will provide an overview of the historical development of hybrid languages, starting with the pioneering work of Prior, through the "revival" in the late eighties and early nineties in Sofia, and ending with the work of Blackburn and Seligman in the late nineties.

2.1 The Foundational Work of Prior

The work of Prior in modal logic and in particular in the modal analysis of time is well known, to the point that he is usually regarded as the inventor of temporal logic. For a detailed discussion of Prior's contributions to this field, together with some biographical information, see [111]. The following discussion is based on [51], a short but very good overview. See also [27], especially Section 4.

Prior is considered one of the most important promoters of the application of modal syntax to the formalisation of a wide variety of phenomena. Less well known is the fact that Prior, in collaboration with Carew Meredith, devised a version of possible worlds semantics roughly at the same time as, but independently of, the work of Carnap on modal semantics and several years before Kripke published his first paper on the topic. Interestingly, this part of Prior's work is already closely related to hybrid logic.

Nowadays, the view that modal logic can be seen as a fragment of first-order or second-order logic is commonplace. This is fairly straightforwards once we observe the possible worlds semantics of modal operators. When reading the earlier work of Prior, however, we should keep in mind that, at that time, most modal intuitions came solely from axiomatics. Nevertheless, in Prior's (unpublished) second book "The Craft of Formal Logic" (completed in 1951) we can find the following passage:

> For the similarity in behaviour between signs of modality and signs of quantity, various explanations may be offered. It may be, for example, that signs of modality are just ordinary quantifiers operating upon a peculiar subject-matter, namely possible states of affairs. . . It would not be quite accurate to describe theories of this

> sort as "reducing modality to quantity." They do reduce modal *distinctions* to distinctions of quantity, but the variables to which the quantifiers are attached retain something modal in their signification — they signify "possibilities", "chances", "possible states of affairs", "possible combinations of truth-values", or the like.

Two things should be noticed in this passage. Firstly, the reference to "possible states of affairs" and even "possible combinations of truth-values," is a very early reference to possible worlds semantics. Secondly, note Prior's strong reservations concerning "reducing modality to quantity". This early intuition on the foundational nature of modality later grew into a mature philosophy in Prior's view that quantification over possible worlds and instants was to be interpreted in terms of modality and tense — which constituted primitive notions — and not vice versa (although he did recognized that the study of both quantity and modality could benefit of each other).

Three years later, in 1954 at the New Zealand Congress of Philosophy, Prior presented a paper (not published until much later as [116]) in which his philosophical position is made more explicit. Working already in the framework of temporal logic, he introduces in this paper the I-calculus (which he will later call the U-calculus). In the I-calculus, propositions of the tense calculus are treated as predicates expressing properties of dates (which are represented by variables). The formula px should be read as "p at x," and I is a binary relation taking dates as arguments where Ixy is read as "y is later than x." Using an arbitrary date x to represent the time of utterance, Fp (intuitively, "the proposition p happens in the future") is equated with $\exists y.(Ixy \wedge py)$ (i.e., "p at some time later than x") and similarly for Pp, "the proposition p happens in the past." Prior mentions already that, by imposing various conditions on the relation I, analogues of the axioms of the tense calculus can be derived in the I-calculus.

Later in the same paper, Prior includes a detailed warning against regarding this interpretation of the tense calculus within the I-calculus as "a metaphysical explanation of what we mean by *is*, *has been* and *will be*"; he stresses that the I-calculus is not "metaphysically fundamental." He explains that F(Socrates is sitting down) means "It is *now* the case that it will be the case that Socrates is sitting down," and there is no genuine way of representing the indexical *now* in the I-calculus (he says that the free variable x is "a complete sham"). He continues: "If there is to be any 'interpretation' of our calculi in the metaphysical sense, it will probably need to be the other way round; that is, the I-calculus should be exhibited as a logical construction out of the PF-calculus rather than *vice versa*." This idea of the primacy of the tense calculus over the I-calculus — or, as he was later to put it, of McTaggart's A-series over the B-series, see [109] — was to become a central and distinctive tenet of his philosophy. These issues form the theme of his final, unfinished, book [119], but they already appear in some earlier articles.

But of course, the reconstruction of the I-calculus within the tense calculus is impossible, as the I-calculus is strictly more expressive than the tense calculus. Prior recognized this fact and investigated ways to extend the expressive power of the tense calculus to permit the reconstruction. This directly led to what we call today *very expressive hybrid languages* (i.e., hybrid languages including the $\forall$ binder). In [117, Chapter V.6], he actually proposes a way to develop the I-calculus inside the tense calculus, and for this he allows instant variables to be used together with propositional variables. He will call this step "the third grade of tense-logical involvement" in [118, Chapter XI], where instant variables are treated as representing (special) propositions.

We see, then, that Prior's development of hybrid languages was rooted in his philosophical convictions, and was instrumental in the implementation of some of his very early intuitions on time and tense. Prior's death in 1969 put an end to these investigations. Notice though, that Prior was never fully satisfied with his solution. It was technically correct (and actually quite bold and ingenious) but he was concerned that, in managing to "upgrade" the tense calculus to full

first-order expressivity, the language had lost its claim to a metaphysical fundamentality. Robert Bull, a student of Prior, pushed the ideas of hybridization further in [46], where he provides an axiomatization and completeness result for a logic containing variables for *paths* on a model, which he calls "history-propositional" variables.

2.2 The Sofia School

As we saw, the roots of hybrid logic go back to Prior and Bull. About fifteen years later in Sofia, Bulgaria, nominals were re-discovered by Gargov, Passy and Tinchev in their investigations on Boolean modal logic and propositional dynamic logic. One of the issues that led them into these investigations was the following asymmetry in the expressive power of the modal language. The union of two accessibility relations is definable in the basic modal language, in the sense that the formula

$$\langle T\rangle p \leftrightarrow \langle R\rangle p \vee \langle S\rangle p$$

is valid on a frame precisely if the accessibility relation interpreting $\langle T\rangle$ is the union of the accessibility relations interpreting $\langle R\rangle$ and $\langle S\rangle$. Moreover, when added to the basic modal language, this formula completely axiomatizes the modal logic of the relevant class of frames.

Surprisingly, *intersection* of accessibility relations is not definable in the same way: it follows from the Goldblatt-Thomason theorem [76] that there is no formula in the basic modal language that is valid on a frame precisely if the accessibility relation of $\langle T\rangle$ is the intersection of the accessibility relation of $\langle R\rangle$ and $\langle S\rangle$. And even though the axiom scheme $\langle T\rangle p \rightarrow (\langle R\rangle p \wedge \langle S\rangle p)$ (together with the standard axioms and rules for the basic polymodal logic) completely axiomatizes the logic of this frame class, it is valid on the larger class where the accessibility relation of $\langle T\rangle$ is contained in the intersection of the accessibility relation of $\langle R\rangle$ and $\langle S\rangle$.

Now, Gargov, Passy and Tinchev showed in [74] that intersection *can* be defined using *nominals*. Indeed, for i a nominal, the axiom scheme

$$\langle T\rangle i \leftrightarrow \langle R\rangle i \wedge \langle S\rangle i$$

defines intersection in the above sense, and exactly axiomatizes the logic of the relevant class of frames (when added to an appropriate base axiomatization)[1]. The same story goes for complementation: there is no formula of the basic modal language that is valid on a frame precisely if the accessibility relation of $\langle R\rangle$ is the complement of the accessibility relation of S, but such a formula exists when nominals are added to the language: $\langle R\rangle i \leftrightarrow \neg\langle S\rangle i$.

This form of capturing the Boolean operations (together with an alternative based on the "sufficiency operator" $\boxminus$) was investigated by Gargov, Passy and Tinchev in [74]. In that paper, the first complete axiomatization of the minimal hybrid language is given. Following [75], recursively define $\Box$- and $\Diamond$-forms as follows: 1) \$ is both a $\Box$- and a $\Diamond$-form (where \$ is a fixed symbol not occurring in the language); 2) If L is a $\Box$-form and φ a formula, then $(\varphi \rightarrow L)$ and $\Box L$ are also $\Box$-forms; and 3) If M is a $\Diamond$-form and φ is a formula, then $(\varphi \wedge M)$ and $(\Diamond M)$ are also $\Diamond$-forms. For F a $\Box$- or $\Diamond$-form and φ a formula, let $F(\varphi)$ be the formula obtained by replacing the unique occurrence of \$ in F by φ. Now, Gargov, Passy and Tinchev showed that any complete axiomatization of the basic modal language, extended with the axioms

$$M(i \wedge \varphi) \rightarrow L(i \rightarrow \varphi) \quad \text{for } i \text{ a nominal, } L \text{ a } \Box\text{-form and } M \text{ a } \Diamond\text{-form}$$

completely axiomatizes the hybrid logic (in the language $\mathcal{H}$) of the class of all frames.

[1] Note that this implies that the Goldblatt-Thomason theorem, in its usual form, does not hold for hybrid languages.

Axiom Schemes:

(A0)	All propositional tautologies
(A1)	$\langle\nu\rangle i$
(A2)	$\langle\nu\rangle(i \wedge \varphi) \to [\nu](i \to \varphi)$
(A3)	$\varphi \to \langle\nu\rangle\varphi$
(A4)	$\langle\nu\rangle\langle\nu\rangle\varphi \to \langle\nu\rangle\varphi$
(A5)	$\varphi \to [\nu]\langle\nu\rangle\varphi$
(A6)	$\langle\alpha\rangle\varphi \to \langle\nu\rangle\varphi$
(A7)	$\langle\alpha\beta\rangle\varphi \to \langle\alpha\rangle\langle\beta\rangle\varphi$
(A8)	$\langle\alpha \cup \beta\rangle i \leftrightarrow \langle\alpha\rangle i \vee \langle\beta\rangle i$
(A9)	$\langle\alpha \cap \beta\rangle i \leftrightarrow \langle\alpha\rangle i \wedge \langle\beta\rangle i$
(A10)	$\langle\bar{\alpha}\rangle i \leftrightarrow [\alpha]\neg i$
(A11)	$\alpha \subset \beta \leftrightarrow [\alpha \cap \bar{\beta}]\bot$
(A12)	$\langle\nu\rangle(i \wedge \langle\alpha^{-1}\rangle j) \leftrightarrow \langle\nu\rangle(j \wedge \langle\alpha\rangle i)$
(A13)	$\langle\varphi?\rangle\psi \leftrightarrow \varphi \wedge \psi$
(A14)	$\langle\alpha^*\rangle\varphi \leftrightarrow \varphi \vee \langle\alpha\rangle\langle\alpha^*\rangle\varphi$
(A15)	$[\alpha](\varphi \to \psi) \to ([\alpha]\varphi \to [\alpha]\psi)$

Rules:

(R1)	If $\vdash [\alpha]\neg i$ for some i not in α, then $\vdash [\alpha]\bot$.
(R2)	If $\vdash [\beta][\alpha^n]\varphi$ for all $n \in \mathbb{N}$, then $\vdash [\beta][\alpha^*]\varphi$.
(R3)	If $\vdash \varphi$, then $\vdash [\nu]\varphi$.
(R4)	If $\vdash \varphi$ and $\vdash \varphi \to \psi$, then $\vdash \psi$

Where φ, ψ are formulas, α, β programs, ν the universal program and i, j nominals.

Figure 1. Axiomatization of CPDL$(\cap, ^-, \subset, ^{-1})$

Besides the minimal hybrid language $\mathcal{H}$, Gargov, Passy and Tinchev also studied a richer hybrid language, obtained by extending propositional dynamic logic (PDL, cf. Chapter 12 of this handbook) with nominals. Intersection of accessibility relations is particularly interesting in this setting, as it can be interpreted as parallelism, or concurrency of programs. Passy and Tinchev [113] propose an extension of PDL with nominals and the universal modality, which they call Combinatory PDL (CPDL). The paper contains an axiomatization of CPDL$(\cap, ^-, \subset, ^{-1})$, combinatory PDL extended with program intersection, complementation, subprograms and inverse, shown in Figure 1. Note that this axiomatization contains an infinitary rule (R2), i.e., an inference rule with infinitely many premises.

Besides the standard axioms and rules of PDL, and the axioms for the universal program ν, notice the definitions of union (A8), intersection (A9), complement (A10), subprogram (A11) and inverse program (A12). Notice also how the presence of the universal program ν helps defining the behaviour of nominals in axioms (A1) and (A2). Finally, notice the "Gabbay-Burgess-style rule" (R1) [67], which ensures that models are named, i.e., each state in the model is the denotation of some nominal (this also implies that models are countable). Axiomatizations for sublanguages of CPDL$(\cap, ^-, \subset, ^{-1})$ are obtained by dropping the corresponding definitions of the absent operators. In particular CPDL, "core" combinatory PDL, is axiomatized by axioms

(A1) to (A8), (A13) to (A15) and rules (R1) to (R4)[2].

Passy and Tinchev proved a number of interesting properties of CPDL (see [115] for further details). For example, they observed that named models (i.e., models in which each state is named by a nominal) can be completely described by a set of formulas of the form $(\neg)@_i p$, $(\neg)@_i\Diamond j$ or $(\neg)@_i j$. Clearly, this property only depends on the expressive power of nominals and @, and hence holds already for $\mathcal{H}(@)$. This observation provides the theoretical basis for automated theorem proving and model building via the definition of Herbrand models (i.e., a model can be represented by the set of elementary formulas which are true in it, see [17]).

With respect to (un)decidability results, naturally the negative results concerning the undecidability of both global and local consequence in PDL [85] transfers to CPDL. Passy and Tinchev provide some (un)decidability results for satisfiability of languages related to CPDL in [115], while Gargov provides in [71] a finitary axiomatization of CPDL and proves the finite model property and decidability of the satisfiability problem for CPDL. Actually, the complexity of satisfiability in CPDL coincides with the one in PDL, EXPTIME-complete [56, 55].

THEOREM 3. *For $\Gamma \cup \{\varphi\}$ a decidable set of CPDL formulas, deciding whether $\Gamma \models^{glo} \varphi$ and $\Gamma \models^{loc} \varphi$ is Π^1_1-complete. On the other hand, satisfiability of CPDL formulas is* EXPTIME-*complete.*

Gargov's axiomatizability result mentioned above uses Segerberg's axiom $\varphi\wedge[\alpha^*](\varphi \to [\alpha]\varphi) \to [\alpha^*]\varphi$ to replace the (R2) rule and shows that the (R1) rule is redundant, but infinitary rules cannot always be eliminated. For example, satisfiability of CPDL($^-$) is highly undecidable (Σ^1_1-complete) from which it follows that no finitary axiomatization can be complete. Passy and Tinchev [115] discuss the issue of eliminability of the infinitary rules in detail (cf. also [98] for more recent results on infinitary axiomatizations of hybrid logics).

We now move into more expressive hybrid languages similar to those used by Prior and Bull. Chapter III of [115] is devoted to CDL, Combinatory Dynamic Logic which allows quantification over state variables. Interestingly, the authors seem to present CDL as an alternative to quantified modal logic, stating that replacing classical quantification (over the domains in each state of the model) by hybrid quantification (over the states themselves) leads to a better behaved system. While this is true, it also leads to a system which does not resemble quantified modal logic! In any case, it is interesting to see that, once nominals have been discovered, explicit quantification over states becomes a natural extension.

The following complete axiomatization of CDL is given in [115]:

	All axioms and rules of CPDL minus (R1), plus
(A16)	$\exists c.c$
(A17)	$\forall c.\varphi \to \varphi[c/d]$
(A18)	$\forall c.[\alpha]\varphi \to [\alpha]\forall c.\varphi$ for c with no free occurrences in α.
(R5)	If $\vdash \varphi$, then $\vdash \forall c.\varphi$.

The Sofia tradition in hybrid logics continues with the work of Goranko. In [72], Gargov and Goranko investigate the basic modal language extended first with nominals and the universal and existential modalities ($\mathcal{H}(\mathsf{E})$), and then with the difference operator D ($\mathcal{ML}(\mathsf{D})$)[3]. They prove that both languages are equivalent with respect to frame definability, and then provide characterizations of frame definability for these languages.

[2] Actually, in [115], the infinitary version of (R1) "If $\vdash [\alpha]\neg i$ for all $i \in \mathsf{NOM}$ then $\vdash [\alpha]\bot$" is discussed, which is necessary for completeness in some extensions of CPDL.

[3] The semantic condition for the difference operator D is $\mathcal{M}, w \models \mathsf{D}\varphi$ iff there is a $w' \neq w$ such that $\mathcal{M}, w' \models \varphi$.

The work of Gargov and Goranko is historically relevant because, within the Sofia school, it marks the start of research on hybrid logics as such, and not as part of their research on extensions of PDL. Around the same time, but independently, Blackburn was studying simple hybrid languages over a Prior-style tense logic [21, 22]. These two lines of research can be considered the origins of the current perspective on hybrid logics.

Goranko is also the first to investigate the $\downarrow$ binder in the context of hybrid logic. In [77], he extends the basic modal language with the universal modality and the $\downarrow$ binder with only a single state variable (though using a slightly different notation). Goranko provides an axiomatization for this logic, and illustrations of its high expressivity (sufficient, for example, to define Kamp's $U(p, q)$ and $S(p, q)$ and Stavi's $U'(p, q)$ and $S'(p, q)$ temporal operators and to simulate Prior's instant variables), and shows that the satisfiability problem for this language is undecidable. He mentions in the same paper that introducing multiple state variables would be possible, and investigates the resulting language in more detail in [78].

In [79], Goranko uses hybrid binders to design CTL$_{rp}$ (CTL with reference pointers), a computation tree logic for finitely branching ω^+-trees, and defines syntactic and semantic interpretations between CTL* and CTL$_{rp}$. In particular, this yields a complete axiomatization for the translations of all valid CTL*-formulas, a step forwards in the search for a complete direct axiomatization of CTL*, a long standing open problem finally solved in [121].

With this we conclude our (necessarily brief) overview of the work on hybrid logics done by the Sofia School. It is interesting to note that most of the languages studied by the Sofia school included the universal modality. In the following years and mainly through the work of Blackburn and Seligman, research in hybrid languages deals with, on the one hand, weak languages containing only nominals (e.g., [23, 33]) and, on the other hand, very expressive languages containing binders (e.g., [31, 35, 37]).

2.3 Very Expressive Hybrid Languages

In the mid-nineties, Blackburn and Seligman [31] studied a number of very expressive hybrid languages, obtained by means of various state variable binders. We will review a few of these binders here, most of which will not return in the remainder of the chapter.

Up to now, we have introduced two hybrid binders, the "classical" $\exists$ and the "more modal" $\downarrow$. Let us review their semantic definitions. Given a model $\mathcal{M} = \langle M, (R^{\mathcal{M}})_{R \in \mathsf{REL}}, V\rangle$, an assignment g in $\mathcal{M}$ and $m \in M$:

$$\begin{array}{lll} \mathcal{M}, g, m \models \exists x.\varphi & \text{iff} & \mathcal{M}, g^x_{m'}, m \models \varphi \text{ for some } m' \in M. \\ \mathcal{M}, g, m \models \downarrow x.\varphi & \text{iff} & \mathcal{M}, g^x_m, m \models \varphi. \end{array}$$

Both quantifiers let us change the value assigned to x, without changing the point of evaluation. In [31] Blackburn and Seligman investigate two other binders which, besides changing the value of the bound variable, also change the point of evaluation:

$$\begin{array}{lll} \mathcal{M}, g, m \models \Sigma x.\varphi & \text{iff} & \mathcal{M}, g^x_{m'}, m' \models \varphi \text{ for some } m' \in M. \\ \mathcal{M}, g, m \models \Downarrow x.\varphi & \text{iff} & \mathcal{M}, g^x_m, m' \models \varphi \text{ for some } m' \in M. \end{array}$$

It is not hard to see that $\Sigma x.\varphi$ is equivalent to $\mathsf{E}{\downarrow} x.\varphi$, whereas $\Downarrow x.\varphi$ is equivalent to ${\downarrow} x.\mathsf{E}\varphi$. The Standard Translation (cf. Chapter 1 of this handbook) may be extended to these hybrid languages, in which case the appropriate clauses for these operators would be as follows (we provide also

the clause for E for comparison):

$$
\begin{array}{lcl}
ST_x(\mathsf{E}\varphi) & = & \exists z.ST_z(\varphi) \quad (z \text{ a variable not in } \varphi) \\
ST_x(\exists y.\varphi) & = & \exists y.ST_x(\varphi) \\
ST_x(\downarrow y.\varphi) & = & \exists y.(y = x \wedge ST_x(\varphi)) \\
ST_x(\Sigma y.\varphi) & = & \exists y.ST_y(\varphi) \\
ST_x(\Downarrow y.\varphi) & = & \exists z.\exists y.(y = x \wedge ST_z(\varphi)) \quad (z \text{ a variable not in } \varphi).
\end{array}
$$

The main result in [31] is that these binders form an expressive hierarchy. If we let $<$ stand for the relation "is strictly less expressive than" then we have that $\mathcal{H}(\downarrow) < \mathcal{H}(\exists) < \mathcal{H}(\Downarrow)$ and $\mathcal{H}(\mathsf{E}) < \mathcal{H}(\Sigma) < \mathcal{H}(\Downarrow)$. The expressivity inclusions are proved using the following equivalences:

$$
\begin{array}{lcl}
\downarrow x.\varphi & \equiv & \exists x.(x \wedge \varphi) \\
\exists x.\varphi & \equiv & \Downarrow z.\Downarrow x.(z \wedge \varphi) \quad (z \text{ a variable not in } \varphi) \\
\mathsf{E}\varphi & \equiv & \Sigma z.\varphi \quad (z \text{ a variable not in } \varphi) \\
\Sigma x.\varphi & \equiv & \Downarrow z.\Downarrow x.(x \wedge \varphi) \quad (z \text{ a variable not in } \varphi).
\end{array}
$$

Moreover, the equivalence $\Downarrow x.\varphi \equiv \downarrow x.\mathsf{E}\varphi$ shows that $\mathcal{H}(\Downarrow) \leq \mathcal{H}(\downarrow, \mathsf{E})$ and hence any language containing an operator from each of the two "branches" in the hierarchy is expressively equivalent to $\mathcal{H}(\Downarrow)$. The strictness of the hierarchy is proved in [31] using different variants of bisimulations, preserving truth of formulas of the various languages. This paper also introduced so-called spypoint arguments, and used them to show that basic hybrid languages enriched with $\downarrow$ lack the finite model property and are undecidable. Spypoint arguments were later used to show a number of complexity and undecidability results in hybrid logic (see, in particular, [8]).

In [141, 142], Tzakova explores some examples of very expressive hybrid languages with binding operators in more detail, both axiomatically and by means of tableaux systems.

We turn now from motivation and historical remarks to recent developments and the current state of the field.

3 MODEL THEORY

Many different hybrid languages were introduced in the previous sections. In this section, we will discuss two languages in more detail, namely $\mathcal{H}(@)$ and $\mathcal{H}(@, \downarrow)$. These two hybrid languages have received most attention in recent literature, and the proofs of the results we will discuss can usually be adapted to other hybrid languages.

3.1 Completeness

One of the most important motivations for the study of hybrid logics has been that the addition of nominals to the modal language makes it possible to prove very general completeness results, using a straightforward adaptation of the Henkin construction for first-order logic.

DEFINITION 4. The logic $\mathbf{K}_{\mathcal{H}(@,\downarrow)}$ is the smallest set of $\mathcal{H}(@, \downarrow)$ formulas that includes all axioms, and is closed under the rules, given in Figure 2. Given a set Σ of $\mathcal{H}(@, \downarrow)$ formulas, $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$ is the logic obtained by adding all formulas in Σ as axioms to $\mathbf{K}_{\mathcal{H}(@,\downarrow)}$, and closing again under the rules in Figure 2. Given a set of $\mathcal{H}(@)$-formulas Σ, $\mathbf{K}_{\mathcal{H}(@)}$ and $\mathbf{K}_{\mathcal{H}(@)} + \Sigma$ are defined analogous to $\mathbf{K}_{\mathcal{H}(@,\downarrow)}$ and $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$, except without the DA axiom scheme (note that this is the only axiom or rule in which $\downarrow$ occurs).

Axioms:	
(CT)	All classical tautologies
($K_\Box$)	$\vdash [R](\varphi \to \psi) \to [R]\varphi \to [R]\psi$
($K_@$)	$\vdash @_i(\varphi \to \psi) \to @_i\varphi \to @_i\psi$
(Selfdual$_@$)	$\vdash @_i\varphi \leftrightarrow \neg @_i \neg\varphi$
(Ref$_@$)	$\vdash @_i i$
(Agree)	$\vdash @_i @_j \varphi \leftrightarrow @_j\varphi$
(Intro)	$\vdash i \to (\varphi \leftrightarrow @_i\varphi)$
(Back)	$\vdash \langle R\rangle @_i\varphi \to @_i\varphi$
(DA)	$\vdash @_i(\downarrow x.\varphi \leftrightarrow \varphi[x/i])$
Rules:	
(MP)	If $\vdash \varphi$ and $\vdash \varphi \to \psi$ then $\vdash \psi$
(Subst)	If $\vdash \varphi$ then $\vdash \varphi^\sigma$, for σ a substitution
(Gen$_@$)	If $\vdash \varphi$ then $\vdash @_i\varphi$
(Gen$_\Box$)	If $\vdash \varphi$ then $\vdash [R]\varphi$
(Name)	If $\vdash @_i\varphi$ and i does not occur in φ, then $\vdash \varphi$
(BG)	If $\vdash @_i\langle R\rangle j \to @_j\varphi$, $j \neq i$ and j does not occur in φ, then $\vdash @_i[R]\varphi$

Figure 2. Axioms and rules for $\mathbf{K}_{\mathcal{H}(@,\downarrow)}$

One note should be made, concerning the substitution rule (Subst). By this rule, one cannot only replace propositional variables uniformly by arbitrary formulas, but one can also replace nominals uniformly by other nominals (note that substituting nominals by formulas does not preserve validity in general).

We call an axiomatization *complete* with respect to a class of frames, if for all formulas φ of the relevant language, φ is derivable in the axiomatization iff φ is valid on the given frame class. An axiomatization is *strongly complete* with respect to a frame class if for every set of formulas Σ and formula φ of the relevant language, $\Sigma \models^{loc} \varphi$ iff there are $\psi_1, \ldots, \psi_n \in \Sigma$ such that $\psi_1 \wedge \cdots \wedge \psi_n \to \varphi$ is derivable.

The following completeness result is taken from [34], but slight variations of it can be found already in [37]. Recall that a formula is *pure* if it contains no propositional variables (but may possibly contain nominals).

THEOREM 5 (Pure completeness).

1. *Let Σ be any set of pure $\mathcal{H}(@)$-formulas. Then $\mathbf{K}_{\mathcal{H}(@)} + \Sigma$ is strongly complete for the class of frames defined by Σ.*

2. *Let Σ be any set of pure $\mathcal{H}(@,\downarrow)$-formulas. Then $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$ is strongly complete for the class of frames defined by Σ.*

By *the frame class defined by* Σ, we mean the class of frames on which each formula in Σ is valid. Many frame properties can be defined using pure hybrid formulas, including properties such as irreflexivity, that cannot be defined in the basic modal language. A precise characterization of frame properties definable by pure formulas will be given in Section 3.2.

The proof of Theorem 5 trades heavily on the presence of the (Name) and (BG) rules. In [34], Blackburn and ten Cate show that, in the case of $\mathcal{H}(@,\downarrow)$, these rules (which are non-orthodox

in the sense that they involve syntactic side conditions) can be replaced by

(Name$_\downarrow$)	$\vdash \downarrow s.(s \to \varphi) \to \varphi$	provided that s does not occur in φ
(BG$_\downarrow$)	$\vdash @_i[R]\downarrow s.@_i\langle R\rangle s$	
(Gen$_\downarrow$)	If $\vdash \varphi$ then $\vdash \downarrow s.\varphi$.	

and an axiomatization with only orthodox rules is obtained, for which Theorem 5 still holds. In the case of $\mathcal{H}(@)$, on the other hand, the (Name) and (BG) rule cannot be eliminated. More precisely, every axiomatization for $\mathcal{H}(@)$ that is complete for arbitrary pure extensions contains either infinitely many rules or rules with side conditions [34].

Part of the present section will be devoted to a proof of Theorem 5. However, before we start, we will mention some other, complementary completeness results.

Theorem 5 resembles in spirit the Sahlqvist completeness theorem for modal logic (cf. Chapter 1 of this handbook). This raises the question of how pure formulas and Sahlqvist formulas relate, both in terms of expressive power and in terms of proof theoretic behaviour. As it turns out, for every modal Sahlqvist formula φ there is a pure sentence ψ of $\mathcal{H}(@,\downarrow)$ that defines the same frame class as φ, and, moreover, ψ can be picked such that $\varphi \to \psi$ is provable in $\mathbf{K}_{\mathcal{H}(@,\downarrow)}$[4]. It follows from this observation that every extension of $\mathbf{K}_{\mathcal{H}(@,\downarrow)}$ with modal Sahlqvist axioms is complete.

However, there are frame properties that can be defined by modal Sahlqvist formulas but not by pure $\mathcal{H}(@)$-formulas. For example, no set of pure $\mathcal{H}(@)$-formulas defines the same frame class as the modal Sahlqvist formula (CR) $\Diamond\Box p \to \Box\Diamond p$. This makes the following result, proved in [140], interesting.

THEOREM 6 (Sahlqvist completeness). *Let Σ be any set of modal Sahlqvist formulas. Then $\mathbf{K}_{\mathcal{H}(@)} + \Sigma$ is strongly complete for the class of frames defined by Σ.*

Completeness does not hold for arbitrary combinations of pure formulas and modal Sahlqvist formulas. Consider the Sahlqvist axiom (CR) given above and the pure formula (NoGrid) $\Diamond(i \wedge \Diamond j) \to \Box(\Diamond j \to i)$. The incompleteness of $\mathbf{K}_{\mathcal{H}(@)} + \{\text{(CR)}, \text{(NoGrid)}\}$ is proved in [140] using a general frame argument.

It should be noted that, when converse modalities are added to the language (as in the basic tense logic), modal Sahlqvist formulas *can* be translated into pure $\mathcal{H}(@)$ formulas. And, indeed, in this case axiomatizations combining pure formulas and modal Sahlqvist formulas are always strongly complete for the relevant frame class [80, 136].

There are a number of well known complete modal logics that cannot be axiomatized by means of Sahlqvist formulas, including PDL, GL and Grz. One might ask what happens when nominals and satisfaction operators are added to these logics. The following result, proved in [20, 136], provides a partial answer. It shows that, under certain condition, a complete axiomatization of a modal logic can be turned into a complete axiomatization of the corresponding hybrid logic (in the language $\mathcal{H}(@)$). Recall that a modal logic *has a master modality* if there is a modality $[*]$ that satisfies the S4 axioms, such that $[*]p \to [R]p$ is derivable for all other modalities $[R]$ in the language (see also Chapter 2 and 4 of this handbook). Furthermore, recall the notion of *admitting filtration* defined in Chapter 3 of this handbook. Informally, a logic defined over a class of frames K admits filtration if each formula φ can be associated with a set of formulas Σ_φ (the "filtration

[4] This essentially follows from the proof by substitutions of the Sahlqvist correspondence theorem (cf. Chapter 1 of this handbook), since the substitutions used only involve a bounded form of quantification. See Section 3.2 for more information on the tight relationship between bounded quantification and $\mathcal{H}(@,\downarrow)$.

set" of φ) such that for each model $\mathcal{M}$ based on a frame in K, and for each formula φ, there is a filtration of $\mathcal{M}$ over Σ_φ of which the underlying frame is in K.

THEOREM 7. *Let Σ be any set of modal formulas such that the modal logic $\mathbf{K}+\Sigma$ is complete, admits filtration and has a master modality. Then $\mathbf{K}_{\mathcal{H}(@)}+\Sigma$ is also complete.*

GL, Grz and PDL all meet the requirements of Theorem 7. Incidentally, a similar transfer result cannot exist for $\mathcal{H}(@,\downarrow)$. Indeed, the $\mathcal{H}(@,\downarrow)$-logic of the frame class defined by GL (i.e., the class of transitive and conversely well-founded frames) is not recursively axiomatizable [136].

We now prove Theorem 5 using a technique similar to that used in a standard, Henkin-style completeness proof for first-order logic [58]. The general argument runs as follows: we will show that every consistent set of formulas can be extended to a maximal consistent set satisfying certain properties. Next, we will construct out of each such maximal consistent set a model, whose domain consists of equivalence classes of nominals. Finally, we show that the constructed model satisfies the original set of formulas, and that the underlying frame satisfies the relevant frame conditions.

The proof of the following lemma is straightforward.

LEMMA 8. *The following formulas and rule are derivable in $\mathbf{K}_{\mathcal{H}(@)}+\Sigma$.*

1. $\vdash @_j k \to (@_j\psi \leftrightarrow @_k\psi)$
2. $\vdash @_j(\psi_1 \wedge \psi_2) \leftrightarrow @_j\psi_1 \wedge @_j\psi_2$
3. $\vdash @_j\neg\psi \leftrightarrow \neg @_j\psi$
4. $\vdash @_j @_k\psi \leftrightarrow @_k\psi$
5. $\vdash @_j\langle R\rangle k \wedge @_k\psi \to @_j\langle R\rangle\psi$
6. *If* $\vdash @_i\langle R\rangle j \wedge @_j\varphi \to \psi$ *then* $\vdash @_i\langle R\rangle\varphi \to \psi$, *provided* $i \neq j$ *and* j *does not occur in* φ *or* ψ.

We can now prove a Lindenbaum Lemma that shows how to extend any consistent set of formulas to a maximally consistent set, but in addition we will ensure that all diamonds are "witnessed" by nominals.

LEMMA 9. *Every $\mathbf{K}_{\mathcal{H}(@,\downarrow)}+\Sigma$-consistent set Γ can be extended to a maximal $\mathbf{K}_{\mathcal{H}(@,\downarrow)}+\Sigma$-consistent set Γ^+ such that*

1. *One of the elements of Γ^+ is a nominal;*
2. *For all variables x, there is a nominal i such that $@_i x \in \Gamma$.*
3. *For all $@_i\langle R\rangle\varphi \in \Gamma$ there is a nominal j such that $@_i\langle R\rangle j \in \Gamma$ and $@_j\varphi \in \Gamma$.*

Proof. By expanding the language with countably many nominals, we can ensure that there are infinitely many nominals that do not occur in Γ, while preserving consistency of Γ. Let $(i_n)_{n\in\mathbb{N}}$ be an enumeration of the nominals of the extended language, and let $(\varphi_n)_{n\in\mathbb{N}}$ be an enumeration of all $\mathcal{H}(@,\downarrow)$-formulas of the extended language. We will construct Γ^+ as the limit of an infinite sequence $\Gamma^0 \subseteq \Gamma^1 \subseteq \Gamma^2 \subseteq \cdots$.

Let Γ^0 denote the set $\Gamma \cup \{i\} \cup \{@_{j_x} x \mid x \in \mathsf{VAR}\}$, where the new formulas use nominals not in Γ, and the j_x are such that if x and y are different variables then also j_x and j_y are different.

It is easy to see that Γ_0 is consistent. For example, the addition of i cannot cause inconsistency because otherwise there are $\varphi_1, \ldots, \varphi_n \in \Gamma$ such that $\vdash_{\mathbf{K}_{\mathcal{H}(@,\downarrow)}+\Sigma} i \rightarrow \neg(\varphi_1 \wedge \cdots \wedge \varphi_n)$. By the (Gen$_@$) rule and the (K$_@$) axiom, it follows that $\vdash_{\mathbf{K}_{\mathcal{H}(@,\downarrow)}+\Sigma} @_i i \rightarrow @_i\neg(\varphi_1 \wedge \cdots \wedge \varphi_n)$. By the (Ref$_@$) axiom and the (MP) rule, $\vdash_{\mathbf{K}_{\mathcal{H}(@,\downarrow)}+\Sigma} @_i\neg(\varphi_1 \wedge \cdots \wedge \varphi_n)$, and hence, by the (Name) rule, $\vdash_{\mathbf{K}_{\mathcal{H}(@,\downarrow)}+\Sigma} \neg(\varphi_1 \wedge \cdots \wedge \varphi_n)$. But this contradicts the fact that Γ is consistent. The case for the additional $@_{j_x}x$ formulas is similar. Notice that the set Γ^0 satisfies already conditions 1 and 2 in the lemma. We only need to ensure condition 3.

For $k \in \mathbb{N}$, define Γ^{k+1} as follows:

1. $\Gamma^{k+1} = \Gamma^k$ if $\Gamma^k \cup \{\varphi_k\}$ is $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$-inconsistent,
2. otherwise
   (a) $\Gamma^{k+1} = \Gamma^k \cup \{\varphi_k\}$ if φ_k is not of the form $@_i\langle R\rangle\psi$.
   (b) $\Gamma^{k+1} = \Gamma^k \cup \{\varphi_k, @_i\langle R\rangle i_m, @_{i_m}\psi\}$ if φ_k is of the form $@_i\langle R\rangle\psi$, where i_m is the first nominal that does not occur in Γ^k or φ_k.

Each step preserves consistency: if Γ^k is $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$-consistent, then so is Γ^{k+1}. The only non-trivial case is (2.2b), and we will prove that also in this case, consistency is preserved.

Let $\Gamma^k \cup \{\varphi_k\}$ be $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$-consistent, let φ_k be of the form $@_i\langle R\rangle\psi$, and suppose for the sake of contradiction that $\Gamma^{k+1} = \Gamma^k \cup \{\varphi_k, @_i\langle R\rangle i_m, @_{i_m}\psi\}$ is not $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$-consistent. Then there are $\varphi_1, \ldots, \varphi_n \in \Gamma^k$ such that $\vdash_{\mathbf{K}_{\mathcal{H}(@,\downarrow)}+\Sigma} (\varphi_k \wedge @_i\langle R\rangle i_m \wedge @_{i_m}\psi) \rightarrow \neg(\varphi_1 \wedge \cdots \wedge \varphi_n)$. It follows by the last clause of Lemma 8 that $\vdash_{\mathbf{K}_{\mathcal{H}(@,\downarrow)}+\Sigma} \varphi_k \rightarrow \neg(\varphi_1 \wedge \cdots \wedge \varphi_n)$. But this contradicts the fact that $\Gamma^+ \cup \{\varphi_k\}$ is $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$-consistent. We conclude that Γ^k is consistent.

Since $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$-consistency is preserved at each stage, it follows that $\Gamma^+ = \bigcup_{n\in\mathbb{N}} \Gamma^n$ is $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$-consistent. It is easy to see that Γ^+ also satisfies the other requirements in Lemma 9. ❑

We can proceed with the proof of Theorem 5.

Proof of Theorem 5. We first treat the case of $\mathcal{H}(@,\downarrow)$. Let Γ be a $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$ consistent set of $\mathcal{H}(@,\downarrow)$-formulas and Γ^+ a maximal $\mathbf{K}_{\mathcal{H}(@,\downarrow)} + \Sigma$-consistent set of $\mathcal{H}(@,\downarrow)$-formulas extending Γ, satisfying the conditions of Lemma 9. For $i \in \mathsf{NOM}$, let $[i] = \{j \mid @_i j \in \Gamma^+\}$.

Define the hybrid model $\mathcal{M} = \langle W, (R^{\mathcal{M}})_{R\in\mathsf{REL}}, V\rangle$, where $W = \{[i] \mid i$ is a nominal occurring in $\Gamma^+\}$, $R^{\mathcal{M}} = \{([i],[j]) \mid @_i\langle R\rangle j \in \Gamma^+\}$, $V(p) = \{[i] \mid @_i p \in \Gamma^+\}$ and $V(i) = \{[i]\}$. Define the valuation g as $g(x) = [i]$ for $@_i x \in \Gamma^+$. Checking that the model and valuation that we obtain in this way are well defined is simple.

Now, for all $\mathcal{H}(@,\downarrow)$-formulas φ and nominals j, $\mathcal{M}, g, [j] \models \varphi$ iff $@_j\varphi \in \Gamma^+$. This truth lemma can be proved by a straightforward induction on φ, using the properties of Γ^+ and Lemma 8. For the inductive step for formulas of the from $\downarrow x.\psi$, we use the fact that Γ^+ contains all substitution instances of the (DA) axiom.

It follows that $\mathcal{M}, g, [i] \models \Gamma^+$, for $i \in \Gamma^+$ (recall that one of the elements of Γ^+ is a nominal). Since $\mathcal{M}$ is a named model (i.e., every point is named by a nominal) and Γ^+ contains all substitution instances of elements of Σ, all formulas in Σ are valid on the underlying frame of $\mathcal{M}$. We conclude that Γ is satisfiable on the class of frames defined by Σ.

For $\mathbf{K}_{\mathcal{H}(@)} + \Sigma$, the same argument applies. Note that the (DA) axiom was only used in the truth lemma, for the inductive step for formulas of the form $\downarrow x.\varphi$.

In the above completeness proof, the role of the non-orthodox rules (Name) and (BG) is to ensure the existence of a named model. Named models have played a crucial role in the development of the model theory of hybrid languages. As we commented in Section 2.2, they were already used by the Sofia school in their axiomatic investigations for combinatory PDL. They are closely related to the notion of a *discrete general frame*, and with the work of Venema [144] completeness for modal logics containing the difference operator D.

3.2 Expressive Power and Characterization

In this section, we investigate the expressive power of the hybrid languages $\mathcal{H}(@)$ and $\mathcal{H}(@, \downarrow)$, both on the level of models and on the level of frames, and we compare it to the basic modal language and the first-order correspondence language. For further details on the results discussed in this section see [8, 136].

Correspondence language and standard translations

From the point of view of first-order logic, nominals are nothing more than constants: they designate elements of the domain of the model. The first-order correspondence language of hybrid logic is therefore most naturally defined as follows.

DEFINITION 10. The *first-order correspondence language* for hybrid logic is the first-order language with equality that contains a unary predicate P for each propositional variable $p \in \mathsf{PROP}$, a binary relation symbol for each modality $R \in \mathsf{REL}$ and a constant for each nominal $i \in \mathsf{NOM}$.

Any hybrid model $\mathcal{M} = \langle M, (R^{\mathcal{M}})_{R \in \mathsf{REL}}, V\rangle$ can be regarded as a model for the first-order correspondence language. The accessibility relations $R^{\mathcal{M}}$ are used to interpret the binary relation symbols, unary predicates are interpreted as the subsets that V assigns to the corresponding propositional variables, and constants are interpreted as the worlds that the corresponding nominals name. In what follows, we will not distinguish between hybrid models and models for the first-order correspondence language, and we will use the notation $\mathcal{M} = \langle M, (R^{\mathcal{M}})_{R \in \mathsf{REL}}, V\rangle$ for both.

The Standard Translation from modal logic into the first-order correspondence language (cf. Chapter 1 of this handbook) can be extended to hybrid languages. The translation for the hybrid language $\mathcal{H}(\mathsf{E}, @, \downarrow)$ is given in Figure 3 (top part), where $s, t \in \mathsf{NOM} \cup \mathsf{SVAR}$, $p \in \mathsf{PROP}$, and $R \in \mathsf{REL}$. Here, we conveniently identify the state variables of hybrid logic with the variables of the first-order correspondence language.

PROPOSITION 11 (ST preserves truth). *For all hybrid formulas φ, hybrid models $\mathcal{M}$, states $w \in M$ and assignments g, $\mathcal{M}, g, m \models \varphi$ iff $\mathcal{M}, g^x_m \models ST_x(\varphi)$, where x is a variable not occurring in φ.*

As it turns out, there is also a converse translation, mapping formulas of the first-order correspondence language to formulas of $\mathcal{H}(\mathsf{E}, @, \downarrow)$. It is given in the bottom part of Figure 3.

PROPOSITION 12 (HT preserves truth). *Let φ be a formula of the first-order correspondence language. Then for every model $\mathcal{M}$, assignment g and for any state w, $\mathcal{M}, g^x_w \models \varphi$ iff $\mathcal{M}, g, w \models {\downarrow} x.HT(\varphi)$.*

It follows that $\mathcal{H}(\mathsf{E}, @, \downarrow)$ is as expressive as the first-order correspondence language. In fact, the satisfaction operators can be defined in terms of E (namely, $@_i\varphi$ is equivalent to $\mathsf{E}(i \wedge \varphi)$),

$$\begin{array}{lcl}
ST_t(\top) & = & \top \\
ST_t(s) & = & (t = s) \\
ST_t(p) & = & P(t) \\
ST_t(\neg\varphi) & = & \neg ST_t(\varphi) \\
ST_t(\varphi \wedge \psi) & = & ST_t(\varphi) \wedge ST_t(\psi) \\
ST_t(\langle R\rangle\varphi) & = & \exists y.(R(t,y) \wedge ST_y(\varphi)) \\
ST_t(\mathsf{E}\varphi) & = & \exists y.ST_y(\varphi) \\
ST_t(@_s\varphi) & = & ST_s(\varphi) \\
ST_t(\downarrow z.\varphi) & = & \exists z.(z = t \wedge ST_t(\varphi))
\end{array}$$

where y is a variable distinct from the term t and not occurring in φ

$$\begin{array}{lcl}
HT(\top) & = & \top \\
HT(R(s,s')) & = & @_s\langle R\rangle s' \\
HT(P(s)) & = & @_s p \\
HT(s = t) & = & @_s t \\
HT(\neg\varphi) & = & \neg HT(\varphi) \\
HT(\varphi \wedge \psi) & = & HT(\varphi) \wedge HT(\psi) \\
HT(\exists x.\varphi) & = & \mathsf{E}\!\downarrow\! x.HT(\varphi)
\end{array}$$

Figure 3. Standard Translation ST and Hybrid Translation HT

and therefore $\mathcal{H}(\mathsf{E}, \downarrow)$ is already as expressive as the first-order correspondence language[5]. This leaves the question open of what is the range of ST for languages weaker than $\mathcal{H}(\mathsf{E}, @, \downarrow)$, i.e., which formulas of the first-order correspondence language are (equivalent to) translations of formulas of these hybrid languages? We will discuss this issue in the next section.

Characterizing expressivity on models

In this section, we address in detail the question of which formulas of the first-order correspondence language are equivalent to (standard translations of) hybrid formulas.

First, let us generalize the notion of bisimulation to hybrid languages.

DEFINITION 13. Let $\mathcal{M} = \langle M, (R^{\mathcal{M}})_{R\in\mathsf{REL}}, V\rangle$ and $\mathcal{N} = \langle N, (S^{\mathcal{N}})_{S\in\mathsf{REL}}, U\rangle$ be hybrid models. A *hybrid bisimulation between* $\mathcal{M}$ *and* $\mathcal{N}$ is a non-empty binary relation $Z \subseteq M \times N$ such that the following clauses hold

(atom) If $Z(m,n)$, then $m \in V(p)$ iff $n \in U(p)$, for $p \in \mathsf{PROP} \cup \mathsf{NOM}$.

(nom) If $V(i) = \{m\}$ and $U(i) = \{n\}$ then $Z(m,n)$, for $i \in \mathsf{NOM}$.

(forth) If $Z(m,n)$ and $R^{\mathcal{M}}(m,m')$, then there is an $n' \in N$ such that $S^{\mathcal{N}}(n,n')$ and $Z(m',n')$.

(back) If $Z(m,n)$ and $S^{\mathcal{N}}(n,n')$, then there is an $m' \in M$ such that $R^{\mathcal{M}}(m,m')$ and $Z(m',n')$.

A formula $\varphi(x_1,\ldots,x_n)$ of the first-order correspondence language is said to be *invariant for bisimulations* if for all bisimulations Z between hybrid models $\mathcal{M}$ and $\mathcal{N}$ and for all assignments g and h with $Z(g(x_k), h(x_k))$ for $k = 1\ldots n$, it is the case that $\mathcal{M}, g \models \varphi$ iff $\mathcal{N}, h \models \varphi$.

[5] A similar translation can be given for $\mathcal{H}(@, \forall)$, see [32].

THEOREM 14. *A formula φ of the first-order correspondence language with at most one free variable x is equivalent to the standard translation of an $\mathcal{H}(@)$-formula iff φ is invariant under hybrid bisimulations.*

The proof is a straightforward generalization of the one for the basic modal language. As a corollary of Theorem 14, we obtain the following syntactic characterization.

COROLLARY 15. *A formula φ of the first-order correspondence language with at most one free variable x is equivalent to the standard translation of an $\mathcal{H}(@)$-formula iff φ is equivalent to a formula generated by the following recursive definition, where t is a term (constant or variable), c is a constant, and x is a variable distinct from t:*

$$\varphi ::= \top \mid P(t) \mid t = c \mid \neg\varphi \mid \varphi \wedge \psi \mid \exists x.(R(t,x) \wedge \varphi).$$

Proof. One direction of the claim follows from the fact that $ST(\varphi)$ is of the given form, for each $\mathcal{H}(@)$-formula φ. As for the other direction, a straightforward induction shows that every first-order formula of the given form is invariant under hybrid bisimulations, and hence every such formula with at most one free variable is equivalent to (the standard translation of) an $\mathcal{H}(@)$-formula. ❑

Let us now consider the language $\mathcal{H}(@, \downarrow)$. First, we will give a syntactic characterization (see [8] for further details). Call a first-order formula *bounded* if it is built up from atomic formulas using the Boolean connectives and bounded quantification of the form $\exists x.(R(s,x) \wedge \cdot)$ or $\forall x.(R(s,x) \rightarrow \cdot)$, where s is a term distinct from the variable x.

THEOREM 16. *A formula φ of the first-order correspondence language with one free variable is equivalent to the standard translation of a $\mathcal{H}(@, \downarrow)$ sentence iff φ is equivalent to a bounded formula.*

Proof. The standard translation of an $\mathcal{H}(@, \downarrow)$ sentence is always a bounded formula of the correspondence language. Conversely, we can extend the translation HT given in Figure 3 with the following clause for bounded quantification:

$$HT(\exists x.(R(s,x) \wedge \psi)) \;=\; @_s\langle R\rangle{\downarrow}x.HT(\psi).$$

In this way, we obtain, for each bounded formula φ of the first-order correspondence language, an $\mathcal{H}(@, \downarrow)$-formula $HT(\varphi)$. Moreover, a straightforward inductive argument shows that $HT(\varphi)$ is equivalent to φ, in the sense of Proposition 12. Recall that the formula φ in the statement of the Theorem contains at most one free variable x, and let φ' be any bounded formula equivalent to φ. It follows that φ' (and hence φ) is equivalent to $ST_x({\downarrow}x.HT(\varphi'))$. ❑

In other words, $\mathcal{H}(@, \downarrow)$ corresponds to the bounded fragment of first-order logic. By means of the notion of generated submodels, we can semantically characterize this fragment.

DEFINITION 17. Let $\mathcal{M} = \langle M, (R^{\mathcal{M}})_{R\in\mathsf{REL}}, V\rangle$ and $\mathcal{N} = \langle N, (R^{\mathcal{N}})_{R\in\mathsf{REL}}, V'\rangle$ be hybrid models. Then $\mathcal{N}$ is a *generated submodel* of $\mathcal{M}$ if $N \subseteq M$ and for all $w, v \in M$ and for any relation R_i, if $w \in N$ and $R_i(w,v)$ then $v \in N$, while R'_i and V' are the restrictions of R_i and V to N respectively. A formula φ is *invariant for generated submodels* if for all models $\mathcal{M}$, $\mathcal{N}$ such that $\mathcal{N}$ is a generated submodel of $\mathcal{M}$, and for all $\mathcal{N}$-assignments g, $\mathcal{M}, g \models \varphi$ if and only if $\mathcal{N}, g \models \varphi$.

THEOREM 18. *A formula φ of the first-order correspondence language is invariant under generated submodels iff φ is equivalent to a bounded formula.*

Proof. Suppose a first-order formula φ is invariant under generated submodels. For convenience, we assume that φ is a sentence (free variables can be replaced by new constants). Let $c_1, \ldots, c_k$ be the constants and $R_1, \ldots, R_m$ be the binary relations occurring in φ, and let P be a new unary predicate. We will use $R(s,t)$ as a shorthand for $\bigvee_{1 \leq i \leq m} R_i(s,t)$. Then the following holds:

$$\{\forall x.(R^n(c_l, x) \to P(x)) \mid 1 \leq l \leq k \text{ and } n \in \mathbb{N}\} \models \varphi \leftrightarrow \varphi^P,$$

where $R^n(x,y)$ is a shorthand for a bounded formula which expresses that y can be reached from x in exactly n steps along R (i.e., $\exists x_1(R(x,x_1) \wedge \exists x_2(R(x_1,x_2) \wedge \cdots(\cdots \wedge x_n = y)\cdots)))$ and φ^P is the result of relativising all quantifiers in φ by P (that is, $\exists x.\varphi$ becomes $\exists x.(P(x) \wedge \varphi)$ and $\forall x.\varphi$ becomes $\forall x.(P(x) \to \varphi)$). By compactness, it follows that there is an $m \in \mathbb{N}$ such that

$$\forall x.(\Big(\bigvee_{1 \leq l \leq k} R^{\leq m}(c_l, x)\Big) \to P(x)) \models \varphi \leftrightarrow \varphi^P.$$

Let φ' be the result of relativising all quantifiers in φ by the formula $\big(\bigvee_{1 \leq l \leq k}(R^{\leq m}(c_l,x))\big)$. It follows that $\models \varphi \leftrightarrow \varphi'$. Finally, φ' is (modulo some simple syntactic manipulations) a bounded sentence. ❑

This result was first proved in the sixties by Feferman and Kreisel [60, 59], and was independently proved by Areces, Blackburn and Marx [8] in the context of hybrid logic.

For any model $\mathcal{M}$ and world w, let $\mathcal{M}_w$ denote the smallest generated submodel of $\mathcal{M}$ containing w. In fact, it is easy to see that the domain of $\mathcal{M}$ contains precisely those worlds that are reachable in finitely many steps from w or from a world named by a nominal. As a corollary of the above results, we know that $\mathcal{M}, w$ and $\mathcal{M}_w, w$ agree on all sentences of $\mathcal{H}(@, \downarrow)$. If we combine this with the fact that all first-order formulas are invariant under potential isomorphisms, we obtain the following:

PROPOSITION 19. *Let $\mathcal{M}$ and $\mathcal{N}$ be models, with corresponding states w, v. If there is a potential isomorphism between $\mathcal{M}_w$ and $\mathcal{N}_v$ connecting w to v, then $\mathcal{M}, w$ and $\mathcal{N}, v$ agree on all $\mathcal{H}(@, \downarrow)$-sentences.*

While the converse does not hold in general, it does hold on ω-saturated models. This means that "potential isomorphisms between point-generated submodels" capture $\mathcal{H}(@, \downarrow)$-indistinguishability in exactly the same way that potential isomorphisms capture first-order indistinguishability.

Characterizing frame definability

Given a set of hybrid formulas Σ, we say that the *frame class defined by* Σ is the class of frames in which every formula of Σ is valid. We say that a frame class is *elementary* (or *first-order definable*) if it is defined by a first-order sentence, in the language with equality and a relation symbol for each $R \in \mathsf{REL}$. The Goldblatt-Thomasson theorem tells us that an elementary frame class is definable by a set of formulas of the basic modal language iff the class is closed under disjoint unions, generated subframes, and bounded morphic images, and its complement is closed under ultrafilter extensions (see Chapter 5 of this handbook for this result and for a definition of the notions involved). In this section, we discuss analogues of this result for hybrid languages.

Due to the increased expressivity of hybrid languages, frame classes definable by hybrid formulas are in general not closed under disjoint unions or bounded morphic images. For example, the class of irreflexive frames, which is not closed under bounded morphic images, is defined in $\mathcal{H}(@)$ by the formula $i \to \neg\Diamond i$, and the class of frames that have exactly one element, which

is not closed under disjoint unions, is defined by the formula i. Nevertheless, frame classes definable in $\mathcal{H}(@)$ are closed under generated subframes, and their complement is closed under ultrafilter extensions. In fact, a slightly stronger closure condition holds, involving a restricted form of bounded morphisms.

DEFINITION 20. Let $\mathcal{F}$ and $\mathcal{G}$ be frames, and let $\mathfrak{ue}\mathcal{G}$ be an ultrafilter extension of $\mathcal{G}$. $\mathcal{G}$ is an *ultrafilter morphic image* of $\mathcal{F}$ if there is a surjective bounded morphism $f : \mathcal{F} \to \mathfrak{ue}\mathcal{G}$ such that $|f^{-1}(u)| = 1$ for all principal ultrafilters $u \in \mathfrak{ue}\mathcal{G}$.

Note first that whenever $\mathcal{G}$ is an ultrafilter morphic image of a frame $\mathcal{F}$, $\mathfrak{ue}\mathcal{G}$ is a bounded morphic image of $\mathcal{F}$. It follows that the validity of modal formulas is preserved under taking ultrafilter morphic images. Secondly, note that every frame is an ultrafilter morphic image of its ultrafilter extension. Hence, if a property of frames is preserved under ultrafilter morphic images, its complement is preserved under taking ultrafilter extensions.

PROPOSITION 21. *All frame classes definable by a set of $\mathcal{H}(@)$-formulas are closed under taking ultrafilter morphic images.*

Proof. Let φ be an $\mathcal{H}(@)$-formula, let $f : \mathcal{F} \to \mathfrak{ue}\mathcal{G}$ be a surjective ultrafilter morphism, and suppose $\mathcal{G} \not\models \varphi$. We will show that $\mathcal{F} \not\models \varphi$.

Let V be a valuation and w a world such that $\langle \mathcal{G}, V\rangle, w \not\models \varphi$. Define the valuation $V^{\mathfrak{ue}}$ on $\mathfrak{ue}\mathcal{G}$ such that $V^{\mathfrak{ue}}(p) = \{u \mid V(p) \in u\}$ for all propositional variables p and $V^{\mathfrak{ue}}(i) = \{u \mid V(i) \in u\}$ for all nominals i. It is easily seen that $V^{\mathfrak{ue}}$ assigns to each nominal a singleton set consisting of a principal ultrafilter, and hence $V^{\mathfrak{ue}}$ is a well-defined hybrid valuation. Moreover, a standard argument [28, Proposition 2.59] shows that for all worlds v and formulas ψ, $\langle \mathcal{G}, V\rangle, v \models \psi$ iff $\langle \mathfrak{ue}\mathcal{G}, V^{\mathfrak{ue}}\rangle, \pi v \models \psi$, where πv is the principal ultrafilter generated by v. It follows that $\langle \mathfrak{ue}\mathcal{G}, V^{\mathfrak{ue}}\rangle, \pi w \not\models \varphi$.

Next, define the valuation V' for $\mathcal{F}$ such that $V'(p) = \{v \mid f(v) \in V^{\mathfrak{ue}}(p)\}$ for all propositional variables p and $V'(p) = \{v \mid f(v) \in V^{\mathfrak{ue}}(i)\}$ for all nominals i. Since f is injective on principal ultrafilters and nominals denote principal ultrafilters in $\mathfrak{ue}\mathcal{G}$, $V'(i)$ is a singleton for all nominals i, and hence $\langle \mathcal{F}, V'\rangle$ is a well-defined hybrid model. Furthermore, a standard argument shows that (the graph of) f is a hybrid bisimulation between $\mathfrak{ue}\mathcal{G}$ and $\mathcal{F}$. Since f is surjective, there is a $u \in \mathcal{F}$ such that $f(u) = \pi w$. By invariance under hybrid bisimulations, $\langle \mathcal{F}, V'\rangle, u \not\models \varphi$, and hence $\mathcal{F} \not\models \varphi$ ❑

We can strengthen Proposition 21 to the following characterization of frame definability in $\mathcal{H}(@)$ [136].

THEOREM 22. *An elementary class of frames is definable by a set of $\mathcal{H}(@)$ formulas iff it is closed under taking ultrafilter morphic images and generated subframes.*

Proof. The easy direction is already discussed above: every frame class defined by a set of $\mathcal{H}(@)$-formulas is closed under taking ultrafilter morphic images and generated subframes. We will now prove the hard direction. Let K be any elementary frame class closed under taking ultrafilter morphic images and generated subframes, and let $Th(K)$ be the set of $\mathcal{H}(@)$-formulas valid on K. To show that K is $\mathcal{H}(@)$-definable, it suffices to show that $Th(K)$ itself defines K.

Suppose that $\mathcal{F} \models Th(K)$ for some frame $\mathcal{F}$ with domain W. For each subset $A \subseteq W$, introduce a propositional variable p_A, and for each $w \in W$, introduce a nominal i_w[6]. Let Δ be

[6]Technically, this might involve adding uncountably many propositional variables and nominals to the language. However, this will not cause any problems below. Of course, individual formulas can only contain finitely many propositional variables and nominals.

the set consisting of the following formulas, for all $A \subseteq W$, $v \in W$ and $R \in \mathsf{REL}$.

$$\begin{array}{ll} p_{-A} \leftrightarrow \neg p_A & \\ p_{A\cap B} \leftrightarrow p_A \wedge p_B & \\ p_{R^{-1}(A)} \leftrightarrow \langle R \rangle p_A & \text{where } R^{-1}(A) = \{w \in W \mid \exists v \in A \text{ such that } wRv\} \\ i_v \leftrightarrow p_{\{v\}}. & \end{array}$$

Let $\Delta_{\mathcal{F}} = \{@_{i_v}[R_{i_1}]\cdots[R_{i_n}]\delta \mid v \in W, \delta \in \Delta, \text{ and } R_{i_1}, \ldots, R_{i_n} \in \mathsf{REL} \text{ with } n \in \mathbb{N}\}$. Intuitively, $\Delta_{\mathcal{F}}$ provides a full description of the frame $\mathcal{F}$. Clearly, $\Delta_{\mathcal{F}}$ is satisfiable on $\mathcal{F}$ under the natural valuation that sends p_A to A and i_v to $\{v\}$. We claim that $\Delta_{\mathcal{F}}$ is satisfiable on K. By compactness (recall that K is elementary), it suffices to show that every finite conjunction δ of elements of $\Delta_{\mathcal{F}}$ is satisfiable on K. But this follows immediately: δ is satisfiable on $\mathcal{F}$ and $\mathcal{F} \models \mathit{Th}(K)$, hence $\neg\delta \notin \mathit{Th}(K)$, i.e., δ is satisfiable on K.

Let $\langle \mathcal{G}, V \rangle \models \Delta_{\mathcal{F}}$ with $\mathcal{G} \in K$. Since K is closed under generated subframes, we may assume that $\mathcal{G}$ is generated by the set of points that are named by a nominal. It then follows that the model $\langle \mathcal{G}, V \rangle$ globally satisfies Δ. Let $\langle \mathcal{G}^*, V^* \rangle$ be an ω-saturated elementary extension of $\langle \mathcal{G}, V \rangle$ (such elementary extensions are known to exist even in the case of uncountable vocabularies). By elementarity, $\mathcal{G}^* \in K$ and $\langle \mathcal{G}^*, V^* \rangle$ globally satisfies Δ.

It can be shown that $\mathfrak{ue}\mathcal{F}$ is an ultrafilter morphic image of $\mathcal{G}^*$, where the ultrafilter morphism f is given by $f(v) = \{A \subseteq W \mid \langle \mathcal{G}^*, V^* \rangle, v \models p_A\}$. See [136] for further details. Since K is closed under ultrafilter morphic images, we conclude that $\mathcal{F} \in K$. ❑

As we already discussed earlier, there is a particular interest in frame conditions definable by *pure* formulas, since these immediately yield complete axiomatizations. It would be worth having a characterization of the properties of frames that can be defined using pure formulas only. Details for such results can be found in [136], here we only state one theorem.

DEFINITION 23. We say that a bisimulation Z between frames $\mathcal{F} = \langle F, (R^{\mathcal{F}})_{R\in\mathsf{REL}} \rangle$ and $\mathcal{G} = \langle G, (R^{\mathcal{G}})_{R\in\mathsf{REL}} \rangle$ *respects a set X of elements* of $\mathcal{G}$ if for all $x \in X$,

1. $Z(w, x)$ and $Z(v, x)$ implies $w = v$, and

2. $Z(w, x)$ and $Z(w, v)$ implies $v = x$.

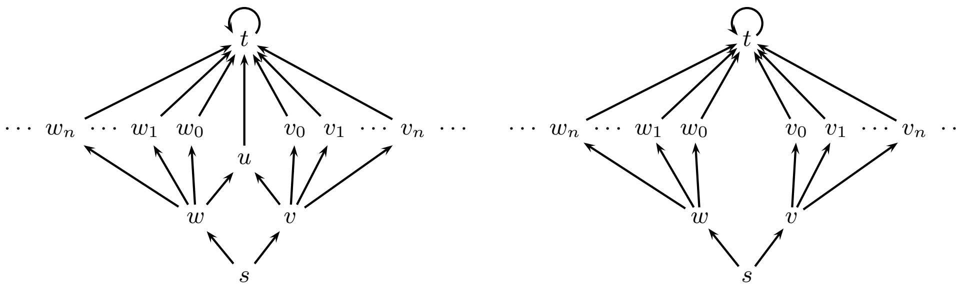
A *bisimulation system* from $\mathcal{F}$ to $\mathcal{G}$ is a function f that assigns to each finite subset $X \subseteq G$ a total bisimulation $f(X) \subseteq F \times G$ respecting X.

THEOREM 24. *A class of frames is defined by a pure $\mathcal{H}(@)$-formula iff it is elementary and closed under taking images of bisimulation systems.*

An example of a frame condition that is not preserved under taking images of bisimulation systems is the Church-Rosser property.

PROPOSITION 25. *The frame condition $\forall xyz.(R(x, y) \wedge R(x, z) \rightarrow \exists u.(R(y, u) \wedge R(z, u)))$ is not preserved under images of bisimulation systems.*

Proof. Consider the two frames $\mathcal{F}_1 = \langle F_1, R^{\mathcal{F}_1} \rangle$ and $\mathcal{F}_2 = \langle F_2, R^{\mathcal{F}_2} \rangle$ shown in Figure 4. Notice that $\mathcal{F}_1$ is identical to $\mathcal{F}_2$, except for the additional point u (and its incoming and outgoing arrows). For any finite set $X \subseteq F_2$, let $f(X) = \{(w, w) \mid w \in F_1\} \cup \{(u, w_k), (u, v_l)\}$, for some $w_k, v_l \notin X$ (note that such w_k and v_l always exist). As is not hard to see, f is a bisimulation system. However, $\mathcal{F}_1$ satisfies the frame condition, while $\mathcal{F}_2$ does not. ❑



$\mathcal{F}_1$ $\mathcal{F}_2$

Figure 4. Church-Rosser is not definable by pure formulas

It follows that the Church-Rosser property cannot be defined by pure formulas of $\mathcal{H}(@)$. A similar example of indefinability is the class of transitive and atomic frames (where *atomicity* means that $\forall x.\exists y.(R(x,y) \wedge \forall z.(R(y,z) \to z = y)))$. This class of frames is defined by the modal formula $(\Diamond\Diamond p \to \Diamond p) \wedge (\Box\Diamond p \to \Diamond\Box p)$, but it cannot be defined by means of pure $\mathcal{H}(@)$-formulas, since it is not closed under images of bisimulation systems.

Finally, let us consider the language $\mathcal{H}(@,\downarrow)$. Interestingly, here the difference in frame definable power between pure formulas and arbitrary formulas is much smaller. In fact, every elementary frame property that can be defined by a set of $\mathcal{H}(@,\downarrow)$-sentences can already be defined by means of a single pure $\mathcal{H}(@,\downarrow)$-sentence. A precise characterization is given in the following theorem.

DEFINITION 26. A frame $\mathcal{F}$ is a *finitely generated subframe* of a frame $\mathcal{G}$, if there is a finite set X of elements of the domain of $\mathcal{G}$, such that $\mathcal{F}$ is the submodel of $\mathcal{G}$ generated by X (i.e., such that $\mathcal{F}$ is the smallest generated submodel of $\mathcal{G}$ whose domain contains all elements of X).

We say that a frame class K *reflects finitely generated subframes* whenever it is the case for all frames $\mathcal{F}$ that, if every finitely generated subframe of $\mathcal{F}$ is in K, then $\mathcal{F} \in K$.

THEOREM 27. *Let K be an elementary frame class. Then the following are equivalent:*

1. *K is defined by a set of $\mathcal{H}(@,\downarrow)$ sentences.*
2. *K is defined by a single pure $\mathcal{H}(@,\downarrow)$ sentence.*
3. *K is closed under taking generated subframes, and reflects finitely generated subframes.*

This result can be extended to formulas containing only a limited number of nominals: let us say that a frame class K reflects n-point generated subframes whenever it is the case for all frames $\mathcal{F}$ that, if every subframe of $\mathcal{F}$ generated by at most n elements is in K, then $\mathcal{F} \in K$. Then Theorem 27 can be refined to the following result [8, 136].

THEOREM 28. *Let K be an elementary frame class and $n \in \mathbb{N}$. Then the following are equivalent:*

1. *K is defined by a set of $\mathcal{H}(@,\downarrow)$ sentences containing (all together) at most n nominals.*
2. *K is defined by a single pure $\mathcal{H}(@,\downarrow)$ sentence containing at most n nominals.*

Language	*Frame classes defined by arbitrary formulas*	*Frame classes defined by pure formulas*
$\mathcal{H}$	closed under ultrafilter morphic images, and if every point-generated subframe of a frame $\mathcal{F}$ is a proper generated subframe of a frame in the class, then $\mathcal{F}$ is in the class	closed under images of bisimulation systems, and if every point-generated subframe of a frame $\mathcal{F}$ is a proper generated subframe of a frame in the class, then $\mathcal{F}$ is in the class
$\mathcal{H}(@)$	closed under ultrafilter morphic images and generated subframes	closed under images of bisimulation systems and generated subframes
$\mathcal{H}(\mathsf{E})$	closed under ultrafilter morphic images	closed under images of bisimulation systems
$\mathcal{H}(@, \downarrow)$	closed under generated subframes and reflecting finitely generated subframes.	closed under generated subframes and reflecting finitely generated subframes.

Figure 5. Elementary frame classes definable in $\mathcal{H}$, $\mathcal{H}(@)$, $\mathcal{H}(\mathsf{E})$ and $\mathcal{H}(@, \downarrow)$

3. *K is closed under taking generated subframes, and reflects $(n + 1)$-generated subframes.*

Note that every modally definable frame class is closed under generated subframes and reflects point-generated subframes. It follows by the above result that every *elementary* modally definable frame class (in particular, every frame class defined by a modal Sahlqvist formula), is defined by a nominal-free pure sentence of $\mathcal{H}(@, \downarrow)$.

The most important results of this section are summarized in Figure 5 which also contains analogous results for the languages $\mathcal{H}$ and $\mathcal{H}(\mathsf{E})$. Again, full details can be found in [136].

3.3 *Interpolation and Beth Definability*

We will now turn to the properties of interpolation and Beth definability. The results in this section are mainly based on [8, 136].

Recall that the modal logic of a class of frames K has interpolation if whenever $\varphi \to \psi$ is valid in K, then there exists a formula θ (called the *interpolant*) such that $\varphi \to \theta$ and $\theta \to \psi$ are valid in K, and all propositional variables occurring in θ occur both in φ and in ψ[7]. This definition can be generalized to hybrid logics in two ways, depending on whether only the propositional variables or also the nominals occurring in the interpolant are required to occur both in φ and in ψ. We will say that a hybrid logic has interpolation *over propositional variables* or *over propositional variables and nominals* to distinguish between these definitions.

The basic hybrid language $\mathcal{H}(@)$ lacks interpolation over propositional variables and nominals [8], as can be seen by the valid implication $i \wedge \Diamond i \to (j \to \Diamond j)$. An interpolant to this implication (which should express that the actual world is related to itself) is not allowed to contain any nominals. It is easily seen, using a bisimulation argument, that no such interpolant exists. Interpolation over propositional variables *does* hold. In fact, it holds relative to many frame classes [140, 136]:

THEOREM 29. *$\mathcal{H}(@)$ has interpolation over propositional variables relative to any frame class definable by a set of first-order universal Horn sentences.*

[7]This is sometimes called *local interpolation* or *arrow interpolation*, and in particular we are presenting it in its semantic version. We will not discuss global interpolation.

For $\mathcal{H}(@, \downarrow)$, we have better results: it has interpolation over propositional variables and nominals relative to many frame classes [8, 136]:

THEOREM 30. *$\mathcal{H}(@, \downarrow)$ has interpolation over propositional variables and nominals relative to any frame class definable by a set of nominal-free $\mathcal{H}(@, \downarrow)$ sentences. Moreover, $\mathcal{H}(@, \downarrow)$ has interpolation over propositional variables relative to any frame class definable by a set of $\mathcal{H}(@, \downarrow)$-sentences (possibly containing nominals).*

Theorem 30 covers many frame classes. Indeed, we saw in the previous section that every modally definable elementary frame class can be defined by a nominal-free sentence of $\mathcal{H}(@, \downarrow)$. It was shown in [30] that the interpolants can be effectively computed from a tableau proof (see also Section 5.3)[8]. The interpolation algorithm presented in [30] is conservative: on purely modal input it computes interpolants in which the hybrid syntactic machinery does not occur.

Given that $\mathcal{H}(@)$ lacks interpolation over propositional variables and nominals and $\mathcal{H}(@, \downarrow)$ has it, and given that $\mathcal{H}(@, \downarrow)$ has an undecidable satisfiability problem (as we will see in the next section), it is natural to ask whether there is any decidable hybrid language with interpolation over propositional variables and nominals. The answer is negative [135]: every extension of the minimal hybrid language $\mathcal{H}$ (satisfying certain regularity conditions such as allowing substitution of one nominal by another) either lacks interpolation or is undecidable. Moreover, $\mathcal{H}(@, \downarrow)$ is the least expressive extension of $\mathcal{H}(@)$ (satisfying the same regularity conditions) with interpolation over propositional variables and nominals.

The following can be seen as a weak version of this result. The proof is illustrative.

THEOREM 31. *If $\mathcal{H}(@)$ has interpolation over propositional variables and nominals on a frame class K, then $\mathcal{H}(@)$ is expressively complete for $\mathcal{H}(@, \downarrow)$ on K (i.e., for each formula $\varphi \in \mathcal{H}(@, \downarrow)$, there exist a formula $\varphi' \in \mathcal{H}(@)$ such that φ and φ' are equivalent on K).*

Proof. Assume that $\mathcal{H}(@)$ has interpolation over propositional variables and nominals on K. We will show that every $\mathcal{H}(@, \downarrow)$ sentence φ is equivalent (on K) to an $\mathcal{H}(@)$-formula, proceeding by induction on the length of φ. The only interesting case here is when φ is of the form $\downarrow x.\psi(x)$. Let i and j be nominals not occurring in $\downarrow x.\psi(x)$. By induction, we know that $\psi(i)$ and $\psi(j)$ are equivalent to $\mathcal{H}(@)$-formulas $\psi'(i)$ and $\psi'(j)$ respectively. Now, the following implication is valid:

$$K \models i \wedge \psi'(i) \to (j \to \psi'(j)).$$

Any interpolant θ for this implication is equivalent to $\downarrow x.\psi(x)$. For, consider any model $\mathcal{M}$ and world w such that $\mathcal{M}, w \models \downarrow x.\psi(x)$. Let $\mathcal{M}[i/w]$ be the model that differs from $\mathcal{M}$ only in the fact that w is the denotation of i. Since i does not occur in $\downarrow x.\psi(x)$, we have that $\mathcal{M}[i/w], w \models \downarrow x.\psi(x)$, hence $\mathcal{M}[i/w], w \models i \wedge \psi(i)$. It follows that $\mathcal{M}[i/w], w \models \theta$. Since i does not occur in θ, it follows that $\mathcal{M}, w \models \theta$. Conversely, suppose $\mathcal{M}, w \models \theta$. Let $\mathcal{M}[j/w]$ be the model that differs from $\mathcal{M}$ only in the fact that j denotes w. Since j does not occur in θ, we have that $\mathcal{M}[j/w], w \models \theta$. It follows that $\mathcal{M}[j/w], w \models j \to \psi(j)$, and hence $\mathcal{M}[j/w], w \models \downarrow x.\psi(x)$. Since j does not occur in $\downarrow x.\psi(x)$, it follows that $\mathcal{M}, w \models \downarrow x.\psi(x)$. ❑

To conclude our discussion on interpolation, we consider the notion of *uniform interpolants*. As is discussed in Chapter 8 of this handbook, the modal logics K, S5, Grz and GL enjoy a very special form of interpolation, called uniform interpolation. For any formula φ, let $\mathsf{PROP}(\varphi)$ be the set of propositional variables occurring in φ. Then a modal logic has uniform interpolation

[8] Theorem 30 is related to a result by Feferman and Kreisel [60, 59] who proved that the bounded fragment of first-order logic has interpolation by means of a cut free sequent calculus.

if for every formula φ and for any $P \subseteq \mathsf{PROP}(\varphi)$, there is a formula φ_P (called a *uniform interpolant*) such that for any formula ψ, if $\mathsf{PROP}(\psi) \cap \mathsf{PROP}(\varphi) \subseteq P$ and $\varphi \to \psi$ is derivable, then $\varphi_P \to \psi$ is derivable.

We can generalize the definition to hybrid logics, and say that a hybrid logic has *uniform interpolation over propositional variables* if for every formula φ and for any $P \subseteq \mathsf{PROP}(\varphi)$, there is a formula φ_P such that for any formula ψ, if $\mathsf{PROP}(\psi) \cap \mathsf{PROP}(\varphi) \subseteq P$, and all nominals occurring in ψ occur in φ, then $\varphi \to \psi$ is valid iff $\varphi_P \to \psi$ is valid. Note the requirement imposed on nominals in this definition. It turns out that the $\mathcal{H}(@)$-logics of the frame classes corresponding to the modal logics K, S5, Grz and GL have uniform interpolation over propositional variables [20, 136].

Finally, to close this section we turn to the Beth definability property. Recall that a logic is said to have the Beth Definability property if, intuitively, every implicit definition can be made explicit. More precisely, let $\Gamma(p)$ be any set of formulas containing the propositional variables p and possibly other propositional variables and nominals. $\Gamma(p)$ defines p implicitly if in all models in which both $\Gamma(p)$ and $\Gamma(p')$ are true at every state, also $p \leftrightarrow p'$ is true at every state (here, p' is a propositional variable not occurring in $\Gamma(p)$, and $\Gamma(p')$ is obtained from $\Gamma(p)$ by replacing all occurrences of p by p'). In other words, $\Gamma(p)$ defines p implicitly if $\Gamma(p) \cup \Gamma(p') \models^{glo} p \leftrightarrow p'$, where $\models^{glo}$ denotes global entailment. The Beth property states that whenever $\Gamma(p)$ defines p implicitly, there exists a formula θ in which p does not occur, such that $\Gamma(p) \models^{glo} p \leftrightarrow \theta$[9]. Clearly, θ is an explicit definition of p, relative to the theory $\Gamma(p)$.

The Beth definability property for a logic is typically established as a corollary of the interpolation property for propositional variables. In particular, the following theorem can be shown using the above interpolation results.

THEOREM 32. *$\mathcal{H}(@, \downarrow)$ has the Beth definability property relative to any frame class defined by a set of $\mathcal{H}(@, \downarrow)$ sentences, and $\mathcal{H}(@)$ has the Beth definability property relative to any frame class defined by a set of first-order universal Horn formulas.*

Surprisingly, the minimal hybrid language $\mathcal{H}$ lacks the Beth property relative to the class of all frames [20].

4 DECIDABILITY AND COMPLEXITY

In this section, we will review the complexity of the satisfiability problem for various hybrid logics. First, let us consider the language $\mathcal{H}(@)$. We start with some good news: the satisfiability problem of $\mathcal{H}(@)$ is PSPACE-complete [6]. We provide a game based argument for the upper bound.

THEOREM 33. *$\mathcal{H}(@)$-satisfiability on the class of all frames is* PSPACE*-complete.*

Proof. We only discuss the mono-modal case (the multi-modal case is a simple extension). The lower bound follows from the PSPACE-hardness of classical modal logic. We show the upper bound by defining, given a formula φ, the notion of a φ-game between two players. We will show that the existential player has a winning strategy for the φ-game iff φ is satisfiable. Moreover, every φ-game stops after at most as many rounds as the modal depth of φ and the information on the playing board is polynomial in the length of φ. This implies that a PSPACE algorithm exists. Fix a formula φ and let d be the number of different nominals appearing in

[9] This is sometimes called the *global Beth property*. We will not discuss the local Beth property here.

φ. A φ-Hintikka set is a maximal consistent set of subformulas of φ. We denote the set of subformulas of φ by $\mathsf{SF}(\varphi)$. The φ-game is played as follows. There are two players, $\forall$belard (male) and $\exists$loise (female). She starts the game by playing a collection $\{X_0, \dots, X_l\}, l \leq d$ of Hintikka sets and specifying a relation R on them. $\exists$loise loses immediately if one of the following conditions is false:

1. X_0 contains φ, and all others X_l contain at least one nominal occurring in φ.
2. no nominal occurs in two different Hintikka sets.
3. for all X_l, for all $@_i\psi \in \mathsf{SF}(\varphi)$, $@_i\psi \in X_l$ iff $\{i, \psi\} \subseteq X_k$, for some k.
4. for all $\Diamond\psi \in \mathsf{SF}(\varphi)$, if $R(X_l, X_k)$ and $\Diamond\psi \notin X_l$, then $\psi \notin X_k$.

Now $\forall$belard may choose an X_l and a "defect-formula" $\Diamond\psi \in X_l$. $\exists$loise must respond with a Hintikka set Y such that

1. $\psi \in Y$ and for all $\Diamond\theta \in \mathsf{SF}(\varphi)$, $\Diamond\theta \notin X_l$ implies that $\theta \notin Y$.
2. for all $@_i\psi \in \mathsf{SF}(\varphi)$, $@_i\psi \in Y$ iff $\{i, \psi\} \subseteq X_k$, for some k.
3. if $i \in Y$ for some nominal i, then Y is one of the Hintikka sets she played at the start. In this case the game stops and $\exists$loise wins.

If $\exists$loise cannot find a suitable Y, the game stops and $\forall$belard wins. If $\exists$loise does find a suitable Y (one that is not covered by the halting clause in item (3) above) then Y is added to the list of played sets, and play continues. $\forall$belard must now choose a defect $\Diamond\psi$ from the last played Hintikka set with the following restriction: in round r he can only choose defects $\Diamond\psi$ such that the modal depth of $\Diamond\psi$ is less than or equal to the modal depth of φ minus r. $\exists$loise must respond as before. She wins if she can survive all his challenges (in other words, he loses if he reaches a situation where he cannot choose any more defects).

The φ-game stops after at most modal depth of φ many rounds. The information on the board is at any stage of the game polynomial in the length of φ. We claim that $\exists$loise has a winning strategy iff φ is satisfiable.

The right-to-left direction is clear: $\exists$loise has a winning strategy if φ is satisfiable, for she need simply play by reading the required Hintikka sets off the model. For the other direction, suppose $\exists$loise has a winning strategy for the φ-game. We create a model $\mathcal{M}$ for φ as follows. The domain M is built in steps by following her winning strategy. M_0 consists of her initial move $\{X_0, \dots, X_n\}$. Suppose M_j is defined. Then M_{j+1} consists of a copy of those Hintikka sets she plays when using her winning strategy for each of $\forall$belard's possible moves played in the Hintikka sets from M_j (except when she plays a Hintikka set from her initial move, then of course we do not make a copy). Let M be the disjoint union of all M_j for j smaller than the modal depth of φ. Set $R(m, m')$ iff for all $\Diamond\psi \in \mathsf{SF}(\varphi)$, $\Diamond\psi \notin m \Rightarrow \psi \notin m'$ holds, and set $V(p) = \{m \in M \mid p \in m\}$. The rules of the game guarantee that nominals are interpreted as singletons.

We claim that the following truth-lemma holds. For all $m \in M$ which she plays in round j (i.e., $m \in M_j$), for all ψ of modal depth less than or equal to the modal depth of φ minus j, $\mathcal{M}, m \models \psi$ if and only if $\psi \in m$. We only discuss the case of $\Diamond$, if $\Diamond\psi \in m$, then $\forall$belard challenged this defect, so $\exists$loise could respond with an m' containing ψ. Since for all $\Diamond\psi \in \mathsf{SF}(\varphi)$, $\Diamond\psi \notin m \Rightarrow \psi \notin m'$ holds, we have $R(m, m')$ and by induction hypothesis $\mathcal{M}, m \models$

$\Diamond\psi$. If $\Diamond\psi \notin m$ but $R(m, m')$ holds, then by our definition of R, $\psi \notin m'$, so again $\mathcal{M}, m \not\models \Diamond\psi$. Since $\exists$loise plays a Hintikka set containing φ in the first round, $\mathcal{M}$ satisfies φ. ❑

Since satisfiability of basic modal formulas on the class of all frames is already PSPACE-complete, we can conclude that, in this case, the addition of nominals does not increase the complexity of the satisfiability problem (up to a polynomial). This is not always the case:

PROPOSITION 34. *$\mathcal{H}$-satisfiability on the class of symmetric frames is* EXPTIME*-complete.*

Proof. For any modal formula φ, let $\varphi' = i \wedge \Diamond\neg i \wedge \Box\Box\Diamond i \wedge \Box(\neg i \to \varphi^{\neg i})$, where i is any nominal and $\varphi^{\neg i}$ is obtained from φ by relativising all modalities with $\neg i$ (that is, $\Diamond\varphi$ becomes $\Diamond(\neg i \wedge \varphi)$ and $\Box\varphi$ becomes $\Box(\neg i \to \varphi)$). It can be easily seen that if φ' holds at a world w in a symmetric model $\mathcal{M}$ then φ holds globally in the submodel of $\mathcal{M}$ generated by w, minus the world w itself. Conversely, a symmetric model on which φ holds globally can easily be turned into a model for φ'. It follows that, on symmetric frames, φ' is satisfiable iff φ is globally satisfiable.

The global satisfiability problem for modal formulas on the class of symmetric frames is known to be EXPTIME-complete [50]. Hence, the satisfiability problem for $\mathcal{H}$ on the class of symmetric frames is EXPTIME-hard. That the problem is inside EXPTIME will follow from Theorem 39. ❑

Note that the proof uses only a single nominal. The satisfiability problem for the modal logic of the class of symmetric frames, **KB**, is only PSPACE-complete [50]. Hence, assuming PSPACE $\neq$ EXPTIME, adding a single nominal already makes the satisfiability problem more complex. A similar blowup holds for tense logic: the satisfiability problem of the basic temporal logic is PSPACE, but the addition of a single nominal moves the complexity to EXPTIME. The complexity drops though when considering linear or branching time models (to NP-complete in the first case and to PSPACE-complete in the second) [7, 110].

Adding nominals can even result in logics that are undecidable and lack the finite model property, as was first observed in the context of description logics [100, 103]. The example below is taken from [20]. Consider the bi-modal language with modalities $\langle R_1\rangle$ and $\langle R_2\rangle$, and let KB23 be the frame class defined by the following modal Sahlqvist formulas:

$$\begin{array}{ll}
\bigwedge_{1\leq k\leq 3}\langle R_1\rangle p_k \to \bigvee_{1\leq k<l\leq 3}\langle R_1\rangle(p_k \wedge p_l) & \text{(at most 2 } R_1\text{-successors)}\\
\bigwedge_{1\leq k\leq 4}\langle R_1\rangle\langle R_1\rangle p_k \to \bigvee_{1\leq k<l\leq 4}\langle R_1\rangle\langle R_1\rangle(p_k \wedge p_l) & \text{(at most 3 two-step } R_1\text{-successors)}\\
p \to [R_2]\langle R_2\rangle p & (R_2 \text{ is symmetric}).
\end{array}$$

PROPOSITION 35. *The modal logic of* KB23 *has the finite model property and is decidable.*

Proof. First, consider the mono-modal logic axiomatized by the first two axioms. This logic is complete for a class of frames that is closed under taking subframes, and it has the bounded width property: no point has more than two successors. It follows that this logic has the finite model property and is decidable. Second, consider the mono-modal logic given by the last axiom. This logic, which is complete for the class of symmetric frames, has the finite model property [49] and its satisfiability problem is complete for PSPACE [50]. Since decidability and the finite model property are preserved under taking fusions [69], the result follows. ❑

PROPOSITION 36. *The $\mathcal{H}$-logic of* KB23 *is undecidable and lacks the finite model property.*

Proof. For any mono-modal formula φ with modality $\langle R_1\rangle$, let $\varphi^* = i\wedge\langle R_2\rangle\neg i\wedge[R_2][R_1]\langle R_2\rangle i\wedge [R_2](\neg i \to \varphi^{\neg i})$. Here again $\varphi^{\neg i}$ is obtained from φ by relativising all modalities with $\neg i$ as above. By the same argument as in the proof of Proposition 34, φ' is satisfiable on $\mathsf{KB23}$ iff φ is globally satisfiable on the class of (mono-modal) frames in which each point has at most two successors and at most three two-step successors. Global satisfiability of modal formulas on the latter frame class is undecidable [133]. It follows that the $\mathcal{H}$-logic of $\mathsf{KB23}$ is also undecidable, and hence, since it is recursively enumerable (as follows from the elementarity of $\mathsf{KB23}$), it lacks the finite model property. ❑

Next, let us consider the language $\mathcal{H}(@,\downarrow)$. As was observed in [6], $\mathcal{H}(@,\downarrow)$ is a *conservative reduction class* of first-order logic. Following [39], we call a fragment of first-order logic a conservative reduction class if there is a computable translation τ mapping first-order formulas to formulas in the fragment, such that for all formulas α, $\tau(\alpha)$ is satisfiable iff α is, and $\tau(\alpha)$ has a finite model iff α has. Every conservative reduction class has an undecidable (in fact Π^0_1-complete) satisfiability problem, as well as an undecidable (in fact Σ^0_1-complete) finite satisfiability problem [39].

THEOREM 37. *$\mathcal{H}(@,\downarrow)$ is a conservative reduction class.*

Proof. The class of first-order formulas with equality in a single binary relation is known to be a conservative reduction class [39]. Now, consider the following translation from this first-order language to $\mathcal{H}(@,\downarrow)$, where i is a fixed nominal:

$$\begin{array}{lcl}
(R(x,y))^* & = & @_x\langle R\rangle y \\
(x=y)^* & = & @_x y \\
(\neg\varphi)^* & = & \neg\varphi^* \\
(\varphi\wedge\psi)^* & = & \varphi^*\wedge\psi^* \\
(\exists x.\varphi)^* & = & @_i\langle R\rangle{\downarrow}x.(\varphi^*).
\end{array}$$

Clearly, $(\cdot)^*$ is a computable function. Moreover, a first-order sentence φ is satisfiable (in a finite model) iff φ^* is satisfiable (in a finite model). First, suppose $\mathcal{M}\models\varphi$. Let $\mathcal{M}'$ be the model obtained from $\mathcal{M}$ by adding a new state w, labelled with nominal i, extending the relation R such that $(w,v)\in R$ for all states v in the domain of M. Then, clearly, $\mathcal{M}'\models\varphi^*$. Moreover, $\mathcal{M}'$ is finite if M is. Conversely, suppose $\mathcal{M},w\models\varphi^*$. Let v be the state in $\mathcal{M}$ labelled by the nominal i, and let $\mathcal{M}'$ be the submodel of $\mathcal{M}$ whose domain consists of all successors of v. Then, clearly, $\mathcal{M}'\models\varphi$. Moreover, $\mathcal{M}'$ is finite if $\mathcal{M}$ is. ❑

Even though the satisfiability problem for $\mathcal{H}(@,\downarrow)$ is undecidable, in certain cases $\mathcal{H}(@,\downarrow)$ is still computationally more attractive than the full first-order language. For instance, the satisfiability problem for $\mathcal{H}(@,\downarrow)$ becomes decidable if we restrict the out-degree of the nodes in the model [139]. Figure 6 lists the results for mono-modal formulas. Here, for a given κ, we consider the class of frames were every node has strictly less than κ successors. In particular, if $\kappa=\omega$, then each state can only have finitely many successors, and if $\kappa=1$, the relation is the empty relation.

The undecidability of $\mathcal{H}(@,\downarrow)$ does not depend on the presence of nominals or propositional variables: even without these, the satisfiability problem is undecidable. Similarly, the undecidability does not depend on nested occurrences of $\downarrow$. One successful way to syntactically restrict the language in order to obtain decidability, is to restrict the interaction between $\downarrow$ and the modalities [105, 139]. In particular, it was proved in [139] that decidability is regained when formulas

Nr. of successors	$\mathcal{H}(@, \downarrow)$	*First-order correspondence language*
$\kappa = 1$	NP-complete	NEXPTIME-complete
$\kappa = 2$	NP-complete	Non-elementary decidable
$3 \leq \kappa < \omega$	NEXPTIME-complete	Π^0_1-complete (co-r.e., not decidable)
$\kappa = \omega$	Σ^0_1-complete (r.e., not decidable)	Σ^1_1-complete (highly undecidable)
$\kappa > \omega$	Π^0_1-complete (co-r.e., not decidable)	Π^0_1-complete (co-r.e., not decidable)

Figure 6. Complexity of the satisfiability problem on mono-modal models with bounded out-degree

of the form $\cdots \Box(\cdots {\downarrow}x.(\cdots \Box \cdots)\cdots)\cdots$ are excluded. In other words, the undecidability of $\mathcal{H}(@, \downarrow)$ is caused by formulas that, when put in negation normal form, contain a $\downarrow$-binder that is both in the scope of a box operator and that contains in its scope a box operator. This result was shown to be tight [139].

To round off this section, we will discuss two useful complexity results that can be used to prove upper bounds for the complexity of various hybrid logics: the *loosely $\forall$-bounded fragment with constants* and the *hybrid μ-calculus*.

Consider any first-order language not containing function symbols, but possibly containing constants. A formula of such a language is called *loosely $\forall$-guarded* if it is built up from possibly negated atomic formulas using conjunction, disjunction, existential quantification and loosely guarded universal quantification, i.e., universal quantification of the form $\forall\vec{x}(\varphi \to \psi)$, where $\vec{x}$ is a sequence of variables and φ is an atomic formula containing all free variables of ψ.

THEOREM 38 ([82, 138]). *The satisfiability problem for loosely $\forall$-guarded first-order formulas is* 2EXPTIME*-complete. It is* EXPTIME*-complete when there is a uniform bound on the number of variables occurring in the formula (but not necessarily on the number of constants).*

Many hybrid logics can be translated into the loosely $\forall$-guarded fragment using only a limited number of variables. For such logics, Theorem 38 provides an EXPTIME upper bound.

The hybrid μ-calculus [124] extends the modal μ-calculus (cf. Chapter 12 of this handbook) with nominals, converse operators and the universal modality. It expressively subsumes many propositional dynamic and temporal logics, such as (hybrid) PDL and CTL. Sattler and Vardi [124] showed by means of automata that the satisfiability problem for the hybrid μ-calculus is EXPTIME-complete. Beside the fact that this result singles out a very expressive hybrid language that is still decidable in EXPTIME, it is interesting because the proof is based on tree automata. For any formula φ, an automaton A_φ on infinite trees is given that accepts precisely the "tree models" of φ. Checking whether φ is satisfiable then reduces to solving the emptiness problem for A_φ. The catch, in the case of the hybrid μ-calculus, is that the standard tree model property fails for this language. The key idea in the proof is that a model of a hybrid μ-formula φ can be transformed into a forest by properly choosing points to witness diamond formulas. See [124] for details.

Below, we will give instead an alternative proof by providing a polynomial time satisfiability preserving translation of the full hybrid μ-calculus into its nominal-free fragment. But first, let us review the syntax and semantics of the language. The hybrid μ-calculus makes use of set variables, which we will write as $x, y, \ldots$, and which should not be confused with the state variables of hybrid languages such as $\mathcal{H}(@, \downarrow)$. The syntax is defined by the following inductive

definition[10]:

$$\varphi ::= p \mid i \mid x \mid \neg\varphi \mid \varphi \wedge \psi \mid \langle R\rangle\varphi \mid \langle \bar{R}\rangle\varphi \mid \mathsf{E}\varphi \mid \mu x.\varphi,$$

where $p \in \mathsf{PROP}$, $i \in \mathsf{NOM}$, $R \in \mathsf{REL}$ and where x is a set variable occurring only positively in φ (i.e., under an even number of negation signs). Since the language contains set variables, the semantics is defined with the help of assignments. Here, an assignment will be a function g that assigns to each set variable a subset of the domain of the model. The semantics, then, is given by the following truth definition.

$\mathcal{M}, g, w \models p$	iff	$w \in V(p)$ for $p \in \mathsf{PROP} \cup \mathsf{NOM}$
$\mathcal{M}, g, w \models x$	iff	$w \in g(x)$
$\mathcal{M}, g, w \models \neg\varphi$	iff	$\mathcal{M}, g, w \not\models \varphi$
$\mathcal{M}, g, w \models \varphi \wedge \psi$	iff	$\mathcal{M}, g, w \models \varphi$ and $\mathcal{M}, g, w \models \psi$
$\mathcal{M}, g, w \models \langle R\rangle\varphi$	iff	there is a $v \in W$ such that $R(w, v)$ and $\mathcal{M}, g, v \models \varphi$
$\mathcal{M}, g, w \models \langle \bar{R}\rangle\varphi$	iff	there is a $v \in W$ such that $R(v, w)$ and $\mathcal{M}, g, v \models \varphi$
$\mathcal{M}, g, w \models \mathsf{E}\varphi$	iff	there is a $v \in W$ such that $\mathcal{M}, g, v \models \varphi$
$\mathcal{M}, g, w \models \mu x.\varphi$	iff	for all $W' \subseteq W$, if $\{v \in W \mid \mathcal{M}, g^x_{W'}, v \models \varphi\} \subseteq W'$ then $w \in W'$.

THEOREM 39 ([124]). *The satisfiability problem for the hybrid μ-calculus is* EXPTIME-*complete.*

Proof. We define a polynomial time satisfiability preserving translation from the full hybrid μ-calculus to its nominal-free fragment, i.e., the modal μ-calculus with converse operators and the existential modality. Since the latter language is EXPTIME complete [143, 48], the result follows.

Consider any formula φ of the hybrid μ-calculus containing nominals $i_1, \ldots, i_n$. For each nominal i_k, introduce a new distinct propositional variable q_k. In the translation we will define, each nominal will be uniformly replaced by the corresponding propositional variable. Clearly, we cannot force these propositional variables to denote singleton sets. We *can*, however, ensure that the formula in question does not distinguish between states named by the same nominal. To this end, we will use $\langle\equiv\rangle\psi$ as a shorthand for the formula $\mu x.(\psi \vee \bigvee_{k\leq n}(q_k \wedge \mathsf{E}(q_k \wedge x)))$, which says that ψ holds either at the current state, or at a state satisfying the same nominal as the current state, or in general at any state reachable from the current world in finitely many steps along the "satisfies the same nominal" relation. Now, define φ^* inductively, as follows:

$$\begin{array}{rcl}
(i_k)^* &=& \langle\equiv\rangle q_k \\
p^* &=& \langle\equiv\rangle p \\
x^* &=& \langle\equiv\rangle x \\
(\neg\psi)^* &=& \neg\psi^* \\
(\psi \wedge \chi)^* &=& \psi^* \wedge \chi^* \\
(\langle R\rangle\psi)^* &=& \langle\equiv\rangle\langle R\rangle\langle\equiv\rangle\psi \\
(\langle \bar{R}\rangle\psi)^* &=& \langle\equiv\rangle\langle \bar{R}\rangle\langle\equiv\rangle\psi \\
(\mathsf{E}\psi)^* &=& \mathsf{E}\psi^* \\
(\mu x.\psi)^* &=& \mu x.\psi^*.
\end{array}$$

Finally, let $\varphi^+ = \varphi^* \wedge \bigwedge_{k\leq n} \mathsf{E}p_k$. Note that φ^+ does not contain any nominals, and is only polynomially longer than φ. We will now show that φ and φ^+ are equi-satisfiable. One direction is trivial: if $\mathcal{M}, w \models \varphi$, then, assigning to each q_k the same (singleton) denotation

[10] Our notation is slightly different from the one used in [124].

as i_k, we obtain that $\mathcal{M}, w \models \varphi^+$ (note that, in this case, $\equiv$ is the identity relation). Conversely, suppose $\mathcal{M}, w \models \varphi^+$, with $\mathcal{M} = \langle W, (R^{\mathcal{M}})_{R \in \mathsf{REL}}, V \rangle$. Let $\equiv$ be the smallest equivalence relation on W such that $v \equiv u$ whenever v and u both satisfy q_k for some $k \leq n$. Let $\widehat{\mathcal{M}} = \langle W/_{\equiv}, (R^{\widehat{\mathcal{M}}})_{R \in \mathsf{REL}}, V' \rangle$, where $W/_{\equiv}$ is the set of $\equiv$-equivalence classes of W,

$$\begin{array}{lll} R^{\widehat{\mathcal{M}}}([v],[u]) & \text{iff} & \text{there are } v' \in [v] \text{ and } u' \in [u] \text{ such that } R^{\mathcal{M}}(v',u'), \\ [v] \in V'(p) & \text{iff} & \text{there is a } v' \in [v] \text{ such that } v' \in V(p), \text{ and} \\ [v] \in V'(i_k) & \text{iff} & \text{there is a } v' \in [v] \text{ such that } v' \in V(q_k). \end{array}$$

By construction, $V'(i_k)$ is a singleton set for each $k \leq n$. Moreover, it follows directly from the definition of $(\cdot)^*$ and $\widehat{\mathcal{M}}$ that, for all formulas ψ of the hybrid μ-calculus, and for all worlds $v \in W$,

$$\widehat{\mathcal{M}}, [v] \models \psi \quad \text{iff} \quad \mathcal{M}, v \models \psi^*.$$

In particular, $\widehat{\mathcal{M}}, [w] \models \varphi$. ❑

5 PROOF THEORY

In this section we discuss proof methods for hybrid logics, and show examples of how to use them. We will first present two "classical" proof systems (a sequent calculus and a natural deduction calculus), and then two others (a tableau calculus and a resolution calculus), which are usually considered more suitable for implementations. We will focus on the languages $\mathcal{H}(@)$ and $\mathcal{H}(@, \downarrow)$.

5.1 Sequent Calculus

The first modern results on proof theory for hybrid logics can be found in the work of Seligman in the area of Situation Theory [128, 129]. This work deals with strong ($\forall$-based) systems, but many of the key ideas underlying hybrid deduction (in particular, the deductive significance of @) were first explored in these papers.

The calculus $\mathbf{S}_{\mathcal{H}(@,\downarrow)}$ in Figure 7 is from [130] where a sound and complete sequent calculus for hybrid logics is developed from a sequent calculus for first-order logics by a series of transformations. In the figure, $\Gamma \vdash \Delta$ is a sequent where Γ and Δ are sets of hybrid formulas and φ, Γ is taken to be $\{\varphi\} \cup \Gamma$. The techniques used are quite general and can be applied to a wide range of hybrid and modal logics. Notice that the calculus is cut free. It can be proved that the cut rule is admissible.

An interesting feature of $\mathbf{S}_{\mathcal{H}(@,\downarrow)}$ is that the calculus is not restricted to @-formulas, as the other calculus we are going to discuss in the following sections. Intuitively, an @-prefixed sequent calculus can be generalized to deal with all formulas by using nominals as follows. A single nominal a on the left side of a sequent is enough to anchor all non @-prefixed formulas to the same element and so removes the need for them to share an @ prefix. The price to pay for this is that the calculus does not have a subformula property, as a proof may contain any number of @-prefixes which are not present in the end sequent (introduced using the $^\wedge$@ rules). But it is easy to prove that only "one layer" of prefixes is needed in any proof, and define a version of the subformula property that takes this into account.

The presence of nominals and the @ operator in the calculus above is crucial. When the underlying modal logic is temporal logic, more flexibility is possible: Demri [57] presents a sequent system for nominal tense logic, which does not contains @.

$$
\begin{array}{cccc}
 & (I) \quad \dfrac{}{\varphi, \Gamma \vdash \Delta, \varphi} & & \\[2ex]
 & (N_L) \quad \dfrac{a, b, \Gamma[a] \vdash \Delta[a]}{a, b, \Gamma[b] \vdash \Delta[b]} & & \\[2ex]
(\neg_L) & \dfrac{\Gamma \vdash \Delta, \varphi}{\neg\varphi, \Gamma \vdash \Delta} & (\neg_R) & \dfrac{\varphi, \Gamma \vdash \Delta}{\Gamma \vdash \Delta, \neg\varphi} \\[2ex]
(\vee_L) & \dfrac{\varphi, \Gamma \vdash \Delta \quad \psi, \Gamma \vdash \Delta}{(\varphi \vee \psi), \Gamma \vdash \Delta} & (\vee_R) & \dfrac{\Gamma \vdash \Delta, \varphi, \psi}{\Gamma \vdash \Delta, (\varphi \vee \psi)} \\[2ex]
(\langle r\rangle_L)^1 & \dfrac{\langle r\rangle a, @_a\varphi, \Gamma \vdash \Gamma}{\langle r\rangle\varphi, \Gamma \vdash \Delta} & (\langle r\rangle_R) & \dfrac{\Gamma \vdash \Delta, @_a\varphi \quad \Gamma \vdash \Delta, \langle r\rangle a}{\Gamma \vdash \Delta, \langle r\rangle\varphi} \\[2ex]
(\downarrow_L) & \dfrac{a, \varphi[x/a], \Gamma \vdash \Delta}{a, \downarrow x.\varphi, \Gamma \vdash \Delta} & (\downarrow_R) & \dfrac{a, \Gamma \vdash \Delta, \varphi[x/a]}{a, \Gamma \vdash \Delta, \downarrow x.\varphi} \\[2ex]
({}^{\vee}@_L) & \dfrac{a, \varphi, \Gamma \vdash \Delta}{a, @_a\varphi, \Gamma \vdash \Delta} & ({}^{\vee}@_R) & \dfrac{a, \Gamma \vdash \Delta, \varphi}{a, \Gamma \vdash \Delta, @_a\varphi} \\[2ex]
({}^{\wedge}@_L) & \dfrac{a, @_a\varphi, \Gamma \vdash \Delta}{a, \varphi, \Gamma \vdash \Delta} & ({}^{\wedge}@_R) & \dfrac{a, \Gamma \vdash \Delta, @_a\varphi}{a, \Gamma \vdash \Delta, \varphi}
\end{array}
$$

$$
(\text{name})^2 \quad \dfrac{a, \Gamma \vdash \Delta}{\Gamma \vdash \Delta} \qquad (\text{term})^3 \quad \dfrac{a, \Gamma \vdash \Delta}{\Gamma \vdash \Delta} \qquad (\text{term}^-)^3 \quad \dfrac{\Gamma \vdash \Delta}{a, \Gamma \vdash \Delta}
$$

Restrictions:

[1] if a does not occur in φ, Γ, Δ.

[2] if a does not occur in Γ, Δ.

[3] if all formulas in Γ, Δ are @-prefixed.

Figure 7. Rules for the Sequent Calculus $\mathbf{S}_{\mathcal{H}(@,\downarrow)}$

EXAMPLE 40. We prove the sequent $\downarrow x.\langle R\rangle(x \wedge p) \vdash p$ in $\mathbf{S}_{\mathcal{H}(@,\downarrow)}$:

$$
\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{}{b, @_a\langle R\rangle b, a, p \vdash p}\,(I)}{b, @_a\langle R\rangle b, a, p \vdash @_a p}\,({}^{\vee}@_R)}{b, @_a\langle R\rangle b, a \wedge p \vdash @_a p}\,(\neg_L), (\neg_R), \text{ and } (\vee_R)}{b, @_a\langle R\rangle b, @_b(a \wedge p) \vdash @_a p}\,({}^{\vee}@_L)}{@_a\langle R\rangle b, @_b(a \wedge p) \vdash @_a p}\,(\text{term})}{a, @_a\langle R\rangle b, @_b(a \wedge p) \vdash @_a p}\,(\text{term}^-)}{a, \langle R\rangle b, @_b(a \wedge p) \vdash p}\,({}^{\wedge}@_L) \text{ and } ({}^{\wedge}@_R)}{a, \langle R\rangle(a \wedge p) \vdash p}\,(\langle R\rangle_L)}{a, \downarrow x.\langle R\rangle(x \wedge p) \vdash p}\,(\downarrow_L)}{\downarrow x.\langle R\rangle(x \wedge p) \vdash p}\,(\text{name})
$$

5.2 Natural Deduction Calculus

Seligman proposed also a natural deduction system (again, not restricted to @-formulas) in [129]. However, the paper only proves soundness and completeness and does not discuss whether the calculus is normalizing. Braüner introduced in [42] an @-prefixed natural deduction calculus for $\mathcal{H}(@, \downarrow, \forall)$ and its sublanguages and established normalization. Figure 8 shows the rules corresponding to the $\mathcal{H}(@, \downarrow)$ fragment.

$$(\wedge_I)\ \frac{@_a\varphi \quad @_a\psi}{@_a(\varphi \wedge \psi)} \qquad (\wedge_{E1})\ \frac{@_a(\varphi \wedge \psi)}{@_a\varphi} \qquad (\wedge_{E2})\ \frac{@_a(\varphi \wedge \psi)}{@_a\psi}$$

$$(\rightarrow_I)\ \frac{\begin{array}{c}[@_a\varphi]\\ \vdots\\ @_a\psi\end{array}}{@_a(\varphi \rightarrow \psi)} \qquad (\rightarrow_E)\ \frac{@_a(\varphi \rightarrow \psi) \quad @_a\varphi}{@_a\psi}$$

$$(\bot_1)^1\ \frac{\begin{array}{c}[@_a\neg\varphi]\\ \vdots\\ @_a\bot\end{array}}{@_a\varphi} \qquad (\bot_2)\ \frac{@_a\bot}{@_c\bot}$$

$$(@_I)\ \frac{@_a\varphi}{@_c@_a\varphi} \qquad (@_E)\ \frac{@_c@_a\varphi}{@_a\varphi}$$

$$([r]_I)^2\ \frac{\begin{array}{c}[@_a\langle r\rangle c]\\ \vdots\\ @_c\varphi\end{array}}{@_a[r]\varphi} \qquad ([r]_E)\ \frac{@_a[r]\varphi \quad @_a\langle r\rangle c}{@_c\varphi}$$

$$(\downarrow_I)^3\ \frac{\begin{array}{c}[@_a c]\\ \vdots\\ @_c\varphi[x/c]\end{array}}{@_a{\downarrow}x.\varphi} \qquad (\downarrow_E)\ \frac{@_a{\downarrow}x.\varphi \quad @_a c}{@_c\varphi[x/c]}$$

$$(\text{Ref})\ \frac{}{@_a a} \qquad (\text{Nom}_1)^4\ \frac{@_a c \quad @_a\varphi}{@_c\varphi} \qquad (\text{Nom}_2)\ \frac{@_a c \quad @_a\langle r\rangle b}{@_c\langle r\rangle b}$$

Restrictions:

1. φ is a propositional variable.
2. c is not free in $@_a[r]\varphi$ or in any undischarged assumptions other than the specified occurrences of $@_a\langle r\rangle c$.
3. c is not free in $@_a{\downarrow}x.\varphi$ or in any undischarged assumptions other than the specified occurrences of $@_a c$.
4. φ is a propositional variable or a nominal.

Figure 8. Rules for the natural deduction calculus $\mathbf{ND}_{\mathcal{H}(@,\downarrow)}$

The system $\mathbf{ND}_{\mathcal{H}(@,\downarrow)}$ can be extended in a complete way with additional inference rules

corresponding to first-order conditions on the accessibility relations expressed by *geometric theories*[11]. And as we said, the system $\mathbf{ND}_{\mathcal{H}(@,\downarrow)}$ enjoys normalization (even when extended with rules for geometric theories), and a suitable version of the subformula property that takes into account the use of @-formulas. See [42], for further details. In [43] Braüner compares his system with Seligman's (actually, a slight variation of Seligman's to ensure closure under substitutions), providing translations of proofs in both directions. These translations allows us to transfer reduction rules between Braüner's and Seligman's calculus, but they are not sufficient to ensure normalization of the latter. Hence, the normalization problem for Seligman's calculus is still open.

EXAMPLE 41. We prove that $\downarrow x.\langle R\rangle(x \wedge p) \to p$ is a tautology in $\mathbf{ND}_{\mathcal{H}(@,\downarrow)}$:

$$
\begin{prooftree}
\AxiomC{$[@_y(\downarrow x.\langle R\rangle(x\wedge p))]^1$}
\AxiomC{}
\RightLabel{(Ref)}
\UnaryInfC{$@_y y$}
\RightLabel{$(\downarrow_E)$}
\BinaryInfC{$@_y\langle R\rangle(y\wedge p)$}
\AxiomC{$[@_y\neg p]^2$}
\AxiomC{$[@_z(y\wedge p)]^3$}
\RightLabel{$(\wedge_{E1})$}
\UnaryInfC{$@_z y$}
\AxiomC{$[@_z(y\wedge p)]^3$}
\RightLabel{$(\wedge_{E2})$}
\UnaryInfC{$@_z p$}
\RightLabel{(Nom_1)}
\BinaryInfC{$@_y p$}
\RightLabel{$(\to_E)$}
\BinaryInfC{$@_y\bot$}
\RightLabel{$(\bot_2)$}
\UnaryInfC{$@_z\bot$}
\RightLabel{$(\to_I)^3$}
\UnaryInfC{$@_z\neg(y\wedge p)$}
\RightLabel{$([R]_E)$}
\UnaryInfC{$@_y[R]\neg(y\wedge p)$}
\RightLabel{$(\to_E)$}
\BinaryInfC{$@_y\bot$}
\RightLabel{$(\bot_1)^2$}
\UnaryInfC{$@_y p$}
\RightLabel{$(\to_I)^1$}
\UnaryInfC{$@_y((\downarrow x.\langle R\rangle(x\wedge p))\to p)$}
\end{prooftree}
$$

5.3 *Tableau Calculus*

In Figure 9 the rules for a tableau calculus for $\mathcal{H}(@,\downarrow)$ are given. This calculus was introduced in [29], where tableau calculi for a family of *quantified* hybrid logics are presented (these are extensions of the propositional calculus defined in [25]). As in the case of natural deduction, the calculus is @-based: to prove the unsatisfiability of φ, apply the rules in Figure 9 to $@_i\varphi$ for i a nominal not in φ. If a closed tableau is found (i.e., a tableau in which each branch contains a pair of formulas $@_j\psi$ and $@_j\neg\psi$), then the original formula is unsatisfiable.

Completeness of the tableau calculus is proved for frame classes that can be axiomatized by pure, nominal free hybrid sentences[12]. Moreover, the tableau calculus can be used for effectively computing interpolants for a pair of formulas φ, ψ such that $\varphi \to \psi$ is a validity. The following result is proved in [30] using Fitting's argument for proving the same property for first-order logic [63].

THEOREM 42. *Given a closed hybrid tableau for $\varphi \to \psi$ using the rules of $\mathbf{T}_{\mathcal{H}(@,\downarrow)}$, the interpolant can be computed effectively.*

[11] A first-order formula is geometric if it is built out of atomic formulas of the form $R(x,y)$ and $x = y$ using only the connectives $\bot$, $\wedge$, $\vee$ and $\exists$. A geometric theory is a finite set of closed first-order formulas each having the form $\forall\bar{x}(\varphi \to \psi)$ where the formulas φ and ψ are geometric.

[12] The completeness proof is interesting: a valid hybrid sentence is translated into a valid first-order sentence in the correspondence language for which first-order closed tableau should exist; the tableau proof is then translated back into a hybrid tableau proof.

Constant Rules:	$(\neg\bot)\ \dfrac{\neg @_s \bot}{\top}$	$(\neg\top)\ \dfrac{\neg @_s \top}{\bot}$	
Negation Rules:	$(@)\ \dfrac{@_s \neg\varphi}{\neg @_s \varphi}$	$(\neg @)\ \dfrac{\neg @_s \neg\varphi}{@_s \varphi}$	
Conjunctive rules:	$(\wedge)\ \dfrac{@_s(\varphi \wedge \vee)}{\begin{array}{c}@_s\varphi\\ @_s\psi\end{array}}$	$(\neg\vee)\ \dfrac{\neg @_s(\varphi \vee \psi)}{\begin{array}{c}\neg @_s\varphi\\ \neg @_s\psi\end{array}}$	$(\neg \rightarrow)\ \dfrac{\neg @_s(\varphi \rightarrow \psi)}{\begin{array}{c}@_s\varphi\\ \neg @_s\psi\end{array}}$
Disjunctive rules:	$(\vee)\ \dfrac{@_s(\varphi \vee \psi)}{@_s\varphi \mid @_s\psi}$	$(\neg\wedge)\ \dfrac{\neg @_s(\varphi \wedge \psi)}{\neg @_s\varphi \mid \neg @_s\psi}$	$(\rightarrow)\ \dfrac{@_s(\varphi \rightarrow \psi)}{\neg @_s\varphi \mid @_s\psi}$
Diamond Rules:	$(\langle r\rangle)\ \dfrac{@_s\langle r\rangle\varphi}{\begin{array}{c}@_s\langle r\rangle t\\ @_t\varphi\end{array}}$ for t new in branch	$(\neg[r])\ \dfrac{\neg @_s[r]\varphi}{\begin{array}{c}@_s\langle r\rangle t\\ \neg @_t\varphi\end{array}}$ for t new in branch	
Box Rules:	$([r])\ \dfrac{@_s[r]\varphi \quad @_s\langle r\rangle t}{@_t\varphi}$	$(\neg\langle r\rangle)\ \dfrac{\neg @_s\langle r\rangle\varphi \quad @_s\langle r\rangle t}{\neg @_t\varphi}$	
@ rules:	$(@)\ \dfrac{@_s @_t\varphi}{@_t\varphi}$	$(\neg @)\ \dfrac{\neg @_s @_t\varphi}{\neg @_t\varphi}$	
	(Ref) $\dfrac{[s \text{ on the branch}]}{@_s s}$	(Nom) $\dfrac{@_s t \quad @_s\varphi}{@_t\varphi}$	(Bridge) $\dfrac{@_s t \quad @_u\langle r\rangle s}{@_u\langle r\rangle t}$
Downarrow Rules:	$(\downarrow)\ \dfrac{@_s{\downarrow}x.\varphi}{@_s\varphi[s/x]}$	$(\neg\downarrow)\ \dfrac{\neg @_s{\downarrow}x.\varphi}{\neg @_s\varphi[s/x]}$	

Figure 9. Rules for the tableau calculus $\mathbf{T}_{\mathcal{H}(@,\downarrow)}$

In a slightly different direction, Tzakova [142] presents a general approach to hybrid tableaux using Fitting-style prefix calculi. Such tableau use nominals both as part of the object language and as meta-logical labels.

Tableau methods have played a crucial role in modern automated reasoning for modal logics, and the best state-of-the-art provers for modal-like logics (such as the description logics provers RACER [84, 83] or FACT [90, 89]) are based on tableaux (see Chapter 13 of this handbook for further details). A variation of the hybrid tableau calculus of Figure 9 has been equipped with heuristics to ensure termination in [38]. The ideas used are related to the techniques used for terminating tableaux for the description logic $\mathcal{SHOIQ}$ [92].

EXAMPLE 43. We prove that ${\downarrow}x.(\langle R\rangle(x \wedge p) \rightarrow p)$ is a tautology in $\mathbf{T}_{\mathcal{H}(@,\downarrow)}$:

1.	$\neg @_i(\downarrow x.(\langle R\rangle(x \wedge p) \to p))$	Negation of the input formula
2.	$\neg @_i(\langle R\rangle(i \wedge p) \to p)$	$(\neg\downarrow)$ in 1
3.	$@_i(\langle R\rangle(i \wedge p)$	$(\neg \to)$ in 2
4.	$\neg @_i p$	$(\neg \to)$ in 2
5.	$@_i\langle R\rangle j$	$(\langle R\rangle)$ in 3
6.	$@_j(i \wedge p)$	$(\langle R\rangle)$ in 3
7.	$@_j i$	$(\wedge)$ in 6
8.	$@_j p$	$(\wedge)$ in 6
9.	$@_i p$	(Nom) in 7 and 8
	$\times$	Clash between 4 and 9

5.4 Resolution Calculus

As we just mentioned, the most successful automated theorem proving implementations for modal logics are based on the tableau method. Much of their outstanding performance is due to the heavy use of several heuristics and optimizations [93]; however, a number of these techniques do not work when the underlying logic allows some form of equality as in the case of hybrid logics. When nominals and satisfaction operators are added, the performance of tableau-based theorem provers is affected. This motivated research on possible alternatives, such as the resolution calculus. The best automated theorem provers for first-order logic are based on resolution, and we have already seen many similarities between hybrid and first-order logics.

Resolution calculi for $\mathcal{H}(@, \downarrow)$ and its sublanguages were introduced in [10, 11]. In a recent paper [14], the calculus for $\mathcal{H}(@)$ was refined to include ordering and selection functions (see [17] for the definitions of these standard notions). The rules are shown in Figure 10. In the figure, $S(C)$ is a selection function and $\succ$ is an admissible order; furthermore, the main premise of each rules is on the right. The calculus works on formulas in negation normal form (i.e., negation can only appear on atomic formulas), and hence an explicit rule for negation is not required. To extend the calculus to $\mathcal{H}(@, \downarrow)$, simply add the rule

$$(\downarrow) \qquad \frac{Cl \cup \{@_t{\downarrow} x.\varphi\}}{Cl \cup \{@_t\varphi[x/t]\}}.$$

Given a formula φ (in negation normal form), let *ClSet*$(\varphi) = \{\{@_i\varphi\}\}$, where i is a nominal not occurring in φ. Define *ClSet*$^*(\varphi)$ — the saturated set of clauses for φ — as the smallest set that includes *ClSet*(φ) and is saturated under the rules of Figure 10 (where saturation means that whenever there are sets matching the antecedent of any rule in *ClSet*$^*(\varphi)$ then also the sets in the consequent should be in *ClSet*$^*(\varphi)$). Then φ is unsatisfiable if and only if $\{\} \in$ *ClSet*$^*(\varphi)$.

The calculus $\mathbf{R}_{\mathcal{H}(@)}$ is implemented in the automated theorem prover HyLoRes [15], which uses an ordering that ensures termination while preserving soundness and completeness.

EXAMPLE 44. We prove that $\downarrow x.\langle R\rangle(x \wedge p) \to p$ is a tautology in $\mathbf{R}_{\mathcal{H}(@,\downarrow)}$. Consider the clause set corresponding to the negation of the formula:

$$(\wedge)\ \ \frac{Cl \cup \{@_t(\varphi_1 \wedge \varphi_2)\}}{\begin{array}{c}Cl \cup \{@_t\varphi_1\}\\ Cl \cup \{@_t\varphi_2\}\end{array}} \qquad (\vee)\ \ \frac{Cl \cup \{@_t(\varphi_1 \vee \varphi_2)\}}{Cl \cup \{@_t\varphi_1, @_t\varphi_2\}}$$

$$(\mathrm{RES})\ \ \frac{Cl_1 \cup \{@_t\varphi\} \quad Cl_2 \cup \{@_t\neg\varphi\}}{Cl_1 \cup Cl_2}$$

$$([r])\ \ \frac{Cl_1 \cup \{@_t\langle r\rangle s\} \quad Cl_2 \cup \{@_t[r]\varphi\}}{Cl_1 \cup Cl_2 \cup \{@_s\varphi\}} \qquad (\langle r\rangle)\ \ \frac{Cl \cup \{@_t\langle r\rangle\varphi\}}{\begin{array}{c}Cl \cup \{@_t\langle r\rangle n\}\\ Cl \cup \{@_n\varphi\}\end{array}}\ \ \begin{array}{l}\text{for } n \text{ a new nominal}\\ \text{and } \varphi \notin \mathsf{NOM}\end{array}$$

$$(@)\ \ \frac{Cl \cup \{@_t@_s\varphi\}}{Cl \cup \{@_s\varphi\}} \qquad (\mathrm{REF})\ \ \frac{Cl \cup \{@_t\neg t\}}{Cl}$$

$$(\mathrm{SYM})\ \ \frac{Cl \cup \{@_s t\}}{Cl \cup \{@_t s\}}\ \text{if } t \succ s \qquad (\mathrm{PARAM})\ \ \frac{Cl_1 \cup \{@_s t\} \quad Cl_2 \cup \{\varphi(s)\}}{Cl_1 \cup Cl_2 \cup \{\varphi(s/t)\}}\ \ \begin{array}{l}\text{if } s \succ t \text{ and}\\ \varphi(s) \succ @_s t\end{array}$$

Restrictions: Let φ and ψ be the displayed formulas in each of the above rules:

- Let $C = C' \cup \{\varphi\}$ be the main premise, then either $S(C) = \{\varphi\}$ or, otherwise, $S(C) = \emptyset$ and $\{\varphi\} \succ C'$.
- Let $D = D' \cup \{\psi\}$ be the auxiliary premise, then $\{\psi\} \succ D'$ and $S(D) = \emptyset$.

Figure 10. Rules for the resolution calculus $\mathbf{R}_{\mathcal{H}(@)}$ with Order and Selection Functions

1. $\{@_i((\downarrow x.\langle R\rangle(x \wedge p))\underline{\triangle}\neg p)\}$ by $(\wedge)$
2. $\{@_i\underline{\downarrow x}.\langle R\rangle(x \wedge p)\}, \{@_i\neg p\}$ by $(\downarrow)$
3. $\{@_i\underline{\langle R\rangle}(i \wedge p)\}, \{@_i\neg p\}$ by $(\langle r\rangle)$
4. $\{@_i\langle R\rangle j\}, \{@_j(i\underline{\triangle}p)\}, \{@_i\neg p\}$ by $(\wedge)$
5. $\{@_j\underline{i}\}, \{@_{\underline{j}}p\}, \{@_i\neg p\}$ by (PARAM)
6. $\{@_i\underline{p}\}, \{@_i\underline{\neg p}\}$ by (RES)
7. $\{\}$.

6 RELATION WITH OTHER FIELDS

In various areas, hybrid logics has been proposed as a convenient extension of modal logics, either because they give rise to smoother proof systems, or because of their greater expressive power. In this section we briefly discuss a number of cases, and provide pointers to the literature.

Temporal Logic. As indicated in the work of Prior and Bull, hybrid languages allow us to make explicit references to specific times (days, dates, years, etc.), and also to cope with temporal indexicals (such as yesterday, today, tomorrow and now). In addition, many temporally relevant frame properties (such as irreflexivity, asymmetry and trichotomy) that cannot be defined by means of modal formulas can be defined with nominals [28]. When nominals and satisfaction operators are added to an interval-based logic, the result is a $\mathsf{Holds}(t, \varphi)$-driven interval logic similar to those introduced in AI by James Allen [2] (where the satisfaction operators play the

role of Holds). By making explicit temporal references possible (combining nominals, satisfaction operators and temporal modalities, one can directly express temporal relations between instants or intervals), hybrid logics remove a serious obstacle to a modal analysis of temporal representation and reasoning.

Nominal tense logics have been studied in detail in [21]. The complexity of the satisfiability problem for a number of hybrid temporal logics is investigated in [7, 65]. The minimal hybrid tense logic $\mathcal{H}(\langle R^{-1}\rangle)$ is EXPTIME over the class of all frames and the class of transitive frames, but the complexity drops to NP-complete over the usual frames for linear time (strict total orders), and to PSPACE-complete over the usual frames for branching time (transitive trees). In [7, 110, 65], results are also given for hybrid languages with the Since and Until operators. Hybrid interval logics were recently studied in [95].

Indexicality and Direct Reference. Hybrid languages are also a powerful resource for studying indexicality in natural language, as an alternative to the more classical use of multi-dimensional modal logic. In the multi-dimensional modal approach, formulas are evaluated at sequences of points, where one point of the sequence is thought of as the point of evaluation, while the others are used as memory locations to store references [96, 146, 66, 52, 53]. Hybrid languages move multi-dimensional logic's sequence of evaluation points from the meta-language to the object language, with hybrid variables acting as names for indices (see [24]), and allowing in this way a natural treatment of such indexicals as 'today.' Moreover, when equipped with the @ operator, hybrid languages offer the 'de-scoping' behavior typical of such multi-dimensional operators as here and there. There are also links between hybrid logic and mathematical aspects of multi-dimensional modal logic, particularly the multi-dimensional modal perspective on cylindric algebra (cf. [106]), as $\downarrow$ and @ can be considered as explicit substitution devices.

Feature Logic. Most unification-based approaches to natural language grammar, such as PATR-II, use attribute value matrices (AVMs) to represent feature structures, where re-entrance in the feature structures is represented by "tags" in the AVMs [123]. There is a tight connection between AVMs and deterministic multi-modal logic, except that there is no clear way to express re-entrance in modal logic. As it turns out, the tags that are used to enforce re-entrance in AVMs correspond in a very natural way to nominals in hybrid logic. Thus, adding nominals is enough to make re-entrance expressible.

Previous approaches to encoding re-entrance in modal logic used more complicated techniques. In particular, Kasper-Rounds logic is essentially a fragment of deterministic propositional dynamic logic with program intersection, where the intersection is used to encoding re-entrance. See [33, 23, 120] for further details.

Dynamic Logic. As we discussed in Section 2.2, hybrid languages were rediscovered, many years after the work of Prior and Bull, by a group of logicians at the Sofia University in Bulgaria. Gargov, Passy and Tinchev were interested in neat axiomatizations of operators in PDL, and they realized that certain operators (e.g., union of programs) are easily captured, whereas others (e.g., program intersection or complement) require extra expressive power. In [113] it is shown that adding nominals is enough to enable natural and succinct characterization of these operators. Adding other kinds of "constants" to the language permits the representation of notions like determinism and looping [73]. In addition, the work of the Sofia school shows how nominals can be used to simplify the construction of models during completeness proofs [114]. See [115] for an excellent overview on combinatory dynamic logics.

For a modern discussion of PDL with nominals (in the framework of description logics) and some new complexity results see [56, 55].

Description Logics. Descriptions logics (DLs) are a family of formalisms that allow the representation of, and reasoning about, conceptual knowledge, in a structured and semantically well-understood manner [16]. They evolved from the original knowledge maintenance system KL-ONE of Brachman and Schmolze [41]. Description logics are discussed in detail in Chapter 13 of this handbook.

In [125] Schild identifies a close connections between description logics and modal logics, and uses it to transfer complexity and axiomatization results between the two areas. This connection is established at the level of concepts: *concepts* in description logic are shown to correspond to *formulas* in modal logic. Description logics, however, usually have two levels of representation. The first level is that of *concepts*, which, like modal formulas, denote subsets of the domain. The second level is that of *terminology boxes* (TBoxes) and *assertion boxes* (ABoxes). Using these, one can specify global conditions on models, such as the 'concept inclusion' $C \sqsubseteq D$, which requires that every individual satisfying the concept C should also satisfy the concept D, and the 'assertion' $a{:}C$, which requires that the individual a satisfies the concept C. The basic modal language is not rich enough to express such constructions. By lifting the correspondence to Converse PDL, Schild managed to account for inference with TBoxes. De Giacomo and Lenzerini [56, 55] further extended these results by encoding also ABoxes in Converse PDL.

While the embedding of DLs into Converse PDL have proved useful, it has two important disadvantages. Complexity-wise, the satisfiability problem of Converse PDL is already EXPTIME-complete and, hence, optimal complexity results cannot always be obtained with this technique. Moreover, the model theory of Converse PDL is complicated, due to the presence of the Kleene star (which requires a weak form of induction). Using the extended expressive power of hybrid languages, assertions can be encoded using satisfaction operators, and concept inclusions can be expressed using the universal modality A. See [12, 4, 36] for detailed discussions on the connections between hybrid and description logics.

Nominals have in fact been independently introduced in DLs. Very early systems like CLASSIC [40] and LOOM [104] already included a form of nominals in the late 80s. Such systems allowed a concept constructor called $\mathcal{O}$ (for "one-of") which permitted enumeration of individuals in the domain of a model. One-of expressions are in fact the same as disjunctions of nominals. The interest in the $\mathcal{O}$ operator dropped during the following years because of complexity issues (as we have seen in Section 4, the presence of nominals can lead to an increase in complexity, and even to undecidability, in the presence of other operators). However, the topic has recently regained interest, as direct reference to individuals seems to be a must for languages for the semantic web, one of the most important modern applications of DLs [94, 91]. The $\mathcal{O}$ operator is now part of the W^{3}C-recommended web ontology language OWL [107].

Information Systems. Nominals have turned up in yet another setting, namely the Polish tradition of modal logics for information systems initiated by Pawlak (see [112]). Themes in this tradition include the development of modal logics of similarity (or relative similarity) and there are strong links with the tradition of rough-set theory. Konikowska [97] has proposed adding nominals to such logics. Her work is motivated primarily by proof-theoretical considerations: the ability to name states leads to simpler and more intuitive proof systems.

Logics of Space. Nominals have found several applications in modal logics of space. In this chapter, we have treated hybrid languages from a relational perspective, viewing them as language for describing relational structures. Another well known semantics for modal logics is in terms of topological spaces [108]. A topological space is a tuple $\langle X, \Omega\rangle$ where X is a nonempty set and Ω is a collection of subsets of X satisfying three conditions: X and $\emptyset$ are elements

of Ω, every union of elements of Ω is in Ω, and every intersection of finitely many elements of Ω is in Ω. A topological model for the basic modal language, now, consists of a topological space $\langle X, \Omega \rangle$ and a valuation $V : \mathsf{PROP} \to \wp(X)$. The truth definition for modal formulas with respect to such topological models is similar to the one for Kripke models, except that the modal operator $\Box$ is interpreted as follows (where $m \in X$): $\langle X, \Omega, V \rangle, m \models \Box\varphi$ iff $\exists O \in \Omega$ such that $m \in O$ and for all $m' \in O$, $\langle X, \Omega, V \rangle, m' \models \varphi$. This topological semantics is useful for spatial reasoning [19, 1] and modelling knowledge [54]. As in the relational semantics, we can study notions such as validity of a modal formula on a topological space, and modally definable properties of topological spaces. It turns out that, as a language for defining properties of topological spaces, the basic modal language is very weak. In particular, none of the familiar topological separation axioms is modally definable [70].

Nominals can be introduced in topological models in the same way as in Kripke models: they are simply propositional variables whose valuation is always a singleton set. It was noted in [70] that, with the help of nominals, more properties of topological spaces can be defined, including the separation axioms T_0 and T_1. Sustretov [134] has recently proved a topological analogue of Theorem 22, characterizing the properties of topological spaces that can be defined by means of $\mathcal{H}(@)$- and $\mathcal{H}(\mathsf{E})$-formulas. Heinemann [87, 86] has investigated hybrid extensions of the bi-modal logic of knowledge and effort presented in [54], in order to obtain complete axiomatization of frame classes that, while relevant for applications, are not expressible in the basic modal language. In [87], Heinemann provides an axiomatization of the class of linear set spaces, using nominals that denote pairs in $X \times \Omega$. In [86], instead, two sorts of nominals are introduced, ranging over elements of X and Ω, respectively, and topological notions like separation and connectedness are axiomatized.

Nominals have also found applications in logics of metric spaces [101].

Second Order Propositional Modal Logic. In [61], the extension of the basic modal language with propositional quantifiers $\exists p$ and $\forall p$ is studied. This language is called *second order propositional modal logic* (SOPML). It was shown in [136, 137] that there is a close connection between SOPML and $\mathcal{H}(@, \downarrow)$:

THEOREM 45. *Every nominal free $\mathcal{H}(@, \downarrow)$-sentence is equivalent to a formula of SOPML. Conversely, if a formula of SOPML has a first-order equivalent, then it is equivalent to a nominal free $\mathcal{H}(@, \downarrow)$-sentence.*

Theorem 45 shows that, in some sense, nominal-free $\mathcal{H}(@, \downarrow)$ is the intersection of SOPML and first-order logic. This connection was used in [136, 137] to transfer a number of expressivity and frame definability results from $\mathcal{H}(@, \downarrow)$ to SOPML. For example, a first-order formula with one free variable is equivalent to a SOPML-formula iff it is invariant under generated submodels; and an elementary class of frames is definable in SOPML iff it is closed under generated submodels and reflects point-generated subframes (see Theorem 27). For more information about SOPML, see Chapter 10 of this handbook.

Modal Predicate Logics. Nominals can also be added on top of a first-order modal basis (cf. Chapter 9 of this handbook). Blackburn and Marx [29] investigate tableau systems for such first-order hybrid logics, while Braüner [44] discusses natural deduction systems. As in the propositional case, the outcome seems to be a better behaved logical system, that comes with general completeness results.

First-order hybrid logics also have advantages in relation to interpolation and Beth definability. Fine [62] showed that interpolation and the Beth definability property fail for quantified S5 with varying domains, and also for any quantified modal logic between K and S5 with constant

domains. In [9] it is shown that these properties are regained when state variables, satisfaction operators and $\downarrow$ are added to the language. Actually, interpolation and the Beth property hold relative to any bounded fragment definable class of skeletons (the first-order modal analogue of frames), with either varying, expanding, contracting or constant domains. Moreover, the interpolant can be obtained constructively using the techniques of [30].

For further details on first-order hybrid logics, see Chapter 9 in this handbook.

Labeled Deduction. In [68] the notation $l{:}\varphi$ is introduced, where the meta-linguistic symbol : associates the meta-linguistic label l with the object language formula φ. Labeled deduction proceeds by manipulating such expressions, using the labels to guide proof search. Labelled deduction has been successfully used to provide complete and well behaved calculi for a wide range of logics, including non-classical logics where the notion of "state" is usually crucial (see, e.g., [145]). For example, Simpson defines in [132] a family of labeled natural deduction calculi for modal intuitionistic logics and shows that they have good proof theoretic properties; while Kurtonina [99] uses labels to provide complete calculi for categorial type logics, for a variety of frame classes.

One way to see why hybrid languages are proof-theoretically natural, is to observe that nominals and satisfaction operators can capture the main ideas of labeled deduction. Hybrid languages "internalize" labeled deduction into the object language: nominals are essentially object-level labels, and the formula $@_l\varphi$ asserts in the object language what $l{:}\varphi$ asserts in the meta-language. Internalization in the particular case of tableaux is discussed in [25], while the case of sequent calculus is presented in [130]. We have seen examples of such calculi in Section 5. In a recent paper, Braüner and de Paiva discuss similar internalized calculi for hybrid versions of intuitionistic modal logics [45].

Model Checking. In this chapter we take satisfiability and consequence as the main inference problems, but other reasoning tasks are also relevant for many applications.

In [64] Franceschet and de Rijke investigate the following model checking problem for a number of hybrid logics: given a model, or a model and an assignment in case of languages with binders, and a formula φ decide whether there is a state in the model satisfying φ. They provide algorithms for model checking and investigate their complexity. Their main results are summarized in Figure 11, where k is the length of the input formula, n and m are the number of nodes and edges in the model, respectively, and r is the nesting degree of hybrid binders. Names listed as $\mathcal{DH}(\cdot)$ correspond to hybrid extensions of converse propositional dynamic logic. We can see that the presence of binders makes model checking PSPACE-complete (as complex as model checking full first-order logic), and it is, in general, exponential in the nesting level of binders. The paper discusses the impact of these results in applications like querying and constraint evaluation over semistructured data.

In [65], a different kind of model checking is investigated, which is used in formal verification. There, a Kripke structure typically represents a computational system, and paths through the structure denote different possible computations. In *linear time model checking*, formulas are evaluated not on the Kripke structure itself, but on the set of paths through it. Actually, two versions of the linear model checking problem can be defined: the existential linear time model checking problem is to determine whether a given formula is satisfied in some path of the model, while the universal linear time model checking problem asks whether the formula is satisfied in all paths.

Unraveling a Kripke structure into a tree carries some complications in the presence of nominals: if the original structure makes a nominal i true in a state which is involved in a cycle (i.e., the

$\mathcal{H}(\langle R^{-1}\rangle, \mathsf{E}, @)$	$\mathrm{O}(k \cdot (n+m))$
$\mathcal{H}(U, S, \mathsf{E}, @)$	$\mathrm{O}(k \cdot n \cdot m)$
$\mathcal{DH}(\mathsf{E}, @)$	$\mathrm{O}(k \cdot (n+m))$
$\mathcal{H}(\downarrow)$	PSPACE-complete
$\mathcal{H}(\mathsf{E}, @, \downarrow)$	PSPACE-complete
$\mathcal{H}_r(\mathsf{E}, @, \downarrow)$	$\mathrm{O}(k \cdot (n+m) \cdot n^r)$
$\mathcal{DH}_r(\mathsf{E}, @, \downarrow)$	$\mathrm{O}(k \cdot (n+m) \cdot n^r)$
$\mathcal{H}(\exists)$	PSPACE-complete
$\mathcal{H}(\mathsf{E}, @, \exists)$	PSPACE-complete
$\mathcal{H}_r(\mathsf{E}, @, \exists)$	$\mathrm{O}(k \cdot (n+m) \cdot n^{2r})$
$\mathcal{DH}_r(\mathsf{E}, @, \exists)$	$\mathrm{O}(k \cdot (n+m) \cdot n^{2r})$

Figure 11. Complexity of model checking different hybrid languages

state is reachable from itself), the "nominal" i will be true in more than one state after unraveling (actually, the denotation of i will be an infinite set). The authors chose to allow such behavior: the only restriction they make is that nominals denote a single state in the original structure, no other conditions are imposed. Under this interpretation, the complexity of linear time model checking for temporal languages coincides with their hybrid extensions: NP-complete (CONP-complete) for $\mathcal{H}(\langle R^{-1}\rangle, @)$ for existential (universal) linear time model checking, and PSPACE for $\mathcal{H}(U, S, @)$.

The Bounded Fragment. We mentioned the bounded fragment of first-order logic in Section 3.2 and in Theorem 16 we established its tight connection with $\mathcal{H}(@, \downarrow)$.

Bounded formulas have been considered in the literature for a long time. In set theory, where bounded quantifiers are of the form $\exists x.(x \in y \wedge \varphi)$ and $\forall x.(x \in y \rightarrow \varphi)$, the bounded fragment was introduced in 1965 by Levy [102], under the name Δ_0. Δ_0-formulas of set theory have the desirable property of being set-theoretically absolute, meaning that whether a Δ_0-formula $\varphi(x_1, \ldots, x_n)$ holds of sets $a_1, \ldots, a_n$ is independent of the universe of set theory in which $a_1, \ldots, a_n$ reside (cf., for instance, [18]). Bounded formulas have also been considered in the context of arithmetic, where bounded quantifiers are of the form $\exists x.(x \leq y \wedge \varphi)$ and $\forall x.(x \leq y \rightarrow \varphi)$. In fact, there is a field of research of its own called *bounded arithmetic*, which is connected to complexity theory (in particular, to the polynomial hierarchy), propositional proof theory, and the length of propositional proofs [47].

Around 1966, Feferman and Kreisel [60, 59] characterized the bounded fragment as the generated submodel invariant fragment of first-order logic. More precisely, they showed that a first-order formula is equivalent to a bounded formula iff it is invariant under generated submodels. Moreover, it was shown in [59] by means of a cut-free sequent calculus that the bounded fragment has interpolation.

7 DISCUSSION

Hybrid logics form a family of natural extensions of modal logic. The naturalness is confirmed by the fact that nominals have been re-invented on several occasions. Hybrid logics offer two important advantages over modal logics: increased expressive power (e.g., in temporal logic, irreflexivity becomes definable when nominals are added to the language) and a simpler proof

theory (there are many proof systems for hybrid logic, and they come with powerful general completeness results). The general question, then, is:

> How much do we gain by extending our language (e.g., how much extra expressive power), and what price do we pay (e.g., what are the complexity theoretic consequences)?

For a number of hybrid languages, we have explored these question systematically in this chapter. In particular, the expressivity of various hybrid languages has been characterized by means of analogues of the Van Benthem theorem and the Goldblatt-Thomason theorem. Concerning complexity, we saw that nominals and satisfaction operators often do not increase the complexity, although in exceptional cases, adding a single nominal can already cause undecidability. For languages containing the $\downarrow$-binder, on the other hand, undecidability seems to be the rule, rather than the exception.

We would like to close this chapter by observing that "hybridization", as an operation on logical languages, can be applied in many contexts. As we discussed, nominals have a natural interpretation not only in the relational (Kripke) semantics, but also in topological and algebraic semantics. The hybrid machinery can be added to the basic modal language, or on top of first-order or higher-order modal languages, and with either a classical or an intuitionistic base. Some of these combinations have been investigated (for instance, several recent papers study topological modal language containing nominals), other remain to be explored.

ACKNOWLEDGEMENTS

We would like to express our gratitude to Ulrike Sattler for her detailed comments and suggestions as second reader for this chapter, and also to Patrick Blackburn who read through earlier versions of the chapter and gave us valuable feedback. Balder ten Cate is supported by NWO grants 612.069.006 and 639.021.508.

1 INTRODUCTION

When can we say that a logic is a *combination* of others? In general, *any* logical system having more than one connective can be considered as a combination of logical systems having fewer connectives. In particular, *any* multimodal logic can be considered as a combination of, say, unimodal logics. So, in this general sense, *any* result on multimodal logics can be considered as a result on combining modal logics. What makes this chapter special among other ones studying multimodal logics is that here we investigate the following kind of problems:

> *Given a family* L *of modal logics and a combination method* C*, do certain properties of the 'component logics'* $L \in \mathsf{L}$ *transfer to their 'combination'* $\mathsf{C}(\mathsf{L})$*?*

Most of the *combination methods* considered in this chapter satisfy the following three criteria:

(C1) They are *finitary*, that is, C is defined only on *finite* families L of modal logics.

(C2) The combination $\mathsf{C}(\mathsf{L})$ of (multi)modal logics from L is a (multi)modal logic itself.

(C3) The combined logic $\mathsf{C}(\mathsf{L})$ is an extension of each component logic $L \in \mathsf{L}$.

For each considered combination method, we discuss in detail the possible transfer of the following two kinds of properties:

- **Axiomatisation/completeness.**
  There are two versions, depending on whether the combination method results in a syntactically or semantically defined logic. In the former case, the question is whether the combination of recursively (finitely) axiomatisable components remains recursively (finitely) axiomatisable, and in the latter, whether the Kripke completeness of the components transfers to their combination.

- **Decidability/complexity of the validity/satisfiability problem.**
  We study whether decidability of the validity problem transfers from the components to their combination and if so, what is the change in complexity. We also discuss the possible transfer of the finite model property.

For transfer results about several other properties (like versions of interpolation, decidability of various consequence relations, etc.) see [23] and the references therein. Combinations of deductive calculi (such as combined tableaux) are not considered either, see Chapter 2 of this handbook for some examples.

Combination methods not satisfying **(C1)–(C3)** are in general out of our scope, though see Section 5 for a discussion.

Notation and terminology. We will mainly consider possible world (or Kripke) semantics. *Kripke models* are pairs $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ that are based on relational structures $\mathfrak{F} = \langle W, R_1, \ldots, R_n \rangle$, where $n > 0$ is a natural number, W is a non-empty set and the R_i are binary relations on it. Such structures are called *n-frames* (or *frames*, for short). We say that an n-frame $\mathfrak{G} = \langle U, S_1, \ldots, S_n \rangle$ is a *subframe* of an n-frame $\mathfrak{F}$ ($\mathfrak{G} \subseteq \mathfrak{F}$, in symbols) if $U \subseteq W$ and $S_i = R_i \cap (U \times U)$, for $i = 1, \ldots, n$. A *path of length k* from point x to point y in an n-frame $\mathfrak{F}$ is a sequence $\langle x_0, \ldots, x_k \rangle$ of points such that $x_0 = x$, $x_k = y$ and $x_i R_j x_{i+1}$, for each $i < k$ and some j, $1 \le j \le n$. We call an n-frame $\mathfrak{F}$ *rooted* if there exists some $x \in W$ such that for every $y \in W$, $y \ne x$ there is a path from x to y. Such an x is called a *root of* $\mathfrak{F}$. We say that $\mathfrak{F}$ is of *depth k* if k is the length of the longest path in $\mathfrak{F}$. If such a longest path does not exist, then we say that $\mathfrak{F}$ is of *infinite depth*. An n-frame $\mathfrak{F}$ is called *tree-like* if it is rooted and $R = \bigcup_{i=1}^{n} R_i$ is weakly connected on the set $\{y \in W \mid yRx\}$ for every $x \in W$. If a tree-like frame is well-founded (i.e., there are no infinite descending R-chains $\ldots Rx_2Rx_1Rx_0$ of points) then we call $\mathfrak{F}$ a *tree*. The *depth* $d^{\mathfrak{F}}(x)$ of a point x in a tree $\mathfrak{F}$ is defined to be the length of the unique path from the root to x. If for no $n < \omega$ the point x is of depth n, then we say that x is of *infinite depth*. By the *co-depth* of a point x in a tree $\mathfrak{F}$ we understand the depth of the subtree of $\mathfrak{F}$ with root x.

Given a natural number n, the *n-modal language* $\mathcal{ML}_n$ has propositional variables $p, q, s, \ldots$, Boolean connectives $\neg$, $\wedge$, $\vee$, $\rightarrow$, $\leftrightarrow$, $\top$, $\bot$, and (unary) modal operators $\Box_1, \ldots, \Box_n$ and $\Diamond_1, \ldots, \Diamond_n$. $\mathcal{ML}_n$-formulas are formed inductively in the usual way. Given an $\mathcal{ML}_n$-formula φ, we let $sub\,\varphi$ denote the set of all subformulas of φ, and $md(\varphi)$ denote the *modal depth* of φ. We will also use the following abbreviations. For every formula φ, let

$$\Box^0\varphi = \varphi \qquad \text{and, for } n < \omega, \quad \Box^{n+1}\varphi = \Box\Box^n\varphi, \quad \Box^{\le n}\varphi = \bigwedge_{k \le n} \Box^k\varphi.$$

The *truth-relation* '$(\mathfrak{M}, w) \models \varphi$' connecting syntax and semantics is defined by induction on the construction of φ as usual. We say that φ is *true in* $\mathfrak{M}$ ($\mathfrak{M} \models \varphi$, in symbols),

if $\mathfrak{M}, w \models \varphi$ for all $x \in W$. A formula φ is said to be *valid in a frame* $\mathfrak{F}$ ($\mathfrak{F} \models \varphi$, in symbols), if $\mathfrak{M} \models \varphi$ for every model $\mathfrak{M}$ that is based on $\mathfrak{F}$. Given a set Σ of formulas, we set

$$\mathsf{Fr}\,\Sigma \;=\; \{\mathfrak{F} \mid \mathfrak{F} \models \varphi,\ \text{for all } \varphi \in \Sigma\}.$$

If $\mathfrak{M} \models \varphi$ for all $\varphi \in \Sigma$ then we say that $\mathfrak{M}$ is a *model for* Σ. Similarly, φ is said to be a *frame for* Σ, if $\mathfrak{F} \in \mathsf{Fr}\,\Sigma$.

By an *n-modal logic* (or *modal logic*[1], for short) we mean any set L of $\mathcal{ML}_n$-formulas that contains all valid formulas of classical propositional logic, the formulas

$$\text{(K)} \qquad \Box_i(p \to q) \to (\Box_i p \to \Box_i q),$$

and is closed under the rules of Substitution, Modus Ponens and Necessitation, for $i = 1, \dots, n$ (see Chapter 2 of this handbook).

Let us briefly discuss two of the most common ways of defining a modal logic: the 'syntactical' way (via axioms) and the 'semantical' way (via a class of intended frames). First, given a set Σ of $\mathcal{ML}_n$-formulas and an n-modal logic L, we say that L *is axiomatised by* Σ, if L is the smallest n-modal logic containing Σ. If Σ can be chosen a recursive (or finite) subset of all $\mathcal{ML}_n$-formulas, then we say that L is *recursively* (*finitely*) *axiomatisable*. And second, given a class $\mathcal{C}$ of n-frames, the set

$$\mathsf{Log}\,\mathcal{C} = \{\varphi \mid \mathfrak{F} \models \varphi,\ \text{for all } \mathfrak{F} \in \mathcal{C}\}$$

is always an n-modal logic. An n-modal logic L is called *Kripke complete* if $L = \mathsf{Log}\,\mathcal{C}$ for some class $\mathcal{C}$ of n-frames. In this case we also say that L is *characterised* (or *determined*) by $\mathcal{C}$. As is well-known, there exist incomplete modal logics, and similarly, there are Kripke complete logics that are not recursively axiomatisable (see Section 3.4 for some examples).

The *validity problem* for an n-modal logic L is the problem of deciding whether a given $\mathcal{ML}_n$-formula belongs to L or not. If this problem is decidable (or recursively enumerable) then we also say that the logic L is *decidable* (or *recursively enumerable*). A related problem is the *satisfiability problem* for L: given φ, decide whether φ is *L-satisfiable*, that is, whether there exists a model $\mathfrak{M}$ for L and a world w in $\mathfrak{M}$ such that $\mathfrak{M}, w \models \varphi$ holds. It is easy to see the connection between the two: $\varphi \in L$ iff $\neg\varphi$ is not L-satisfiable. Given a recursively enumerable logic L, we can have a decision algorithm for L if we can enumerate those formulas that are not in L. Clearly, this can be done if:

- the class of finite frames for L is recursively enumerable (up to isomorphism, of course), and
- L has the *finite model property*[2], that is

$$L = \mathsf{Log}\,\{\mathfrak{F} \in \mathsf{Fr}\,L \mid \mathfrak{F} \text{ is finite}\}.$$

This chapter is not self-contained in the sense that we discuss well-known modal logics like **K**, **S5**, **KD45**, **K4**, **S4**, **K4.3**, **GL**, **Grz**, **Alt**, etc. without defining them. We also use without explicit reference standard notions and results from basic modal logic,

[1] We consider here what are usually called *normal* modal logics only.

[2] It would be more precise to call this *finite frame property*. However, as is well-known, it is equivalent to saying that $L = \{\varphi \mid \mathfrak{M} \models \varphi,\ \text{for all finite models } \mathfrak{M} \text{ for } L\}$.

such as p-morphisms and disjoint unions, generated subframes, unravelling, results on Sahlqvist formulas and canonicity, etc. For notions and statements not defined or proved here, see other chapters in this handbook or [12, 10].

2 FUSION OF MODAL LOGICS

Within the constraints **(C1)**–**(C3)** above, the formation of *fusions* (also known as *independent joins*), is the simplest and perhaps the most natural way of combining modal logics:

DEFINITION 1. Let L_1 and L_2 be two modal logics formulated in languages $\mathcal{ML}_n$ and $\mathcal{ML}_m$ in such a way that they have disjoint sets of modal operators (say, $\Box_1, \dots, \Box_n$ and $\Box_{n+1}, \dots, \Box_{n+m}$, respectively). Then the *fusion*

$$L_1 \otimes L_2$$

of L_1 *and* L_2 is the smallest $(n+m)$-modal logic L containing both L_1 and L_2.

It is easy to see that if each L_i is axiomatised by a set Σ_i of axioms (written in the respective languages) then $L_1 \otimes L_2$ is axiomatised by the union $\Sigma_1 \cup \Sigma_2$. This means that *no* axiom containing modal operators from both of the languages of L_1 and L_2 is required to axiomatise $L_1 \otimes L_2$. In other words, in fusions the modal operators of the component logics are kind of 'independent,' they 'do not interact'.

The formation of fusions is clearly an associative binary operation on modal logics. Therefore, one can define the fusion

$$L_1 \otimes L_2 \otimes \cdots \otimes L_n$$

of n modal logics in a straightforward way, for any natural number $n \geq 2$. Observe that well-known multimodal logics like $\mathbf{K}_n$ or $\mathbf{S5}_n$ are the fusions of their unimodal 'counterparts':

$$\mathbf{K}_n = \underbrace{\mathbf{K} \otimes \cdots \otimes \mathbf{K}}_{n}, \qquad \mathbf{S5}_n = \underbrace{\mathbf{S5} \otimes \cdots \otimes \mathbf{S5}}_{n}.$$

The formation of fusions as a combination method does satisfy criterion **(C3)**, as the following result of Thomason [78] shows:

THEOREM 2. *The fusion of consistent modal logics is a conservative extension of the components.*

2.1 Transfer results

We begin with the following result of Kracht and Wolter [48], and Fine and Schurz [16] stating that *Kripke completeness* of the components transfers to their fusion:

THEOREM 3. *If modal logics* L_1 *and* L_2 *are characterised by classes of frames* $\mathcal{C}_1$ *and* $\mathcal{C}_2$*, respectively, and if* $\mathcal{C}_1$ *and* $\mathcal{C}_2$ *are closed under the formation of disjoint unions and isomorphic copies, then the fusion* $L_1 \otimes L_2$ *of* L_1 *and* L_2 *is characterised by the class*

$$\mathcal{C}_1 \otimes \mathcal{C}_2 = \big\{ \langle W, R_1, \dots, R_n, S_1, \dots, S_m \rangle \mid \langle W, R_1, \dots, R_n \rangle \in \mathcal{C}_1,\ \langle W, S_1, \dots, S_m \rangle \in \mathcal{C}_2 \big\}.$$

It should be clear that if $\mathcal{C}_1$ and $\mathcal{C}_2$ determine logics L_1 and L_2, respectively, then all frames in $\mathcal{C}_1 \otimes \mathcal{C}_2$ are frames for the fusion $L_1 \otimes L_2$. Let us outline the proof of the converse statement, i.e., that $\mathcal{C}_1 \otimes \mathcal{C}_2$ actually characterises $L_1 \otimes L_2$. To simplify notation, we assume that L_1 and L_2 are unimodal logics with the boxes $\Box_1$ and $\Box_2$, respectively. The fusion $L = L_1 \otimes L_2$ is then a bimodal logic in the language $\mathcal{ML}_2$.

With each $\mathcal{ML}_2$-formula φ of the form $\Box_i\psi$ $(i = 1, 2)$ we associate a new variable q_φ which will be called the *surrogate* of φ. For an $\mathcal{ML}_2$-formula φ containing no surrogate variables, denote by $\varphi^{\mathbf{1}}$ the formula that results from φ by replacing all its subformulas of the form $\Box_2\psi$, which are not within the scope of other $\Box_2$, with their surrogate variables $q_{\Box_2\psi}$. So $\varphi^{\mathbf{1}}$ is a unimodal formula containing only $\Box_1$. Let

$$\Theta^{\mathbf{1}}(\varphi) = \{p \mid p \text{ is a variable in } \varphi\} \cup \{\chi \in sub\,\Box_2\psi \mid \Box_2\psi \in sub\,\varphi\}.$$

The formula $\varphi^{\mathbf{2}}$ and the set $\Theta^{\mathbf{2}}(\varphi)$ are defined symmetrically.

Suppose now that φ is satisfiable in a model based on a frame for L. We need to construct a frame in $\mathcal{C}_1 \otimes \mathcal{C}_2$ satisfying φ. As we know only how to build frames for the unimodal fragments of L, the frame is constructed step-by-step alternating between $\Box_1$ and $\Box_2$.

Note first that since L_1 is characterised by $\mathcal{C}_1$, there is a model $\mathfrak{M}$ based on a frame in $\mathcal{C}_1$ and satisfying $\varphi^{\mathbf{1}}$ at a point r. Our aim now is to ensure that the formulas of the form $\Box_2\psi$ have the same truth-values as their surrogates $q_{\Box_2\psi}$. To do this, with each point x in $\mathfrak{M}$ we can associate the formula

$$\varphi_x = \bigwedge\{\psi \in \Theta^{\mathbf{1}}(\varphi) \mid (\mathfrak{M}, x) \models \psi^{\mathbf{1}}\} \wedge \bigwedge\{\neg\psi \mid \psi \in \Theta^{\mathbf{1}}(\varphi),\ (\mathfrak{M}, x) \not\models \psi^{\mathbf{1}}\},$$

construct a model $\mathfrak{M}_x$ based on a frame in $\mathcal{C}_2$ and satisfying $\varphi_x^{\mathbf{2}}$ in a world y, and then hook $\mathfrak{M}_x$ to $\mathfrak{M}$ by identifying x and y. After that we can switch to $\Box_1$ and in the same manner ensure that formulas $\Box_1\psi$ have the same truth-values as $q_{\Box_1\psi}$ at all points in every $\mathfrak{M}_x$, and so on. In this construction we use the fact that $\mathcal{C}_1$ and $\mathcal{C}_2$ are closed under isomorphic copies and disjoint unions: the $\mathfrak{M}_x$ should be mutually disjoint and the final model is the union of the models constructed at each step. Note that this construction is a special case of *fibring semantics* that is called iterated *dovetailing* [19, 20].

However, to realise this quite obvious scheme, we must be sure that $\varphi_x^{\mathbf{2}}$ is really satisfiable in a frame for L_2, which may impose some restrictions on the models we choose. First, in the construction above it is enough to deal with points x accessible from r in at most $md(\varphi)$ steps; no other point has any influence on the truth of φ at r. Let X be the set of all such points. Now, a sufficient and necessary condition for φ_x to be satisfiable in a frame for L (and so for $\varphi_x^{\mathbf{2}}$ to be satisfiable in a frame for L_2) can be formulated using the following general description of formulas of type φ_x.

Suppose Γ is a finite set of formulas closed under subformulas. Define the *consistency-set* $C(\Gamma)$ *of* Γ by taking

$$C(\Gamma) = \{\psi_\Delta \mid \Delta \subseteq \Gamma\},$$

where for $\Delta \subseteq \Gamma$,

$$\psi_\Delta = \bigwedge\{\chi \mid \chi \in \Delta\} \wedge \bigwedge\{\neg\chi \mid \chi \in \Gamma - \Delta\}.$$

In particular, for all $x \in X$, we have $\varphi_x \in C(\Theta^{\mathbf{1}}(\varphi))$. Given a formula φ, define

$$\Sigma_1(\varphi) = \{\psi \in C(\Theta^{\mathbf{1}}(\varphi)) \mid \neg\psi \notin L\}, \qquad \Sigma_2(\varphi) = \{\psi \in C(\Theta^{\mathbf{2}}(\varphi)) \mid \neg\psi \notin L\}.$$

The formulas in $\Sigma_i(\varphi)$ can be regarded as 'state descriptions' of the points in the possible models with respect to the formulas in $\Theta^{\mathbf{i}}(\varphi)$. In particular, for all $x \in X$, φ_x is satisfiable in a frame for L iff $\varphi_x \in \Sigma_1(\varphi)$. In other words, we should start with a model $\mathfrak{M}$ satisfying $\varphi^{\mathbf{1}} \wedge \Box_1^{\leq md(\varphi)}(\bigvee \Sigma_1(\varphi))^{\mathbf{1}}$ at a point r. Of course, the subsequent models $\mathfrak{M}_x$ must satisfy $\varphi_x^{\mathbf{2}} \wedge \Box_2^{\leq md(\varphi)}(\bigvee \Sigma_2(\varphi_x))^{\mathbf{2}}$ at all points $x \in X$, and so on. The interested reader may find more details in [48], [16].

Since the closure under *finite* disjoint unions is enough when we work with finite frames, we obtain the following:

THEOREM 4. *If both L_1 and L_2 are modal logics having the finite model property, then their fusion $L_1 \otimes L_2$ has the finite model property as well.*

As is shown by Wolter [82], *decidability* of the components also transfers to their fusion:

THEOREM 5. *If L_1 and L_2 are both decidable modal logics then $L_1 \otimes L_2$ is decidable as well.*

Further results showing that other important properties (such as Halldén completeness, decidability of the global consequence relation, uniform interpolation property) of modal logics are preserved under fusions were obtained in [48, 82].

As is discussed in Chapter 6 of this handbook, from the algebraic point of view every modal logic L can be regarded as the equational theory of modal algebras generated by the equations $\{`\varphi = 1' \mid \varphi \in L\}$. Thus, the problem of whether decidability is preserved under the formation of fusions of modal logics is an instance of the more general question: under which conditions does the decidability of two equational theories T_1 and T_2 imply the decidability of the union $T_1 \cup T_2$. The shared Boolean connectives impose special conditions on these equational theories; see the results of Ghilardi [29] that put the fusion construction to this more general context. Other extensions of Theorem 5 to fusions sharing not only the Booleans but also a universal modality and nominals are discussed in [30], and to fusions of non-normal modal logics in [6, 4].

2.2 Complexity of fusions

Unlike the properties considered above, upper complexity bounds do not always transfer under the formation of fusions (the lower bounds are inherited by Theorem 2 as long as we take fusions of consistent logics). The known decision procedures provide a time complexity bound for the fusion that is non-deterministic and one exponent higher than the maximal time complexity of the components. However, in general it is not known whether this increase in complexity is unavoidable. In particular, it is not known whether PSPACE- or EXPTIME-completeness transfers under the formation of fusions (see Theorem 7 below for some special cases when it actually does).

The following characterisation of the transfer of coNP-completeness was given by Spaan [77]. In order to formulate her theorem, we require the following notion. Say that a frame $\langle W', R' \rangle$ is a *skeleton subframe* of a frame $\langle W, R \rangle$ if $W' \subseteq W$ and $R' \subseteq R$. We use $\circ$ to denote reflexive points and $\bullet$ for irreflexive ones.

THEOREM 6. *Suppose that the unimodal logics L_1 and L_2 are characterised by classes $\mathcal{C}_1$ and $\mathcal{C}_2$ of frames, respectively, that are closed under the formation of isomorphic copies and disjoint unions. Then there are the following three cases for the complexity of $L_1 \otimes L_2$ (below $\{i, j\} = \{1, 2\}$):*

(1) $L_1 \otimes L_2$ *is* CONP-*complete.*

(2) $\mathcal{C}_i$ *consists of disjoint unions of singleton frames. In this case* $L_1 \otimes L_2$ *is polynomially reducible to* $\mathsf{Log}(\mathcal{C}_j)$.

(3) $L_1 \otimes L_2$ *is* PSPACE-*hard, whenever one of the following six cases holds:*

(i) $\bullet\!\leftarrow\!\bullet\!\rightarrow\!\bullet$ *and* $\bullet\!\rightarrow\!\bullet$ *are skeleton subframes of some frames in* $\mathcal{C}_i$ *and* $\mathcal{C}_j$, *respectively;*

(ii) $\circ\!\rightarrow\!\bullet\!\rightarrow\!\bullet$ *and* $\bullet\!\rightarrow\!\bullet$ *are skeleton subframes of some frames in* $\mathcal{C}_i$ *and* $\mathcal{C}_j$, *respectively;*

(iii) $\bullet\!\rightarrow\!\circ\!\rightarrow\!\bullet$ *and* $\bullet\!\rightarrow\!\bullet$ *are skeleton subframes of some frames in* $\mathcal{C}_i$ *and* $\mathcal{C}_j$, *respectively;*

(iv) $\bullet\!\rightarrow\!\bullet\!\rightarrow\!\bullet$ *and* $\circ\!\rightarrow\!\bullet$ *are skeleton subframes of some frames in* $\mathcal{C}_i$ *and* $\mathcal{C}_j$, *respectively;*

(v) $\bullet\!\rightarrow\!\bullet\!\rightarrow\!\bullet$ *and* $\circ\!\rightarrow\!\bullet$ *are skeleton subframes of a frame in* $\mathcal{C}_i$ *and* $\bullet\!\leftrightarrow\!\bullet$ *is a skeleton subframe of a frame in* $\mathcal{C}_j$;

(vi) $\bullet\!\rightarrow\!\bullet\!\rightarrow\!\bullet$ *and* $\circ\!\rightarrow\!\bullet$ *are skeleton subframes of a frame in* $\mathcal{C}_i$ *and* $\bullet\!\rightarrow\!\circ$ *is a skeleton subframe of a frame in* $\mathcal{C}_j$.

A close inspection of this result shows that almost all interesting fusions are PSPACE-hard. (An exception is the fusion **Alt** $\otimes$ **Alt** of two **Alt** logics that is CONP-complete by Theorem 6. We remind the reader that **Alt** is the CONP-complete logic determined by all *functional* frames.) In fact, the proof of Halpern and Moses [35] can be easily modified to obtain the following result on a matching upper bound for several 'standard' fusions:

THEOREM 7. *Let* $n > 1$ *and* $L_i \in \{\mathbf{K}, \mathbf{T}, \mathbf{K4}, \mathbf{S4}, \mathbf{KD45}, \mathbf{S5}\}$, *for all* $1 \leq i \leq n$. *Then* $L_1 \otimes \cdots \otimes L_n$ *is* PSPACE-*complete.*

Note that while **K**, **T**, **K4** and **S4** are PSPACE-complete themselves, **KD45** and **S5** are CONP-complete.

3 PRODUCT OF MODAL LOGICS

The formation of Cartesian products of various structures—vector and topological spaces, algebras, etc.—is a standard mathematical way of capturing the multidimensional character of our world. In modal logic, products of Kripke frames are natural constructions allowing us to reflect interactions between modal operators representing time, space, knowledge, actions, etc. The product construction as a combination method on modal logics was introduced in [74, 75, 24] and has been used in applications in computer science and artificial intelligence ever since (see, e.g., [68, 15, 7, 69, 18], and [23] and references therein).

DEFINITION 8. The *product* of two n-frames frames $\mathfrak{F}_1 = \langle W_1, R_1^1, \dots, R_1^n \rangle$ and $\mathfrak{F}_2 = \langle W_2, R_2^1, \dots, R_2^m \rangle$ is the $(n+m)$-frame

$$\mathfrak{F}_1 \times \mathfrak{F}_2 = \langle W_1 \times W_2, R_h^1, \dots, R_h^n, R_v^1, \dots, R_v^m \rangle$$

where $W_1 \times W_2 = \{\langle u, v\rangle \mid u \in W_1,\ v \in W_2\}$ and, for all $u_1, u_2 \in W_1$ and $v_1, v_2 \in W_2$,

$$\begin{array}{lll} \langle u_1, v_1\rangle\, R_h^i\, \langle u_2, v_2\rangle & \text{iff} & u_1 R_1^i u_2 \ \text{ and } \ v_1 = v_2 \quad (1 \leq i \leq n), \\ \langle u_1, v_1\rangle\, R_v^j\, \langle u_2, v_2\rangle & \text{iff} & u_1 = u_2 \ \text{ and } \ v_1 R_2^j v_2 \quad (1 \leq j \leq m). \end{array}$$

Such a frame will be called a *product frame*. The subscripts h and v appeal to the geometrical intuition of considering the R_h^i as 'horizontal' accessibility relations in $\mathfrak{F}_1 \times \mathfrak{F}_2$ and the R_v^j as 'vertical' ones; see Fig. 1 for an illustration.

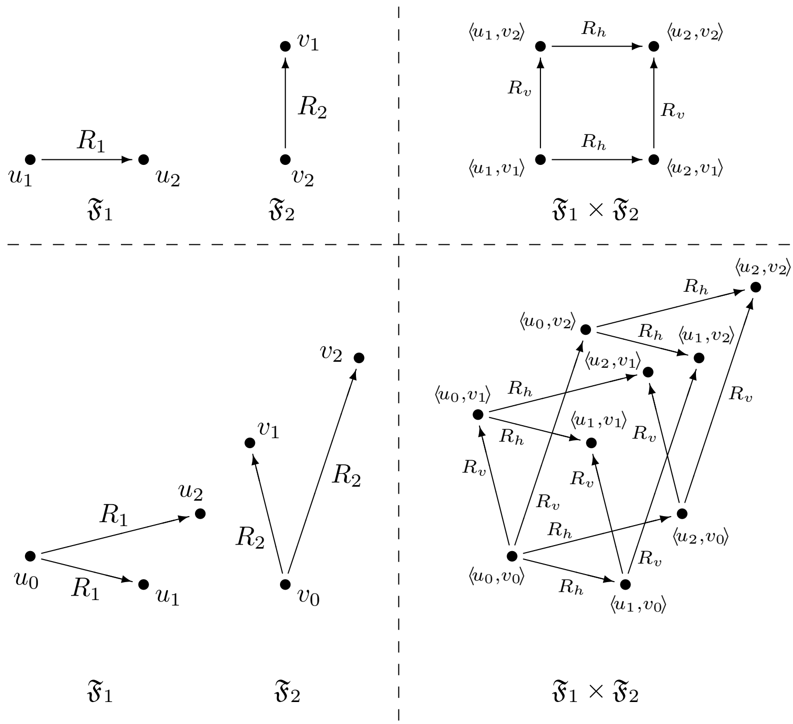

Figure 1. Product frames.

It is not hard to see that the product construction commutes with the three basic operations on frames:

PROPOSITION 9. *For all frames $\mathfrak{F}$, $\mathfrak{G}$, $\mathfrak{H}$, $\mathfrak{H}_i$, $i \in I$, the following hold:*

(i) *If $\mathfrak{F}$ is a p-morphic image of $\mathfrak{H}$, then $\mathfrak{F} \times \mathfrak{G}$ is a p-morphic image of $\mathfrak{H} \times \mathfrak{G}$.*

(ii) *If $\mathfrak{F}$ is a generated subframe of $\mathfrak{H}$, then $\mathfrak{F} \times \mathfrak{G}$ is a generated subframe of $\mathfrak{H} \times \mathfrak{G}$.*

(iii) *If $\mathfrak{F}$ is a disjoint union of $\mathfrak{H}_i$, $i \in I$, then $\mathfrak{F} \times \mathfrak{G}$ is isomorphic to the disjoint union of $\mathfrak{H}_i \times \mathfrak{G}$, $i \in I$.*

Products of Kripke frames can be used to define a natural combination method on modal logics:

DEFINITION 10. Let L_1 and L_2 be two Kripke complete modal logics formulated in languages $\mathcal{ML}_n$ and $\mathcal{ML}_m$ in such a way that they have disjoint sets of modal operators (say, $\Box_1, \ldots, \Box_n$ and $\Box_{n+1}, \ldots, \Box_{n+m}$, respectively). Then the *product of L_1 and L_2* is the modal logic

$$L_1 \times L_2 \;=\; \mathsf{Log}\{\mathfrak{F}_1 \times \mathfrak{F}_2 \mid \mathfrak{F}_i \in \mathsf{Fr}L_i,\ i = 1, 2\}.$$

For example, $\mathbf{K}_n \times \mathbf{K}_m$ is the $(n+m)$-modal logic determined by all product frames $\mathfrak{F}_1 \times \mathfrak{F}_2$, where $\mathfrak{F}_1$ is an n-frame and $\mathfrak{F}_2$ an m-frame; $\mathbf{S4} \times \mathbf{S5}$ is the bimodal logic determined by all product frames $\mathfrak{F}_1 \times \mathfrak{F}_2$ such that $\mathfrak{F}_1$ is reflexive and transitive, and $\mathfrak{F}_2$ is an equivalence frame.

Note that the product of Kripke complete modal logics is always Kripke complete by definition. It is important to emphasise that in order to make the product construction a well-defined combination method on Kripke complete modal logics, we have to consider products of *all* possible Kripke frames for L_1 and L_2. The reason is that even if $\mathsf{Log}\,\mathcal{C}_1 = \mathsf{Log}\,\mathcal{C}_1'$ and $\mathsf{Log}\,\mathcal{C}_2 = \mathsf{Log}\,\mathcal{C}_2'$, then we can have

$$\mathsf{Log}\{\mathfrak{F}_1 \times \mathfrak{F}_2 \mid \mathfrak{F}_i \in \mathcal{C}_i,\ i=1,2\} \ \neq\ \mathsf{Log}\{\mathfrak{F}_1 \times \mathfrak{F}_2 \mid \mathfrak{F}_i \in \mathcal{C}_i',\ i=1,2\},$$

see [23] for examples.

There are several attempts for extending the product construction from Kripke complete logics to arbitrary modal logics, mainly by considering product-like constructions on Kripke models, see [37, 23]. All the suggested methods so far result in sets of formulas that are not closed under the rule of Substitution, thus do not satisfy our criterion **(C2)**. Van Benthem *et al.* [79] show that by defining a product-like operator on their topological semantics, one can get back the *fusion* of modal logics determined by transitive frames.

Once the two-dimensional definition is given, there are essentially two ways of defining products of three or more modal logics. First, we can generalise in a straightforward way the definitions above. To simplify notation, from now on we will mostly consider products of unimodal frames and logics only. (However, we will discuss the multimodal versions in those cases when it does make a difference.)

DEFINITION 11. Given a natural number $n > 1$, the *product* of frames $\mathfrak{F}_1 = \langle W_1, R_1\rangle$, $\mathfrak{F}_2 = \langle W_2, R_2\rangle$, ..., $\mathfrak{F}_n = \langle W_n, R_n\rangle$ is the n-frame

$$\mathfrak{F}_1 \times \cdots \times \mathfrak{F}_n \ =\ \big\langle W_1 \times \cdots \times W_n, \bar{R}_1, \ldots, \bar{R}_n\big\rangle$$

where, for each $i = 1, \ldots, n$, $\bar{R}_i$ is a binary relation on $W_1 \times \cdots \times W_n$ such that

$$\langle u_1, \ldots, u_n\rangle\, \bar{R}_i\, \langle v_1, \ldots, v_n\rangle \quad \text{iff} \quad u_i R_i v_i \ \text{ and } \ u_k = v_k, \quad \text{for } k \neq i.$$

Then, given Kripke complete (uni)modal logics L_i formulated in the language having $\Box_i$ $(i = 1, \ldots, n)$, the *product of* $L_1, \ldots, L_n$ is the n-modal logic

$$L_1 \times \cdots \times L_n \ =\ \mathsf{Log}\{\mathfrak{F}_1 \times \cdots \times \mathfrak{F}_n \mid \mathfrak{F}_i \in \mathsf{Fr}L_i,\ i = 1, \ldots, n\}.$$

For example, $\mathbf{K}^n = \overbrace{\mathbf{K} \times \cdots \times \mathbf{K}}^{n}$ is the logic determined by all n-dimensional product frames; $\mathbf{S5}^n$ is the logic determined by all product frames $\mathfrak{F}_1 \times \cdots \times \mathfrak{F}_n$, where each $\mathfrak{F}_i$ is a (possible different) equivalence frame.

The second way would be to define $L_1 \times \cdots \times L_n$ as $(((L_1 \times L_2) \times L_3) \times \cdots \times L_{n-1}) \times L_n$. The easily established fact that the frame $\mathfrak{F}_1 \times \cdots \times \mathfrak{F}_n$ is isomorphic to

$$(((\mathfrak{F}_1 \times \mathfrak{F}_2) \times \mathfrak{F}_3) \times \cdots \times \mathfrak{F}_{n-1}) \times \mathfrak{F}_n$$

might seem to suggest that the two definitions are equivalent. However, the situation is not that simple. For example, it is not known whether the equalities

$$\mathbf{K}^4 \ \stackrel{?}{=}\ \mathbf{K}^3 \times \mathbf{K} \qquad \text{and} \qquad \mathbf{S5}^4 \ \stackrel{?}{=}\ \mathbf{S5}^3 \times \mathbf{S5}$$

hold. The problem here is that $\mathbf{K}^4$ is characterised by the class of products of four 1-frames, while $\mathbf{K}^3 \times \mathbf{K}$ by the class of products of *arbitrary* (that is, not necessarily product) 3-frames for $\mathbf{K}^3$ and 1-frames for $\mathbf{K}$. Now, the thing is that these arbitrary $\mathbf{K}^3$-frames are not necessarily isomorphic to product frames (in fact, we do not even know what they look like; see Theorem 25).

For this reason, we take Definition 11 above as the 'official' definition of higher dimensional product logics. Note, however, that in Section 3.3 we provide a characterisation of arbitrary (countable) frames for $\mathbf{K}\times\mathbf{K}$ and $\mathbf{S5}\times\mathbf{S5}$ (among many other two-dimensional product logics), and prove—with the help of this characterisation—that for many three-dimensional products the two definitions actually coincide. For instance,

$$\mathbf{K}^3 \;=\; (\mathbf{K}\times\mathbf{K})\times\mathbf{K} \qquad \text{and} \qquad \mathbf{S5}^3 \;=\; (\mathbf{S5}\times\mathbf{S5})\times\mathbf{S5},$$

see Corollary 23.

3.1 General transfer results

Compared to fusions, there are very few general transfer results for products. In fact, as we shall see in Sections 3.3 and 3.4, for many cases the lack of transfer of finite axiomatisability and decidability is the 'norm'.

In this section we discuss some basic properties of the product construction and the very few general transfer results about it. To begin with, observe that in the definition of product logics it is enough to consider only *rooted* frames for the component logics. Indeed, the inclusion

$$L_1\times\cdots\times L_n \;\subseteq\; \mathsf{Log}\{\mathfrak{F}_1\times\cdots\times\mathfrak{F}_n \mid \mathfrak{F}_i \text{ is a rooted frame for } L_i,\ i=1,\dots,n\}$$

should be clear. To show the converse, suppose $\varphi\notin L_1\times\cdots\times L_n$, i.e., φ is refuted at a point $\langle u_1,\dots,u_n\rangle$ in some model based on a product frame $\mathfrak{F}_1\times\cdots\times\mathfrak{F}_n$, where $\mathfrak{F}_i$ is a frame for L_i, $i=1,\dots,n$. For each i, let $\mathfrak{G}_i$ be the subframe of $\mathfrak{F}_i$ generated by u_i. Then $\mathfrak{G}_i$ is also a frame for L_i, for $i=1,\dots,n$. On the other hand, it is readily checked that $\mathfrak{G}_1\times\cdots\times\mathfrak{G}_n$ is isomorphic to the subframe of $\mathfrak{F}_1\times\cdots\times\mathfrak{F}_n$ generated by $\langle u_1,\dots,u_n\rangle$. Thus we obtain the following:

PROPOSITION 12. *For all Kripke complete modal logics $L_1,\dots,L_n$,*

$$L_1\times\cdots\times L_n \;=\; \mathsf{Log}\{\mathfrak{F}_1\times\cdots\times\mathfrak{F}_n \mid \mathfrak{F}_i \textit{ is a rooted frame for } L_i,\ i=1,\dots,n\}.$$

For instance, $\mathbf{S5}^n$ is determined by products of universal frames $\langle W_i, W_i\times W_i\rangle$, $i=1,\dots,n$. Moreover, each such 'universal product frame' is a p-morphic image of a *cubic universal product frame*, i.e., the nth power of the same universal frame $\langle W, W\times W\rangle$. Indeed, it is easy to see that if a set W is such that there are surjections $f_i : W\to W_i$, for $i=1,\dots,n$, then the map f defined by

$$f(w_1,\dots,w_n)=\langle f_1(w_1),\dots,f_n(w_n)\rangle$$

is a p-morphism from the frame $\langle W, W\times W\rangle^n$ onto

$$\langle W_1, W_1\times W_1\rangle\times\cdots\times\langle W_n, W_n\times W_n\rangle\,.$$

Such a set and surjections can be found, for example, by taking the disjoint union of the W_i as W and defining f_i so that it is the identity map on W_i and arbitrary otherwise. Therefore, we obtain:

PROPOSITION 13. $\mathbf{S5}^n$ *is determined by the class of all cubic universal product frames.*

The formation of products as a combination method satisfies criterion **(C3)**, as the following proposition shows:

PROPOSITION 14. *For all Kripke complete modal logics $L_1, \dots, L_n$,*

$$L_1 \otimes \cdots \otimes L_n \ \subseteq \ L_1 \times \cdots \times L_n.$$

Proof. Given a product frame $\mathfrak{F}_1 \times \cdots \times \mathfrak{F}_n = \left\langle W_1 \times \cdots \times W_n, \bar{R}_1, \dots, \bar{R}_n \right\rangle$ such that each $\mathfrak{F}_i = \langle W_i, R_i \rangle$ is a frame for L_i $(i = 1, \dots, n)$, fix some $1 \leq i \leq n$. For every $n-1$-tuple $\bar{u}_i = \langle u_1, \dots, u_{i-1}, u_{i+1}, \dots, u_n \rangle$ with $u_j \in W_j$, for $j \neq i$, we take the set

$$W_{\bar{u}_i} = \{\langle u_1, \dots, u_n \rangle \mid u_i \in W_i,\ \langle u_1, \dots, u_{i-1}, u_{i+1}, \dots, u_n \rangle = \bar{u}_i\},$$

and let $S_{\bar{u}_i}$ be the restriction of $\bar{R}_i$ to $W_{\bar{u}_i}$, i.e., $S_{\bar{u}_i} = \bar{R}_i \cap (W_{\bar{u}_i} \times W_{\bar{u}_i})$. Then we have:

- $\langle W_{\bar{u}_i}, S_{\bar{u}_i} \rangle$ is isomorphic to $\langle W_i, R_i \rangle$;
- $\left\langle W_1 \times \cdots \times W_n, \bar{R}_i \right\rangle$ is the disjoint union of the frames $\langle W_{\bar{u}_i}, S_{\bar{u}_i} \rangle$, for all $n-1$-tuples $\bar{u}_i$.

❑

As we shall see in Section 3.3, the inclusion in Proposition 14 is proper: product logics always include certain *interactions* between the modal operators of their components. Note, however, that the modal operators within each component are not affected by these interactions, that is, the product $L_1 \times \cdots \times L_n$ of consistent Kripke complete logics $L_1, \dots, L_n$ is a *conservative extension* of each of them. One can even show a slightly stronger statement:

PROPOSITION 15. *Let $L_1, \dots, L_n, L_{n+1}$ be consistent Kripke complete unimodal logics. Then the logic $L_1 \times \cdots \times L_n \times L_{n+1}$ is a conservative extension of $L_1 \times \cdots \times L_n$, i.e., for every $\mathcal{ML}_n$-formula φ,*

$$\varphi \in L_1 \times \cdots \times L_n \quad \textit{iff} \quad \varphi \in L_1 \times \cdots \times L_n \times L_{n+1}.$$

Proof. We prove this only for the case $L_1 = \cdots = L_n = L$; the general case is considered in a similar way. First, it is readily checked that for any $n+1$-dimensional product frame

$$\mathfrak{F} = \left\langle W_1 \times \cdots \times W_n \times W_{n+1}, \bar{R}_1, \dots, \bar{R}_n, \bar{R}_{n+1} \right\rangle,$$

the projection map $f(w_1, \dots, w_n, w_{n+1}) = \langle w_1, \dots, w_n \rangle$ is a p-morphism from the 'n-reduct'

$$\mathfrak{F}_{(n)} = \left\langle W_1 \times \cdots \times W_n \times W_{n+1}, \bar{R}_1, \dots, \bar{R}_n \right\rangle$$

of $\mathfrak{F}$ onto the n-dimensional product frame $\mathfrak{F}^- = \left\langle W_1 \times \cdots \times W_n, \bar{R}_1, \dots, \bar{R}_n \right\rangle$.

Now suppose that $\varphi \in L^{n+1}$ and $\mathfrak{G}$ is an n-dimensional product frame for L^n. As L is consistent and Kripke complete, there exists a frame $\mathfrak{H}$ for L. Then the product $\mathfrak{F} = \mathfrak{G} \times \mathfrak{H}$ is a frame for L^{n+1}, and so $\mathfrak{F} \models \varphi$. Since $\mathfrak{F}^- = \mathfrak{G}$, we finally obtain $\mathfrak{G} \models \varphi$.

Conversely, suppose that $\varphi \in L^n$, and let $\mathfrak{F}$ be an $n+1$-dimensional product frame for L^{n+1}. Then clearly $\mathfrak{F}^-$ is a frame for L^n, and so $\mathfrak{F} \models \varphi$. ❑

A useful property of certain product logics that sometimes they are determined by their *countable* product frames:

THEOREM 16. *Let L_i be a Kripke complete unimodal logic such that $\mathsf{Fr}L_i$ is first-order definable in the language having equality and a binary predicate symbol R_i, for each $i = 1, \dots, n$. Then $L_1 \times \cdots \times L_n$ is determined by the class of its countable product frames.*

Proof. For each i, let Γ_i denote the first-order theory defining $\mathsf{Fr}L_i$ in the language $\mathcal{L}_n$ having equality and binary predicate symbols $R_1, \dots, R_n$. Now let $\mathcal{L}_n^\times$ be the $n+1$-sorted extension of $\mathcal{L}_n$ that has the binary predicate symbols $R_1, \dots, R_n$ of sort 0, countably many unary predicate symbols $P_0, P_1, \dots$ of sort 0, and for each sort i ($i = 1, \dots, n$) a unary function symbol f_i taking an argument of sort 0 and returning a value of sort i. For each $\phi \in \Gamma_i$, denote by ϕ' the formula obtained by substituting $f_i(x)$ for all occurrences of each variable x in ϕ ($i = 1, \dots, n$). Let

$$\Sigma = \{\phi' \mid \phi \in \Gamma_i,\ i = 1, \dots, n\} \cup \{\pi\},$$

where π is the following sentence:

$$\begin{aligned} &\forall x \forall y \ \big(f_1(x) = f_1(y) \wedge \cdots \wedge f_n(x) = f_n(y) \to x = y\big) \\ &\qquad \wedge \forall x_1 \dots \forall x_n \exists y \ \big(f_1(y) = x_1 \wedge \cdots \wedge f_n(y) = x_n\big) \\ &\qquad\qquad \wedge \bigwedge_{i=1}^{n} \forall x \forall y \ \Big(x R_i y \ \leftrightarrow \ \big(f_i(x) R_i f_i(y) \wedge \bigwedge_{\substack{j=1 \\ j \neq i}}^{n} f_j(x) = f_j(y)\big)\Big) \end{aligned}$$

(here x and y are variables of sort 0, and x_i is of sort i, for $i = 1, \dots, n$). Now suppose that $\varphi \notin L_1 \times \cdots \times L_n$, for some $\mathcal{ML}_n$-formula φ. Then φ is not true in a model $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ based on the product $\mathfrak{F}_1 \times \cdots \times \mathfrak{F}_n$ of frames $\mathfrak{F}_i = \langle W_i, S_i \rangle$ such that $\mathfrak{F}_i \models \Gamma_i$ for $i = 1, \dots, n$. Define a first-order $\mathcal{L}_n^\times$-structure I by taking

$$I = \big\langle W_1 \times \cdots \times W_n, W_1, \dots, W_n; \bar{S}_1, \dots, \bar{S}_n, \mathfrak{V}(p_0), \mathfrak{V}(p_1), \dots, pr_1, \dots, pr_n \big\rangle,$$

where $pr_i : W_1 \times \cdots \times W_n \to W_i$ are the projection functions. It is easy to see that $I \models \Sigma$. Since without the extra sorts and the projections I is nothing but the modal model $\mathfrak{M}$ considered as a first-order structure, we also have $I \not\models \forall x \varphi^\star(x)$ (where $\varphi^\star$ is the *standard translation* of φ). In other words, $\Sigma' = \Sigma \cup \{\exists x \neg \varphi^\star(x)\}$ is true in I. By the downward Löwenheim–Skolem–Tarski theorem, there is a countable first-order $\mathcal{L}_n^\times$-structure

$$J = \big\langle U, U_1, \dots, U_n; , R_1^J, \dots, R_n^J, P_0^J, P_1^J, \dots, f_1^J, \dots, f_n^J \big\rangle$$

such that $J \models \Sigma'$. For each $i = 1, \dots, n$, define

$$Q_i = \{\big\langle f_i^J(u), f_i^J(v) \big\rangle \mid \langle u, v \rangle \in R_i^J\},$$

and for each $j < \omega$,

$$P_j^{I'} = \{\big\langle f_1^J(w), \dots, f_n^J(w) \big\rangle \mid w \in P_j^J\}.$$

Since $J \models \pi$, the map $h(w) = \big\langle f_1^J(w), \dots, f_n^J(w) \big\rangle$ is an isomorphism between J and the first-order $\mathcal{L}_n^\times$-structure

$$I' = \Big\langle U_1 \times \cdots \times U_n, U_1, \dots, U_n; \bar{Q}_1, \dots, \bar{Q}_n, P_0^{I'}, P_1^{I'}, \dots, pr_1, \dots, pr_n \Big\rangle.$$

Thus, $I' \models \Sigma$ and $I' \not\models \forall x \varphi^\star(x)$. Let $\mathfrak{G}_i = \langle U_i, Q_i \rangle$, $i = 1, \dots, n$. Define a valuation $\mathfrak{W}$ in the (countable) product frame $\mathfrak{G} = \mathfrak{G}_1 \times \cdots \times \mathfrak{G}_n$ by taking $\mathfrak{W}(p_j) = P_j^{I'}$ for $j < \omega$. As without the extra sorts and the projections I' is just a (countable) modal model $\mathfrak{N} = \langle \mathfrak{G}, \mathfrak{W} \rangle$ considered as a first-order structure, this means that φ is not true in $\mathfrak{N}$.

Note that in fact we have also proved that

$$\varphi \in L_1 \times \cdots \times L_n \qquad \text{iff} \qquad \Sigma \models \forall x \varphi^\star(x), \tag{1}$$

for any $\mathcal{ML}_n$-formula φ. ❑

In many cases recursive enumerability of the components transfers to their product:

THEOREM 17. *Let L_i be a Kripke complete unimodal logic such that $\mathsf{Fr}L_i$ is definable by a recursive set of first-order sentences in the language having equality and a binary predicate symbol R_i, for each $i = 1, \dots, n$. Then the product logic $L_1 \times \cdots \times L_n$ is recursively enumerable.*

Proof. We use the notation of the proof of Theorem 16. Since now the sets Γ_i are recursive, Σ is recursive as well. And since the consequence relation of first-order logic is recursively enumerable, it follows from (1) that $L_1 \times \cdots \times L_n$ is recursively enumerable. ❑

3.2 Connections with other formalisms

The product construction shows up in various disguises, here we discuss three examples: first-order logics, 'interpreted systems' for temporal epistemic logics, and modal extensions of description logics.

First-order classical and modal logics

Let us fix a natural number $n > 0$ and consider the fragment of classical first-order logic that

- uses n individual variables $x_1, \dots, x_n$,
- contains neither equality, nor individual constants, nor function symbols, and
- whose atomic formulas are of the form $P(x_1, \dots, x_n)$, where P is an n-ary predicate symbol.

This fragment can be regarded as the '*n-variable substitution- and equality-free fragment*' of classical first-order logic. The following map $\cdot^\bullet$ provides a one-to-one correspondence between formulas of this fragment and $\mathcal{ML}_n$-formulas:

$$\begin{array}{rclcrcl} P_i(x_1, \dots, x_n)^\bullet & = & p_i & \qquad & (\varphi \wedge \psi)^\bullet & = & \varphi^\bullet \wedge \psi^\bullet, \\ (\neg \varphi)^\bullet & = & \neg \varphi^\bullet, & & (\exists x_i \psi)^\bullet & = & \Diamond_i \psi^\bullet \qquad (1 \le i \le n). \end{array}$$

It is not hard to see that, for every first-order formula of the fragment,

$$\varphi \text{ is first-order valid} \quad \text{iff} \quad \varphi^\bullet \in \mathbf{S5}^n.$$

Indeed, every first-order structure $I = \left\langle D^I, \dots, P_i^I, \dots \right\rangle$ can be considered as a modal model $\mathfrak{M}(I) = \langle \langle W, \dots, R_i, \dots \rangle, \mathfrak{V} \rangle$, where

- W is the set of all variable assignments in I, i.e., the set of all functions from the variables $x_1, \dots, x_n$ into D^I;
- $\mathfrak{a} R_i \mathfrak{b}$ iff $\mathfrak{a}(x_j) = \mathfrak{b}(x_j)$ for all variables x_j different from x_i, $1 \le i \le n$;
- $\mathfrak{V}(p_i) = P_i^I$.

The set W of all assignments in I can be regarded as the n^{th} Cartesian power of the domain D^I. The underlying frame of $\mathfrak{M}(I)$ then turns into a product frame for $\mathbf{S5}^n$: the nth power of the universal $\mathbf{S5}$-frame $\langle D^I, D^I \times D^I \rangle$. On the other hand, $\mathbf{S5}^n$ is determined by such cubic universal product frames by Proposition 13.

The idea of such a 'modal approach' to classical first-order logic was suggested by Quine [66] and Kuhn [51] and fully realised by Venema [80]. 'Approximating' first-order logic with logical systems of propositional character was an important motive in the *algebraic* treatment of classical first-order logic; see the work of Tarski and his school [38, 39, 1, 11, 13, 34, 62]. The modal algebras (see Chapter 6 of this handbook) corresponding to the product logic $\mathbf{S5}^n$ are known in the algebraic logic literature as *diagonal-free cylindric set algebras of dimension n.*

As is shown in [23], a similar connection can be established between n-variable fragments of quantified modal logics L (with constant domains) and $n+1$-dimensional product logics of the form

$$L \times \overbrace{\mathbf{S5} \times \cdots \times \mathbf{S5}}^{n}.$$

Temporal epistemic logics

Here we briefly discuss the connections to the 'interpreted systems' approach proposed by Fagin *et al*. [15] which gives rise to various combinations of propositional temporal and epistemic logics ranging from fusions to products of these logics.

Suppose S is a non-empty set (of 'states') and $\mathfrak{F} = \langle T, < \rangle$ is a strict linear order (the 'flow of time'). Suppose also that $\mathcal{R}$ is a non-empty set of functions from T to S (the available 'runs of events' over $\mathfrak{F}$), and let $R_1, \dots, R_n$ be binary relations on $T \times \mathcal{R}$. Then the tuple

$$\mathfrak{S} = \langle T, \mathcal{R}, <, R_1, \dots, R_n \rangle$$

is called a *interpreted system.* A *valuation* $\mathfrak{V}$ *in* $\mathfrak{S}$ is a function from the set of propositional variables into the set 2^S of all subsets of S. The pair $\mathfrak{M} = \langle \mathfrak{S}, \mathfrak{V} \rangle$ is called a *model based on* $\mathfrak{S}$.

We interpret the modal language $\mathcal{ML}_{n+1}$ at $\langle$timepoint,run$\rangle$ pairs in these models. $\Box_1$ represents the temporal operator 'always in the future', while $\Box_2, \dots, \Box_{n+1}$ represent the respective knowledge of n agents:

- $(\mathfrak{M}, \langle t, f \rangle) \models p$ iff $f(t) \in \mathfrak{V}(p)$,
- $(\mathfrak{M}, \langle t, f \rangle) \models \varphi \wedge \psi$ iff $(\mathfrak{M}, \langle t, f \rangle) \models \varphi$ and $\langle t, f \rangle \models \psi$,
- $(\mathfrak{M}, \langle t, f \rangle) \models \neg\varphi$ iff not $(\mathfrak{M}, \langle t, f \rangle) \models \varphi$,
- $(\mathfrak{M}, \langle t, f \rangle) \models \Box_1\varphi$ iff $(\mathfrak{M}, \langle t', f \rangle) \models \varphi$ whenever $f' > f$,
- $(\mathfrak{M}, \langle t, f \rangle) \models \Box_i\varphi$ iff $(\mathfrak{M}, \langle t', f' \rangle) \models \varphi$ whenever $\langle t, f \rangle\, R_{i-1}\, \langle t', f' \rangle$ $(i = 2, \dots, n+1)$.

We say that φ *is true in* $\mathfrak{M}$ if $(\mathfrak{M}, \langle t, f\rangle) \models \varphi$ holds, for every $\langle t, f\rangle \in T \times \mathcal{R}$.

Given a propositional temporal logic $\mathsf{Log}\,\mathcal{C}_1$ determined by a class $\mathcal{C}_1$ of strict linear orders and an n-modal epistemic logic L determined by a class $\mathcal{C}_2$ of n-frames, we can obtain a 'combined' temporal-epistemic logic by considering all $\mathcal{ML}_{n+1}$-formulas that are true in all models that are based on interpreted systems of the form $\langle T, \mathcal{R}, <, R_1, \dots, R_n\rangle$ such that $\langle T, <\rangle \in \mathcal{C}_1$ and $\langle T \times \mathcal{R}, R_1, \dots, R_n\rangle \in \mathcal{C}_2$. By Theorem 3, this combined logic is just the *fusion* of $\mathsf{Log}\,\mathcal{C}_1$ and L.

By imposing various constraints on interpreted systems, we can reflect some interesting features of agents. An interpreted system $\mathfrak{S}$ models agents who *know the time* if, for all $t, t' \in T$, $f, f' \in \mathcal{R}$, and $i = 1, \dots, n$,

$$\langle t, f\rangle\, R_i\, \langle t', f'\rangle \text{ implies } t = t'.$$

In other words, if A_i believes that at moment t relative to an evolution f the pair $\langle t', f'\rangle$ represents a possible state of affairs, then $t = t'$. So at each moment t the agents are assumed to know that the clock is at t. Systems represented by structures of this type are known as *synchronous.*

An interpreted system models agents who *do not learn* if, for all agents A_i, $f, f' \in \mathcal{R}$ and $t, t' \in T$, we have

$$\langle t, f\rangle\, R_i\, \langle t', f'\rangle \text{ implies } \forall s \geq t\ \exists s' \geq t'\ \ \langle s, f\rangle\, R_i\, \langle s', f'\rangle\,.$$

Intuitively, an agent A_i does not learn if, whenever it regards w as a possible state of affairs at moment t, then it regards w as a possible state of affairs at every moment $s \geq t$ as well. Under the condition that agents know the time, this means that if agent A_i regards an evolution f' as possible at t then it regards f' as possible at every $s > t$. Similarly, an interpreted system models agents who *do not forget* if, for all A_i, $t, t' \in T$ and $f, f' \in \mathcal{R}$, we have

$$\langle t, f\rangle\, R_i\, \langle t', f'\rangle \text{ implies } \forall s \leq t\ \exists s' \leq t'\ \ \langle s, f\rangle\, R_i\, \langle s', f'\rangle\,.$$

Systems of this type are known also as systems with *perfect recall.*

If an interpreted system models agents who know time, do not forget and do not learn, then, for all agents A_i, $t, t' \in T$ and $f, f' \in \mathcal{R}$, we have

$$\langle t, f\rangle\, R_i\, \langle t', f'\rangle \text{ implies } t = t' \text{ and } \forall s\ \ \langle s, f\rangle\, R_i\, \langle s, f'\rangle\,.$$

Thus, the interpretation of $\mathcal{ML}_{n+1}$-formulas in $\mathfrak{S}$ corresponds to evaluating them in the *product* of frames $\mathfrak{F} = \langle T, <\rangle$ and $\langle \mathcal{R}, S_1, \dots, S_n\rangle$, where

$$f S_i f' \quad \text{iff} \quad \exists t, t' \in T\ \ \langle t, f\rangle\, R_i\, \langle t', f'\rangle \quad \text{iff} \quad \forall t \in T\ \ \langle t, f\rangle\, R_i\, \langle t, f'\rangle\,.$$

'Modal' description logics

As is discussed in Chapter 13 of this handbook, originally *description logics* have been designed and used as a formalism for knowledge representation and reasoning only in 'static' application domains. Later on, several attempts have been made in the literature in order to extend description logics with 'dynamic' features such as knowledge as time- or action-dependence, beliefs of different agents, etc. (see, e.g., [72, 71, 57, 32, 7, 3, 5,

84, 86, 88]). Here we briefly describe a simple 'modal' extension of the basic concept language $\mathcal{ALC}$ (see Chapter 13 of this handbook) and its connection to products.

Imagine, for instance, a car salesman John who, besides standard ABox and TBox knowledge bases (see Chapter 13 of this handbook), also wants to include 'modalised' concepts such as describing a $\mathsf{Customer}$ as

$$\mathsf{Homo\_sapiens} \sqcap \langle \text{sometime in the past} \rangle\, \exists \mathsf{buys.Car},$$

or a $\mathsf{Potential\_customer}$ as

$$[\text{John believes}]\, \langle \text{eventually} \rangle\, \mathsf{Customer}.$$

Concept descriptions in the extended concept language $\mathcal{ML}_n^{\mathcal{ALC}}$ that is able to express these can be formed according to the following rules:

$$C, D \quad \to \quad A \mid \top \mid \bot \mid \neg C \mid C \sqcap D \mid C \sqcup D \mid \forall r.C \mid \exists r.C \mid \Box_i C \mid \Diamond_i C,$$

where A ranges over concept names, r ranges over role names, and $i = 1, \dots, n$.

The intended semantics of $\mathcal{ML}_n^{\mathcal{ALC}}$ is defined as follows. An $\mathcal{ML}_n^{\mathcal{ALC}}$-*interpretation with constant domains and roles* is a pair $\mathfrak{M} = \langle \mathfrak{F}, I \rangle$ in which $\mathfrak{F} = \langle W, R_1, \dots, R_n \rangle$ is an n-frame and I is a function associating with each $w \in W$ a usual $\mathcal{ALC}$-interpretation

$$I(w) = \big\langle \Delta, \dots, A^{\mathfrak{M},w}, \dots, r, \dots \big\rangle$$

(that is, Δ is a nonempty set, $A^{\mathfrak{M},w} \subseteq \Delta$ for each concept name A, and $r \subseteq \Delta \times \Delta$ for each role name r). The (world-dependent) interpretation of concept names is inductively extended to arbitrary concept descriptions. Here we give the definition for the new 'modal' constructors only:

$$(\Box_i C)^{\mathfrak{M},w} = \bigcap_{wR_iv} C^{\mathfrak{M},v}, \qquad (\Diamond_i C)^{\mathfrak{M},w} = \bigcup_{wR_iv} C^{\mathfrak{M},v}.$$

Now given a Kripke complete n-modal logic L, we say that a concept description C is $L_{\mathcal{ALC}}$-*satisfiable* (with an empty knowledge base) if there is an $\mathcal{ML}_n^{\mathcal{ALC}}$-interpretation (with constant domains and roles) $\mathfrak{M} = \langle \mathfrak{F}, I \rangle$ and a world w in $\mathfrak{F}$ such that $\mathfrak{F}$ is a frame for L and $C^{\mathfrak{M},w} \neq \emptyset$.

Now, by extending the correspondence between $\mathcal{ALC}$ (with m role names) and the modal logic $\mathbf{K}_m$ (see Chapter 13 of this handbook), it is straightforward to see that $L_{\mathcal{ALC}}$-satisfiability coincides with $L \times \mathbf{K}_m$-satisfiability.

3.3 Axiomatising products

Product logics are defined in a semantical way: they are logics determined by classes of product frames, and so Kripke complete by definition. Therefore, the proper 'transfer' question to ask is how a possible axiomatisation for a product logic relates to axiomatisations of its components.

To begin with, observe that the following properties hold in every product frame of the form $\langle W, R_1, \dots, R_n \rangle$, for all $i, j = 1, \dots, n$, $i \neq j$:

- *left commutativity*: $\forall x, y, z \in W \big(xR_jy \wedge yR_iz \to \exists u \in W\,(xR_iu \wedge uR_jz)\big)$,

- *right commutativity*: $\forall x, y, z \in W \big(xR_iy \wedge yR_jz \to \exists u \in W\,(xR_ju \wedge uR_iz)\big)$,
- *Church–Rosser property*: $\forall x, y, z \in W \big(xR_jy \wedge xR_iz \to \exists u \in W\,(yR_iu \wedge zR_ju)\big)$,

see Fig. 2.

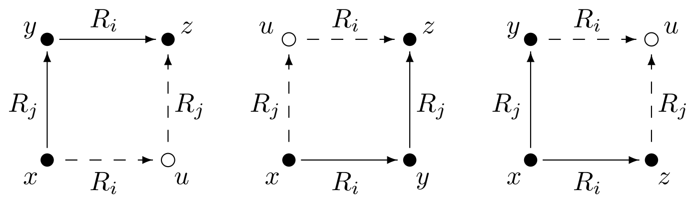

Figure 2. Left and right commutativity and Church–Rosser properties.

These properties can also be expressed by modal formulas. One can easily check that an arbirtary (not necessarily product) n-frame is left commutative iff it validates the formulas

$$\boldsymbol{com}^{\boldsymbol{l}}_{ij} \;=\; \Diamond_j\Diamond_i p \to \Diamond_i\Diamond_j p,$$

it is right commutative iff it validates

$$\boldsymbol{com}^{\boldsymbol{r}}_{ij} \;=\; \Diamond_i\Diamond_j p \to \Diamond_j\Diamond_i p,$$

and it is Church–Rosser iff it validates

$$\boldsymbol{chr}_{ij} \;=\; \Diamond_i\Box_j p \to \Box_j\Diamond_i p.$$

The corresponding left and right commutativity axioms can be combined into a single *commutativity* axiom

$$\boldsymbol{com}_{ij} \;=\; \boldsymbol{com}^{\boldsymbol{l}}_{ij} \wedge \boldsymbol{com}^{\boldsymbol{r}}_{ij}.$$

DEFINITION 18. Given modal logics L_i formulated in the language having $\Box_i$ ($i = 1, \dots, n$), the *commutator*

$$[L_1, \dots, L_n]$$

of $L_1, \dots, L_n$ is the smallest n-modal logic containing all the L_i and the axioms $\boldsymbol{com}_{ij}$ and $\boldsymbol{chr}_{ij}$, for all $i, j = 1, \dots, n$, $i \neq j$.

Note that the commutator of (finitely) axiomatisable modal logics is always (finitely) axiomatisable by definition. Moreover, since the axioms $\boldsymbol{com}_{ij}$ and $\boldsymbol{chr}_{ij}$ are Sahlqvist formulas, we also have:

PROPOSITION 19. *The commutator of canonical logics is canonical, and so Kripke complete.*

It is worth noting that even if all components are Kripke complete, their commutator is not necessarily so: non-examples are [**K4**, **GL.3**] and [**GL**, **Grz.3**], see Section 3.4.

Commutators are natural candidates for axiomatising products. As $\boldsymbol{com}_{ij}$ and $\boldsymbol{chr}_{ij}$ are valid in every product frame, by Proposition 14 we always have that

$$[L_1, \dots, L_n] \;\subseteq\; L_1 \times \cdots \times L_n, \tag{2}$$

whenever $L_1, \dots, L_n$ are Kripke complete modal logics. Those tuples of logics $L_1, \dots, L_n$ for which the converse inclusion also holds are called *product-matching*.

Axiomatising two-dimensional product logics

We begin with a general result of Gabbay and Shehtman [24] stating that certain pairs of modal logics are always product-matching.

Consider the first-order language with equality and a binary predicate R. A formula ψ in this language is called *positive* if it is built up from atoms using only $\wedge$ and $\vee$. A sentence of the form

$$\forall x \forall y \forall \bar{z} \, \big(\psi(x, y, \bar{z}) \to R(x, y)\big)$$

is said to be a *universal Horn sentence* if $\psi(x, y, \bar{z})$ is a positive formula. We call an $\mathcal{ML}$-formula φ a *Horn formula*, if there is a universal Horn sentence φ_H such that, for all frames $\mathfrak{F}$,

$$\mathfrak{F} \models \varphi \qquad \text{iff} \qquad \mathfrak{F} \models \varphi_H.$$

An $\mathcal{ML}$-formula is called *variable free* if it contains no propositional variables, i.e., all its atomic subformulas are constants $\bot$ or $\top$.

DEFINITION 20. A modal logic is called *Horn axiomatisable* if it is axiomatisable by only Horn and variable-free formulas.

It is not hard to see that if L is a Kripke complete and Horn axiomatisable logic then $\mathsf{Fr}L$ is defined by the set

$$\Gamma_L = \{\varphi_H \mid \varphi \text{ is a Horn axiom of } L\} \ \cup \ \{\varphi^\star \mid \varphi \text{ is a variable-free axiom of } L\} \qquad (3)$$

of first-order formulas (here $\varphi^\star$ is the *standard translation* of φ). Examples of Kripke complete Horn axiomatisable logics are **K**, **D**, **K4**, **S4**, **KD45**, **T**, **S5**.

THEOREM 21. *Let L_1 and L_2 be Kripke complete and Horn axiomatisable modal logics. Then*

$$L_1 \times L_2 \ = \ [L_1, L_2].$$

Proof. The heart of the proof is the following lemma that can be proved by constructing the necessary p-morphism in a step-by-step manner, see [23, Lemmas 5.2 and 5.8].

LEMMA 22. *Let L_1 and L_2 be Kripke complete and Horn axiomatisable unimodal logics. Then every countable rooted 2-frame for $[L_1, L_2]$ is a p-morphic image of a product frame for $L_1 \times L_2$.*

Now, by Proposition 19, $[L_1, L_2]$ is determined by the class of commutative and Church–Rosser frames from $\mathsf{Fr}(L_1 \otimes L_2)$. By (3), this class is first-order definable in the language with equality and two binary predicate symbols. Let $\varphi \notin [L_1, L_2]$. Then, using the standard translation $\varphi^\star$ of φ and the downward Löwenheim–Skolem–Tarski theorem, it is not hard to see that we can have a countable rooted 2-frame $\mathfrak{F}$ for $[L_1, L_2]$ refuting φ. Now, using Lemma 22, we can find a product frame $\mathfrak{G}$ for $L_1 \times L_2$ having $\mathfrak{F}$ as its p-morphic image. By Proposition 9, it follows that $\mathfrak{G} \not\models \varphi$, and so $\varphi \notin L_1 \times L_2$. Therefore, $L_1 \times L_2 \subseteq [L_1, L_2]$. The converse inclusion has already been shown as (2). ❑

As a corollary of Theorem 21 we obtain that finite axiomatisability of two Kripke complete and Horn axiomatisable logics transfers to their product. An interesting corollary of Lemma 22 is the following:

COROLLARY 23. *Let L_1, L_2 and L_3 be Kripke complete and Horn axiomatisable unimodal logics. Then*

$$L_1 \times L_2 \times L_3 \;=\; (L_1 \times L_2) \times L_3 \;=\; L_1 \times (L_2 \times L_3).$$

Unfortunately, no other general result is known about axiomatisations of two-dimensional products. In Section 3.4 we shall see several examples of pairs of finitely axiomatisable modal logics whose products are not even recursively enumerable. Such are, for instance, $\mathsf{Log}\{\langle \mathbb{N}, < \rangle\} \times \mathsf{Log}\{\langle \mathbb{N}, < \rangle\}$, $\mathbf{K4} \times \mathbf{GL.3}$ and $\mathbf{S4} \times \mathbf{Grz.3}$.

Moreover, Theorem 21 cannot be generalised even to logics whose classes of frames are definable by *universal* first-order formulas. As the following theorem shows, for many transitive logics L, the pairs of '$\mathbf{K4.3}$ and L' and '$\mathbf{Grz.3}$ and L' are not product-matching:

THEOREM 24. (i) [23] *Let L be any Kripke complete logic containing* $\mathbf{K4}$ *and having the two-element reflexive chain as its frame. Then* $\mathbf{K4.3} \times L \neq [\mathbf{K4.3}, L]$.

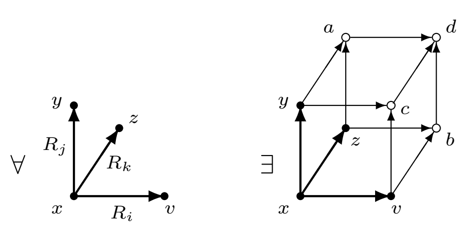
(ii) [24] *Let L_1 be any Kripke complete logic containing* $\mathbf{Grz}$ *and having the two-element reflexive chain as its frame. Let L_2 be any Kripke complete logic containing* $\mathbf{S4}$ *and having either* (a) *the two-element reflexive chain or* (b) *the two-element cluster as its frame. Then* $L_1 \times L_2 \neq [L_1, L_2]$.

There are many open questions in the area. For instance, it is not known whether such 'standard' products like $\mathbf{K4.3} \times \mathbf{K}$ or $\mathbf{K4.3} \times \mathbf{S5}$ or $\mathbf{K4.3} \times \mathbf{K4.3}$ are product-matching, or even finitely axiomatisable (they are recursively enumerable by Theorem 17). In general, no examples for pairs of logics are known that are not product-matching, but whose product is finitely axiomatisable.

Axiomatising higher dimensional product logics

Tuples of more than two modal logics are almost never product-matching. To begin with, it is straightforward to see that all n-dimensional product frames $\langle W, R_1, \dots, R_n \rangle$ satisfy the following 'cubifying' properties whenever $n \geq 3$ and $i, j, k = 1, \dots, n$ are distinct:

$$\begin{aligned}\Phi_{ijk} \;=\; & \forall x, y, z, v \in W \big(xR_iv \wedge xR_jy \wedge xR_kz \;\rightarrow\; \exists a, b, c, d \in W \\ & (vR_jc \wedge vR_kb \wedge yR_ic \wedge yR_ka \wedge zR_ib \wedge zR_ja \wedge aR_id \wedge bR_jd \wedge cR_kd)\big).\end{aligned}$$



It is not hard to see that, say, a 3-frame $\mathfrak{F}$ for $[\mathbf{K}, \mathbf{K}, \mathbf{K}]$ satisfies property Φ_{123} iff the following modal formula $\boldsymbol{cub}_{123}$ is valid in $\mathfrak{F}$ (cf. [39, 3.2.67] and [52]):

$$\begin{aligned}\boldsymbol{cub}_{123} \;=\; & [\Diamond_1(\Box_2 p_{12} \wedge \Box_3 p_{13}) \;\wedge\; \Diamond_2(\Box_1 p_{21} \wedge \Box_3 p_{23}) \;\wedge\; \Diamond_3(\Box_1 p_{31} \wedge \Box_2 p_{32}) \\ & \wedge\; \Box_1\Box_2(p_{12} \wedge p_{21} \rightarrow \Box_3 q_3) \;\wedge\; \Box_1\Box_3(p_{13} \wedge p_{31} \rightarrow \Box_2 q_2) \\ & \wedge\; \Box_2\Box_3(p_{23} \wedge p_{32} \rightarrow \Box_1 q_1)] \;\longrightarrow\; \Diamond_1\Diamond_2\Diamond_3(q_1 \wedge q_2 \wedge q_3)\,.\end{aligned}$$

Thus $\boldsymbol{cub}_{123}$ belongs to $\mathbf{K}^3$. On the other hand, Fig. 3 shows a 23-element frame for $[\mathbf{K}, \mathbf{K}, \mathbf{K}]$ (that is, a 3-frame satisfying $\boldsymbol{com}_{ij}$ and $\boldsymbol{chr}_{ij}$ for $i, j = 1, 2, 3$, $i \neq j$) that refutes $\boldsymbol{cub}_{123}$ (see again [39, 3.2.67]). So $[\mathbf{K}, \mathbf{K}, \mathbf{K}]$ and $\mathbf{K}^3$ are different.

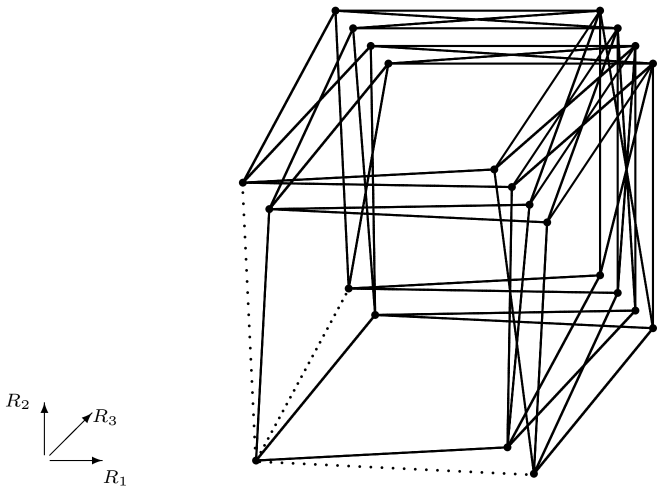


Figure 3. A frame for $[\mathbf{K}, \mathbf{K}, \mathbf{K}]$ that refutes $\boldsymbol{cub}_{123}$.

Moreover, in many cases the addition of cubifying properties does not help either. As is shown by Johnson [44] in the algebraic setting of diagonal-free cylindric algebras, $\mathbf{S5}^n$ is not finitely axiomatisable whenever $n \geq 3$. Generalisations of the cubifying properties are used in [52] to show that $\mathbf{K}^n$ is not finitely axiomatisable either for $n \geq 3$. Moreover, the following general result of [42] shows how hopeless the situation really is:

THEOREM 25. *Let $n \geq 3$ and let L be any n-modal logic such that $\mathbf{K}^n \subseteq L \subseteq \mathbf{S5}^n$. Then L is not finitely axiomatisable. Moreover, it is undecidable whether a finite n-frame is a frame for L.*

On the other hand, if frames for the component logics do not allow branching (like in the functional frames for **Alt**), then counterexamples like the above one do not work, and in fact the cubifying properties follow from the Church–Rosser properties. The following result of [24] says that any tuple of **Alt** logics is product-matching. It can be proven in a way similar to the proof of Theorem 21 above.

THEOREM 26. *For any natural number $n > 1$,* $\mathbf{Alt}^n = \overbrace{[\mathbf{Alt}, \ldots, \mathbf{Alt}]}^{n}$.

There are several interesting open questions concerning the axiomatisation of higher (≥ 3) dimensional product logics. For instance, it is not known whether logics like $\mathbf{K}^n$ or $\mathbf{S5}^n$ are axiomatisable using finitely many propositional variables, or whether $\mathbf{S5}^n$ is finitely axiomatisable over $\mathbf{K}^n$. Though logics like $\mathbf{K}^n$ or $\mathbf{S5}^n$ are known to be recursively enumerable by Theorem 17, no intuitive 'concrete' axiomatisation is known for most of them.

3.4 Decision problems and complexity of products

There are three basic approaches to establishing decidability of modal logics:

(1) Given such a logic L, one can try to prove that L has the finite model property (fmp). Even without a recursive bound on the size of the models, this can yield decidability if L is recursively enumerable, and the class of finite frames for L is recursively enumerable as well (up to isomorphism, of course). This is the case for instance if L is finitely axiomatisable.

(2) Even if a logic L does not enjoy the fmp, then one can try to show that it is characterised by some class of perhaps infinite models having a certain 'regular structure,' say, constructed from repeating finite pieces, so called 'blocks' or 'mosaics.'

(3) The third approach is to try to reduce the decision problem for L to another problem that is already known to be decidable (say, to the decision problem for another modal logic, or a suitable monadic second-order theory, or some problem about tree automata).

All three approaches have been successfully applied to uni- and multimodal logics; see e.g., [22, 12, 90]. As products of modal logics are special multimodal logics, in principle the same approaches can be applied to them as well.

As concerns (1), there is an even more tempting way. One can try to show the finite model property w.r.t. the 'intended' models, that is, those that are based on product frames. (It is important to stress that in general there are frames for product logics which are *not* product frames.)

DEFINITION 27. A modal logic L has the *product fmp* if L is characterised by the class of its finite product frames.

Note that by Proposition 14, for every product frame $\mathfrak{F} = \mathfrak{F}_1 \times \cdots \times \mathfrak{F}_n$ and product logic $L = L_1 \times \cdots \times L_n$,

$$\mathfrak{F} \models L \quad \text{iff} \quad \mathfrak{F}_i \models L_i, \text{ for all } 1 \leq i \leq n.$$

Obviously, the product fmp implies the fmp. As we shall see below, the converse does not necessarily hold.

We can enumerate the formulas that are not in a product logic L (and thereby obtain a decision algorithm for L whenever L is recursively enumerable) if

- L has the product fmp, and
- finite product frames for L are recursively enumerable (up to isomorphism).

The latter property clearly holds if L is a product of finitely axiomatisable Kripke complete logics such as **K**, **K4**, **K4.3**, **S5**, etc., so this approach looks very promising. Unfortunately, it is easy to see that most products of well-known unimodal logics lack the product fmp. Here is an example for a simple bimodal formula that 'forces' infinite product frames even for logics like **K4** $\times$ **K** or **K4** $\times$ **S5**:

$$\Box_1^+ \Diamond_2 p \wedge \Box_1^+ \Box_2 (p \to \Diamond_1 \Box_1^+ \neg p) \tag{4}$$

(here $\Box_1^+ \psi$ abbreviates $\psi \wedge \Box_1 \psi$). However, as we shall see below, two-dimensional product logics with at least one $\mathbf{S5}_n$- or $\mathbf{K}_n$-component can have the (usual, 'abstract') fmp.

Products with '$\mathbf{S5}_n$- and $\mathbf{K}_n$-like' logics are usually decidable

Filtration.

Originating in the 1940s, the *filtration method* is one of the oldest and most well-known techniques for finite model property proofs in modal logic. Here we discuss how it can be used to show the fmp of two-dimensional product logics where one component is a special kind of Horn axiomatisable logic and the other is $\mathbf{S5}_n$ or $\mathbf{K}_n$.

A *QTC-logic* is a modal logic axiomatised by a finite set of formulas where each axiom is either variable-free or of the form

$$\Box_i p \to \Box_i^j p \quad (j \geq 0) \qquad \text{or} \qquad \Diamond_k \Box_k p \to p.$$

The following theorem is due to Shehtman [76]:

THEOREM 28. *Let L_1 be a QTC-logic and L_2 be either $\mathbf{S5}_n$ or $\mathbf{K}_n$. Then $L_1 \times L_2$ has the fmp.*

As it is easy to see that every QTC-logic is Horn axiomatisable, by Theorem 21 we obtain:

THEOREM 29. *Let L_1 be a QTC-logic and L_2 be either $\mathbf{S5}_n$ or $\mathbf{K}_n$. Then $L_1 \times L_2$ is decidable.*

Proof. We illustrate the proof of Theorem 28 by showing that $\mathbf{K4} \times \mathbf{K}$ has the fmp. Suppose $\varphi \notin \mathbf{K4} \times \mathbf{K}$ for some $\mathcal{ML}_2$-formula φ. We will construct a model refuting φ that is based on a finite frame for $[\mathbf{K4}, \mathbf{K}]$. As $[\mathbf{K4}, \mathbf{K}] = \mathbf{K4} \times \mathbf{K}$ by Theorem 21, this would suffice.

As is well-known, every rooted Kripke frame is a p-morphic image of an intransitive tree. Therefore, by Propositions 9 and 12, we may assume that there exists a model $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ refuting φ and based on the product $\mathfrak{F} = \langle W, \bar{R}_1, \bar{R}_2 \rangle$ of a transitive frame and an intransitive tree of depth $md(\varphi)$. Thus, $\langle W, \bar{R}_1 \rangle$ is transitive, $\langle W, \bar{R}_2 \rangle$ is the disjoint union of intransitive trees of depth $md(\varphi)$, and $\bar{R}_1$ and $\bar{R}_2$ have the commutativity and Church–Rosser properties. For each $x \in W$, let $tree(x) = \langle W_x, \bar{R}_{2,x} \rangle$ denote the intransitive tree x belongs to.

We define an equivalence relation $\sim$ on W. For all $x, y \in W$, let $x \sim y$ iff there exists a relation $E \subseteq W_x \times W_y$ satisfying the following properties:

- xEy
- for every $u \in W_x$ there is $v \in W_y$ such that uEv,
- for every $u \in W_y$ there is $v \in W_x$ such that uEv,
- for all $u \in W_x$, $v, z \in W_y$,
  - if uEv and $v\bar{R}_{2,y}z$ then there is $z' \in W_x$ such that $u\bar{R}_{2,x}z'$ and $z'Ez$,
  - if uEv and $z\bar{R}_{2,y}v$ then there is $z' \in W_x$ such that $z\bar{R}_{2,x}u$ and $z'Ez$,
- for all $u \in W_y$, $v, z \in W_x$,
  - if uEv and $v\bar{R}_{2,x}z$ then there is $z' \in W_y$ such that $u\bar{R}_{2,y}z'$ and $z'Ez$,
  - if uEv and $z\bar{R}_{2,x}v$ then there is $z' \in W_y$ such that $z\bar{R}_{2,y}u$ and $z'Ez$,

- for all $u \in W_x$, $v \in W_y$, and propositional variables $p \in sub\,\varphi$, $u \in \mathfrak{V}(p)$ iff $v \in \mathfrak{V}(p)$.

(In other words, E should be a bisimulation between $\langle W_x, \bar{R}_{2,x}, \bar{R}_{2,x}^{-1}\rangle$ and $\langle W_y, \bar{R}_{2,y}, \bar{R}_{2,y}^{-1}\rangle$ w.r.t. $sub\,\varphi$ that connects x and y.)

Now we define a new model $\mathfrak{M}^{\sim} = \langle \mathfrak{F}^{\sim}, \mathfrak{V}^{\sim}\rangle$ based on $\mathfrak{F}^{\sim} = \left\langle W^{\sim}, \bar{R}_1^{\sim}, \bar{R}_2^{\sim}\right\rangle$ as follows:

- $W^{\sim} = \{[x] \mid x \in W\}$, where $[x]$ denotes the $\sim$-equivalence class of x;
- for all $x, y \in W$,
$$[x]\bar{R}_2^{\sim}[y] \qquad \text{iff} \qquad \exists x'\exists y'\ (x' \sim x,\ y' \sim y \text{ and } x'\bar{R}_2 y');$$
- $\bar{R}_1^{\sim}$ is the transitive closure of the relation $\bar{R}_1^{\bullet}$ defined by taking, for all $x, y \in W$,
$$[x]\bar{R}_1^{\bullet}[y] \qquad \text{iff} \qquad \exists x'\exists y'\ (x' \sim x,\ y' \sim y \text{ and } x'\bar{R}_1 y');$$
- $\mathfrak{V}^{\sim}(p) = \{[x] \mid x \in \mathfrak{V}(p)\}$, for all $p \in sub\,\varphi$, and $\mathfrak{V}^{\sim}(q) = \emptyset$, for all other propositional variables q.

We claim that

$$\mathfrak{M}^{\sim} \text{ refutes } \varphi, \text{ and} \tag{5}$$
$$\left\langle W^{\sim}, \bar{R}_1^{\sim}, \bar{R}_2^{\sim}\right\rangle \text{ is a finite frame for } [\mathbf{K4}, \mathbf{K}]. \tag{6}$$

Claim (5) follows from the fact that $\mathfrak{M}^{\sim}$ is a *filtration* of $\mathfrak{M}$ in the sense that, for all $x, y \in W$, $i = 1, 2$, the following two conditions hold:

- if $x\bar{R}_i y$ then $[x]\bar{R}_i^{\sim}[y]$,
- if $[x]\bar{R}_i^{\sim}[y]$ then $(\mathfrak{M}, y) \models \psi$ whenever $\Box_i\psi \in sub\,\varphi$ and $(\mathfrak{M}, x) \models \Box_i\psi$.

($\bar{R}_2^{\sim}$ and $\bar{R}_1^{\sim}$ are known as the *least filtration* and the *Lemmon* (or *least transitive*) *filtration*, respectively; see e.g., [12, 31].) By induction on the construction of ψ, the reader can readily check that for every $\psi \in sub\,\varphi$ and every $x \in W$,

$$(\mathfrak{M}, x) \models \psi \qquad \text{iff} \qquad (\mathfrak{M}^{\sim}, [x]) \models \psi,$$

which yields (5).

To prove (6), observe first that $\bar{R}_1^{\sim}$ is transitive by definition. Using the definition of $\sim$, it is straightforward to show that $\sim$ commutes with $\bar{R}_2$. Then this fact can be used to show that $\bar{R}_1^{\sim}$ and $\bar{R}_2^{\sim}$ commute and have the Church–Rosser property.

Finally, we show that $W^{\sim}$ is finite. Observe first that since bisimilar paths are of equal length, if $x \sim y$ then both the depth and the co-depth of x and y (in the trees *tree*(x) and *tree*(y), respectively) are the same. Moreover, for all x, y, z, if $[x]\bar{R}_2^{\sim}[y]$, $[x]\bar{R}_2^{\sim}[z]$ and $y \not\sim z$ then the submodels generated by $[y]$ and $[z]$ in $\mathfrak{M}^{\sim}$ are not isomorphic (as far as propositional variables occurring in φ are concerned). So we have

$$|W^{\sim}| \ \leq \ \sum_{k=0}^{md(\varphi)} n_k(\varphi), \tag{7}$$

where $n_0(\varphi) = 2^{|sub\,\varphi|}$ and $n_{k+1}(\varphi) = 2^{|sub\,\varphi|} \cdot 2^{n_k(\varphi)}$. ❑

Observe that the bound in (7) is non-elementary in the size of φ. In fact, it is not known whether there exists an elementary decision algorithm for $\mathbf{K}\times\mathbf{K}$ or $\mathbf{K4}\times\mathbf{K}$. Note however that products of $\mathbf{K}$ with 'richer' dynamic and temporal logics, such as $\mathbf{PDL}\times\mathbf{K}$ and $\mathbf{PTL}\times\mathbf{K}$ are known to be non-elementary; see [23]. The same applies to products with $\mathbf{S5}_n$ whenever $n \geq 2$.

On the other hand, if one component-logic is not $\mathbf{K}$ but (unimodal) $\mathbf{S5}$, then one can do better. As is shown by Gabbay and Shehtman [24], in these cases the equivalence relation $\sim$ on worlds becomes more easily 'characterisable'. Namely, for each world x in W, let

$$\Sigma(x) = \{\psi \in sub\,\varphi \mid (\mathfrak{M}, x) \models \psi\},$$

and for $x, y \in W$, put

$$x \sim y \qquad \text{iff} \qquad \Sigma(x) = \Sigma(y) \ \text{ and } \ \{\Sigma(z) \mid x\bar{R}_2 z\} = \{\Sigma(z) \mid y\bar{R}_2 z\}.$$

As now each world $[x]$ in $\mathfrak{M}^{\sim}$ is uniquely determined by the pair $\big\langle \Sigma(x), \{\Sigma(z) \mid x\bar{R}_2 z\}\big\rangle$ of sets, we have the better, double-exponential bound

$$|W^{\sim}| \ \leq \ 2^{|sub\,\varphi|} \cdot 2^{2^{|sub\,\varphi|}}$$

on the size of the filtrated model. So the filtration method yields a coN2EXPTIME decision algorithm for products of QTC-logics with $\mathbf{S5}$.

Quasimodels.

If L is Kripke complete but not a QTC-logic then $L \times \mathbf{K}_n$ and $L \times \mathbf{S5}_n$ are out of the scope of Theorem 28. Yet, many of these products can be shown to be decidable by the *quasimodel method*. This method was first developed in the series of papers [84, 85, 86, 88] on description logics with various modal and temporal operators, and then extended to products in [83, 23] and to fragments of first-order modal and temporal logics in [87, 43, 89].

The idea is to finitise the '$\mathbf{K}_n$- (or $\mathbf{S5}_n$-)bit' of the models first, then build some kind of structure that manages to keep enough information about its 'two-dimensional' character on the one hand, and can be used to prove decidability (even if it is not necessarily finite) on the other.

We fix a Kripke complete modal logic L and an $\mathcal{ML}_2$-formula φ, and define the notion of an $L \times \mathbf{K}$-*quasimodel for* φ as follows. By a *type* for φ we mean any subset $\boldsymbol{t}$ of $sub\,\varphi$ which is *Boolean-saturated* (in the sense that, for instance,

- $\psi \wedge \chi \in \boldsymbol{t}$ iff $\psi \in \boldsymbol{t}$ and $\chi \in \boldsymbol{t}$, for every $\psi \wedge \chi \in sub\,\varphi$,
- $\neg\psi \in \boldsymbol{t}$ iff $\psi \notin \boldsymbol{t}$, for every $\neg\psi \in sub\,\varphi$,

and so on for the other Boolean connectives). A *quasistate candidate* for φ is a pair $\langle\langle T, <\rangle, \boldsymbol{t}\rangle$, where $\langle T, <\rangle$ is a finite intransitive tree of depth $\leq md(\varphi)$ and $\boldsymbol{t}$ a labeling function associating with each $x \in T$ a type $\boldsymbol{t}(x)$ for φ. (So we can think of a quasistate candidate as a tree of types.) Two quasistate candidates $\langle\langle T, <\rangle, \boldsymbol{t}\rangle$ and $\langle\langle T', <'\rangle, \boldsymbol{t}'\rangle$ are called *isomorphic* if there is an isomorphism f between the trees $\langle T, <\rangle$ and $\langle T', <'\rangle$ such that $\boldsymbol{t}(x) = \boldsymbol{t}'(f(x))$, for all $x \in T$. A quasistate candidate $\langle\langle T, <\rangle, \boldsymbol{t}\rangle$ is called a *quasistate* for φ if the following conditions hold:

(qm1) ($\Diamond_2$-*saturation*) For all $x \in T$ and $\Diamond_2\psi \in sub\,\varphi$,

$$\Diamond_2\psi \in \boldsymbol{t}(x) \quad \text{iff} \quad \exists y \in T\ \big(x < y\ \wedge\ \psi \in \boldsymbol{t}(y)\big).$$

(qm1′) (*smallness*) For all $x, x_1, x_2 \in T$ such that $x < x_1$, $x < x_2$ and $x_1 \neq x_2$, the structures $\langle\langle T^{x_1}, <^{x_1}\rangle, \boldsymbol{t}^{x_1}\rangle$ and $\langle\langle T^{x_2}, <^{x_2}\rangle, \boldsymbol{t}^{x_2}\rangle$ are not isomorphic,

where $\langle T^{x_i}, <^{x_i}\rangle$ is the subtree of $\langle T, <\rangle$ generated by x_i, and $\boldsymbol{t}^{x_i}$ is the restriction of $\boldsymbol{t}$ to T^{x_i}, $i = 1, 2$. Clearly,

$$b(\varphi) = \sum_{k=0}^{md(\varphi)} n_k(\varphi) \tag{8}$$

is an upper bound for the number of different quasistates for φ (cf. (7)). The number of points in any quasistate for φ is bounded by

$$n_0(\varphi) + \sum_{k=1}^{md(\varphi)} \prod_{j=1}^{k} n_{md(\varphi)-j}(\varphi) \leq b(\varphi)^{md(\varphi)}.$$

In what follows, we assume that nonisomorphic quasistates are disjoint and that isomorphic quasistates actually coincide.

A *basic structure* of depth m for φ is a pair $\langle \mathfrak{F}, \boldsymbol{q}\rangle$ such that $\mathfrak{F} = \langle W, R\rangle$ is a frame for L and $\boldsymbol{q}$ a function associating with each $w \in W$ a quasistate $\boldsymbol{q}(w) = \langle\langle T_w, <_w\rangle, \boldsymbol{t}_w\rangle$ for φ such that the depth of each $\langle T_w, <_w\rangle$ is m.

Let $\langle \mathfrak{F}, \boldsymbol{q}\rangle$ be a basic structure for φ of depth m and let $k \leq m$. A *k-run through* $\langle \mathfrak{F}, \boldsymbol{q}\rangle$ is a function r giving for each $w \in W$ a point $r(w) \in T_w$ of depth k. (That is, a run 'goes along' the frame $\mathfrak{F}$ and chooses a (location of a) type of the same depth from each type-tree $\langle T_w, <_w\rangle$.) Given a set $\mathfrak{R}$ of runs, we denote by $\mathfrak{R}_k$ the set of all k-runs from $\mathfrak{R}$. Clearly, if $\mathfrak{R}_0$ is not empty, then it is a singleton set, with its only member r_0 being the run through the roots of the quasistates.

A run r is called *coherent* if

$$\forall w \in W\, \forall \Diamond_1\psi \in sub\,\varphi\ \Big(\exists v \in W\ \big(wRv\ \wedge\ \psi \in \boldsymbol{t}_v(r(v))\big)\ \rightarrow\ \Diamond_1\psi \in \boldsymbol{t}_w(r(w))\Big),$$

and *saturated* if

$$\forall w \in W\, \forall \Diamond_1\psi \in sub\,\varphi\ \Big(\Diamond_1\psi \in \boldsymbol{t}_w(r(w))\ \rightarrow\ \exists v \in W\ \big(wRv\ \wedge\ \psi \in \boldsymbol{t}_v(r(v))\big)\Big).$$

Finally, we say that a quadruple $\mathfrak{Q} = \langle \mathfrak{F}, \boldsymbol{q}, \mathfrak{R}, \lhd\rangle$ is an $L \times \mathbf{K}$-*quasimodel for* φ (*based on* $\mathfrak{F}$) if $\mathfrak{F}$ is a frame for L, $\langle \mathfrak{F}, \boldsymbol{q}\rangle$ is a basic structure for φ of depth $m \leq md(\varphi)$ such that

(qm2) $\exists w_0 \in W\ \varphi \in \boldsymbol{t}_{w_0}(x_0)$, where x_0 is the root of $\langle T_{w_0}, <_{w_0}\rangle$,

$\mathfrak{R}$ is a set of coherent and saturated runs through $\langle \mathfrak{F}, \boldsymbol{q}\rangle$, and $\lhd$ is a binary relation on $\mathfrak{R}$ satisfying the following conditions:

(qm3) for all $r, r' \in \mathfrak{R}$, if $r \lhd r'$ then $r(w) <_w r'(w)$ for all $w \in W$;

(qm4) $\mathfrak{R}_0 \neq \emptyset$, and for all $k < m$, $r \in \mathfrak{R}_k$, $w \in W$ and $x \in T_w$, if $r(w) <_w x$ then there is $r' \in \mathfrak{R}_{k+1}$ such that $r'(w) = x$ and $r \lhd r'$.

Now, having the notion of a quasimodel been defined, what we need is the 'quasimodel truth-lemma:'

LEMMA 30. *Given a Kripke complete modal logic L, an $\mathcal{ML}_2$-formula φ is satisfiable in a product frame $\mathfrak{F} \times \mathfrak{G}$ for $L \times \mathbf{K}$ iff there is an $L \times \mathbf{K}$-quasimodel for φ based on $\mathfrak{F}$.*

Proof. ($\Leftarrow$) Suppose $\langle \mathfrak{F}, \boldsymbol{q}, \mathfrak{R}, \lhd \rangle$ is an $L \times \mathbf{K}$-quasimodel for φ. Take the product frame $\mathfrak{F} \times \langle \mathfrak{R}, \lhd \rangle$ and define a valuation $\mathfrak{V}$ in it as follows:

$$\mathfrak{V}(p) = \{ \langle w, r \rangle \mid p \in \boldsymbol{t}_w(r(w)) \}$$

for every propositional variable p. Let $\mathfrak{M} = \langle \mathfrak{F} \times \langle \mathfrak{R}, \lhd \rangle, \mathfrak{V} \rangle$. One can show by an easy induction on the construction of $\psi \in sub\,\varphi$ that for every $\langle w, r \rangle$ in $\mathfrak{M}$ we have

$$(\mathfrak{M}, \langle w, r \rangle) \models \psi \quad \text{iff} \quad \psi \in \boldsymbol{t}_w(r(w)).$$

In view of **(qm2)** and $\mathfrak{R}_0 \neq \emptyset$ (which we have by **(qm4)**), it follows that φ is satisfied in $\mathfrak{M}$.

($\Rightarrow$) Suppose that φ is satisfied in a model $\mathfrak{M}$ based on the product $\mathfrak{F} \times \mathfrak{G}$ of frames $\mathfrak{F} = \langle W, R \rangle$ and $\mathfrak{G} = \langle \Delta, < \rangle$. By Proposition 9 (i), we may assume that $\mathfrak{G}$ is an intransitive tree of depth $m \leq md(\varphi)$ and $(\mathfrak{M}, \langle w_0, x_0 \rangle) \models \varphi$ for some $w_0 \in W$, with x_0 being the root of $\mathfrak{G}$. With every pair $\langle w, x \rangle \in W \times \Delta$ we associate the type

$$\boldsymbol{t}(w, x) = \{ \psi \in sub\,\varphi \mid (\mathfrak{M}, \langle w, x \rangle) \models \psi \}.$$

Now we have to construct a quasistate $\langle \langle T_w, <_w \rangle, \boldsymbol{t}_w \rangle$ for each $w \in W$. The obvious choice of $T_w = \Delta$, $<_w = <$ and $\boldsymbol{t}_w(x) = \boldsymbol{t}(w, x)$ does not work, because Δ can be infinite. So let us make it finite in such a way that the resulting structure still satisfies **(qm1)** and also complies with the smallness condition **(qm1′)**. Fix a $w \in W$ and define a binary relation $\sim_w$ on Δ as follows. If $x, y \in \Delta$ are of co-depth 0 (i.e., they are leaves of $\mathfrak{G}$) then

$$x \sim_w y \quad \text{iff} \quad \boldsymbol{t}(w, x) = \boldsymbol{t}(w, y).$$

For $x, y \in \Delta$ of co-depth k ($0 < k \leq md(\varphi)$), let

$$\begin{aligned} x \sim_w y \quad \text{iff} \quad \boldsymbol{t}(w, x) = \boldsymbol{t}(w, y) \quad & \text{and} \;\; \forall z \in \Delta \big(x < z \;\rightarrow\; \exists z' \in \Delta \, (y < z' \wedge z \sim_w z') \big) \\ & \text{and} \;\; \forall z \in \Delta \big(y < z \;\rightarrow\; \exists z' \in \Delta \, (x < z' \wedge z \sim_w z') \big). \end{aligned}$$

Clearly $\sim_w$ is an equivalence relation on Δ. Denote by $[x]_w$ the $\sim_w$-equivalence class of x and put

$$\begin{aligned} &\Delta_w = \{ [x]_w \mid x \in \Delta \}, \\ &[x]_w R_w [y]_w \quad \text{iff} \quad \exists y' \in [y]_w \; x < y', \\ &\boldsymbol{l}_w([x]_w) = \boldsymbol{t}(w, x). \end{aligned}$$

The structure $\langle \langle \Delta_w, R_w \rangle, \boldsymbol{l}_w \rangle$ is almost a quasistate, just $\langle \Delta_w, R_w \rangle$ is not necessarily a tree. The tree $\langle T_w, <_w \rangle$ we need can be obtained by unraveling $\langle \Delta_w, R_w \rangle$:

$$\begin{aligned} &T_w = \{ \langle [x_0]_w, \dots, [x_k]_w \rangle \mid k \leq m, \; [x_0]_w R_w [x_1]_w R_w \dots R_w [x_k]_w \}, \\ &u <_w v \quad \text{iff} \quad u = \langle [x_0]_w, \dots, [x_k]_w \rangle, \quad v = \langle [x_0]_w, \dots, [x_k]_w, [x_{k+1}]_w \rangle \\ &\qquad\qquad\quad \text{and} \;\; [x_k]_w R_w [x_{k+1}]_w. \end{aligned}$$

Finally, let $\boldsymbol{t}_w(\langle [x_0]_w, \ldots, [x_k]_w\rangle) = \boldsymbol{l}_w([x_k]_w) = \boldsymbol{t}(w, x_k)$. It is not hard to see that, for any $w \in W$, $\langle\langle T_w, <_w\rangle, \boldsymbol{t}_w\rangle$ is a quasistate for φ. Moreover, by taking $\boldsymbol{q}(w) = \langle\langle T_w, <_w\rangle, \boldsymbol{t}_w\rangle$ for each $w \in W$, we obtain a basic structure $\langle \mathfrak{F}, \boldsymbol{q}\rangle$ for φ satisfying **(qm2)**.

It remains to define appropriate runs through $\langle \mathfrak{F}, \boldsymbol{q}\rangle$. To this end, for each $k \leq m$ and each sequence $\langle x_0, \ldots, x_k\rangle$ of points in Δ such that $x_0 < \cdots < x_k$, take the map

$$r : w \mapsto \langle [x_0]_w, \ldots, [x_k]_w\rangle ,$$

and let $\mathfrak{R}$ be the set of all such maps. For $r, r' \in \mathfrak{R}$, let $r \lhd r'$ iff $r(w) <_w r'(w)$ for all $w \in W$. It is straightforward to check that $\langle \mathfrak{F}, \boldsymbol{q}, \mathfrak{R}, \lhd\rangle$ is an $L \times \mathbf{K}$-quasimodel for φ. ❑

Note that $L \times \mathbf{S5}$-quasimodels are considerably simpler than $L \times \mathbf{K}$-quasimodels: instead of trees of types it is enough to consider *sets* of types only as quasistates. Similarly to the filtration case, this results in better upper bounds on the size of the constructed structures. On the other hand, $L \times \mathbf{K}_n$- and $L \times \mathbf{S5}_n$-quasimodels (for $n \geq 2$) are similar to the above complex ones, and one even has to take into account the several different accessibility relations when defining quasistates.

Although quasistates in quasimodels are always finite, quasimodels themselves are usually infinite (since the frame $\mathfrak{F}$ can be infinite). Depending on the component logics in question, there can be several ways of using them to prove decidability of products:

- In the simplest cases one can manage to find a finite quasimodel for φ and then to construct a finite product model out of it, thereby showing that the logic has the product fmp. This can be done in the case of $\mathbf{K} \times \mathbf{K}$. Moreover, for $\mathbf{S5} \times \mathbf{S5}$ and $\mathbf{K} \times \mathbf{S5}$ the resulting product model is of exponential size (see Chapter 3 of this handbook), so these logics are decidable in coNEXPTIME.

- In some cases, it can be shown that there is a quasimodel for φ iff there exists a *finite* set $\mathcal{S}$ of *finite* 'partial' quasimodels (called *blocks* or *mosaics*) satisfying some effectively checkable conditions and that the cardinality of $\mathcal{S}$ as well as the size of each block in it do not exceed a number effectively computable from φ. The 'effectively checkable conditions' are supposed to guarantee that blocks can be used as 'small mosaic pieces' to construct the quasimodel we need.

- In some cases, the statement that a quasimodel exists can be translated into monadic second-order logic or reduced to other known decidable problems.

Here we illustrate the second and the third techniques by showing—in two different ways—that $\mathbf{K4.3} \times \mathbf{K}$ is decidable. Note that the formula (4) shows that this logic lacks the product fmp, and it is not known whether it has the fmp.

Quasimodels and mosaics.

Throughout, we fix an $\mathcal{ML}_2$-formula φ. A *block for* φ is a quadruple

$$\mathfrak{B}^{uv} = \langle \mathfrak{F}^{uv}, \boldsymbol{q}^{uv}, \mathfrak{R}^{uv}, \lhd^{uv}\rangle$$

such that

- $\mathfrak{F}^{uv} = \langle \{u, v\}, <\rangle$ is a 2-element strict linear order with $u < v$,

- $\langle \mathfrak{F}^{uv}, \boldsymbol{q}^{uv}\rangle$ is a basic structure for φ of depth m, for some $m \leq md(\varphi)$,

- $\mathfrak{R}^{uv}$ is a set of runs through $\langle \mathfrak{F}^{uv}, \boldsymbol{q}^{uv} \rangle$ such that, for all $r \in \mathfrak{R}^{uv}$ and $\Diamond_1 \psi \in sub\,\varphi$,
$$\text{if } \psi \in \boldsymbol{t}_v(r(v)) \text{ or } \Diamond_1\psi \in \boldsymbol{t}_v(r(v)) \text{ then } \Diamond_1\psi \in \boldsymbol{t}_u(r(u)),$$
- $\lhd^{uv}$ is a binary relation on $\mathfrak{R}^{uv}$ satisfying **(qm3)** and **(qm4)**.

We remind the reader that quasistates occurring in such a block are denoted by
$$\boldsymbol{q}^{uv}(u) = \langle \langle T_u, <_u \rangle, \boldsymbol{t}_u \rangle \quad \text{and} \quad \boldsymbol{q}(v)^{uv} = \langle \langle T_v, <_v \rangle, \boldsymbol{t}_v \rangle .$$

Observe that a block is almost a **K4.3** $\times$ **K**-quasimodel. The only thing missing is that its runs are (though coherent) not necessarily saturated. That is why we need an appropriate collection of blocks: By sticking them properly together, we can 'fix the defects' and converge to a real quasimodel.

To this end, we call a set $\mathcal{S}$ of blocks for φ *satisfying* if the following properties hold:

(ssb1) all blocks in $\mathcal{S}$ are of the same depth m, for some $m \leq md(\varphi)$;

(ssb2) $\mathcal{S}$ contains a block satisfying **(qm2)**;

(ssb3) for every $\mathfrak{B}^{uv}$ in $\mathcal{S}$, if $\Diamond_1\psi \in \boldsymbol{t}_v(r(v))$ for some run $r \in \mathfrak{R}^{uv}$ then there exist a block $\mathfrak{B}^{vw}$ in $\mathcal{S}$ and a sequence $\langle x_s \in T_w \mid s \in \mathfrak{R}^{uv} \rangle$ of points in T_w such that

- $\boldsymbol{q}^{uv}(v) = \boldsymbol{q}^{vw}(v)$,
- for every $s \in \mathfrak{R}^{uv}$, the function p defined by $p(v) = s(v)$, $p(w) = x_s$ is a run in $\mathfrak{R}^{vw}$,
- for all $s, s' \in \mathfrak{R}^{uv}$, if $s \lhd^{uv} s'$ then $x_s <_w x_{s'}$,
- $\psi \in \boldsymbol{t}_w(x_r)$;

(ssb4) for every block $\mathfrak{B}^{uv}$ in $\mathcal{S}$, if $\Diamond_1\psi \in \boldsymbol{t}_u(r(u))$, $\psi \notin \boldsymbol{t}_v(r(v))$ and $\Diamond_1\psi \notin \boldsymbol{t}_v(r(v))$ for some run $r \in \mathfrak{R}^{uv}$ then there are blocks $\mathfrak{B}^{uw}$ and $\mathfrak{B}^{wv}$ in $\mathcal{S}$ and a sequence $\langle x_s \in T_w \mid s \in \mathfrak{R}^{uv} \rangle$ of points in T_w such that

- $\boldsymbol{q}^{uv}(u) = \boldsymbol{q}^{uw}(u)$, $\boldsymbol{q}^{uw}(w) = \boldsymbol{q}^{wv}(w)$, $\boldsymbol{q}^{wv}(v) = \boldsymbol{q}^{uv}(v)$,
- for every $s \in \mathfrak{R}^{uv}$, the function p' defined by $p'(u) = s(u)$, $p'(w) = x_s$ is a run in $\mathfrak{R}^{uw}$, and the function p'' defined by $p''(w) = x_s$, $p''(v) = s(v)$ is a run in $\mathfrak{R}^{wv}$,
- for all $s, s' \in \mathfrak{R}^{uv}$, if $s \lhd^{uv} s'$ then $x_s <_w x_{s'}$,
- $\psi \in \boldsymbol{t}_w(x_r)$.

On the one hand, it is straightforward to see that one can effectively check whether there exists a satisfying set of blocks for φ. On the other hand, it is well-known that every rooted frame for **K4.3** is a p-morphic image of a sufficiently large strict linear order, so by Propositions 9 and 12, **K4.3** $\times$ **K** is determined by product frames whose first component is a strict linear order. As satisfiability in a single element strict linear order is trivially decidable, to establish the decidability of **K4.3** $\times$ **K**, it is enough to prove the following 'block lemma:'

LEMMA 31. *There is a* $\mathbf{K4.3} \times \mathbf{K}$*-quasimodel for* φ *based on a strict linear order with* ≥ 2 *elements iff there is a satisfying set of blocks for* φ.

Proof. The construction of a satisfying set from a quasimodel is easy. Suppose that $\mathfrak{Q} = \langle \mathfrak{F}, \boldsymbol{q}, \mathfrak{R}, \lhd \rangle$ is a quasimodel for φ, with $\mathfrak{F} = \langle W, R \rangle$ being a strict linear order with ≥ 2 elements. For all $u, v \in W$ such that uRv, define the *restriction* $\mathfrak{Q}^{uv}$ of $\mathfrak{Q}$ to the 2-element strict linear order on $\{u, v\}$ in the natural way. It is straightforward to check that these $\mathfrak{Q}^{uv}$ are blocks and that the collection $\mathcal{S}$ of them is a satisfying set.

Now we show how a quasimodel for φ can be constructed from a satisfying set $\mathcal{S}$ of blocks for φ. Starting from a block satisfying **(qm2)**, we will build a series of larger and larger quasimodel-like structures having not necessarily saturated runs. The 'defects' of these runs are 'corrected' one by one in such a way that the sequence of structures 'converges' to a quasimodel.

To begin with, we call a quadruple $\mathfrak{Q} = \langle \mathfrak{F}, \boldsymbol{q}, \mathfrak{R}, \lhd \rangle$ a *weak quasimodel for* φ if the following conditions hold:

(wq1) $\mathfrak{F} = \langle W, R \rangle$ is a finite strict linear order, $W = \{w_0, w_1, \dots, w_m\}$ for some $m > 0$, $w_0 R w_1 R \dots R w_m$, and $\langle \mathfrak{F}, \boldsymbol{q} \rangle$ is a basic structure for φ satisfying **(qm2)**;

(wq2) $\mathfrak{R}$ is a set of runs through $\langle \mathfrak{F}, \boldsymbol{q} \rangle$ such that for all $i < j \leq m$, $r \in \mathfrak{R}$ and $\Diamond_1 \psi \in sub\, \varphi$,

$$\text{if } \psi \in \boldsymbol{t}_{w_j}(r(w_j)) \text{ or } \Diamond_1 \psi \in \boldsymbol{t}_{w_j}(r(w_j)) \text{ then } \Diamond_1 \psi \in \boldsymbol{t}_{w_i}(r(w_i)),$$

(wq2′) $\lhd$ is a binary relation on $\mathfrak{R}$ satisfying **(qm4)** and such that, for all $r, s \in \mathfrak{R}$,

$$r \lhd s \qquad \text{iff} \qquad r(w_i) <_{w_i} s(w_i) \;\text{ for all } i \leq m,$$

(wq3) for every $i < m$, the restriction of $\mathfrak{Q}$ to the two-element strict linear order on $\{w_i, w_{i+1}\}$ is a block in $\mathcal{S}$.

(Note that property **(wq2′)** is a bit stronger than **(qm3)**.) Now take a triple $\langle i, r, \Diamond_1 \psi \rangle$ such that $i \leq m$, $r \in \mathfrak{R}$ and $\Diamond_1 \psi \in sub\, \varphi$. Such a triple is called a *defect in* $\mathfrak{Q}$ if $\Diamond_1 \psi \in \boldsymbol{t}_{w_i}(r(w_i))$ and for all j such that $i < j \leq m$, $\psi \notin \boldsymbol{t}_{w_j}(r(w_j))$ and $\Diamond_1 \psi \notin \boldsymbol{t}_{w_j}(r(w_j))$. If $i = m$ then such a defect is called an *end-defect*, otherwise it is a *middle-defect*.

We construct a sequence $\langle \mathfrak{Q}_n \mid n < \omega \rangle$ of weak quasimodels which 'converges' to a real quasimodel for φ. Take a block $\mathfrak{Q}_0 = \langle \mathfrak{F}_0, \boldsymbol{q}_0, \mathfrak{R}_0, \lhd_0 \rangle$ in $\mathcal{S}$ satisfying **(qm2)**. Clearly, it is a weak quasimodel for φ as well. Suppose now that we have already constructed $\mathfrak{Q}_n = \langle \mathfrak{F}_n, \boldsymbol{q}_n, \mathfrak{R}_n, \lhd_n \rangle$ such that $\mathfrak{F}_n = \langle W_n, R_n \rangle$, $W_n = \{w_0, w_1, \dots, w_m\}$ and $w_0 R_n w_1 R_n \dots R_n w_m$. If the set D_n of all defects in $\mathfrak{Q}_n$ is empty then we are done: $\mathfrak{Q}_n$ is obviously a quasimodel for φ. Otherwise, we take some $d = \langle i, r, \Diamond_1 \psi \rangle$ from D_n.

Case 1: d is a middle-defect, that is, $i < m$. By **(wq3)**, the restriction $\mathfrak{Q}^{w_i w_{i+1}}$ of $\mathfrak{Q}_n$ to the two-element strict linear order on $\{w_i, w_{i+1}\}$ is a block in $\mathcal{S}$. Choose two blocks $\mathfrak{B}^{w_i w}$ and $\mathfrak{B}^{w w_{i+1}}$ according to **(ssb4)** (with $u = w_i$ and $v = w_{i+1}$). We may assume that $w \notin W_n$. Define a basic structure $\langle \mathfrak{F}_n^d, \boldsymbol{q}_n^d \rangle$ by taking

$$\begin{aligned}
&W_n^d = W_n \cup \{w\},\\
&R_n^d = R_n \cup \{\langle w_j, w \rangle \mid j \leq i,\, w_j \in W_n\} \cup \{\langle w, w_j \rangle \mid i < j \leq m,\, w_j \in W_n\},\\
&\mathfrak{F}_n^d = \langle W_n^d, R_n^d \rangle,\\
&\boldsymbol{q}_n^d(v) = \begin{cases} \boldsymbol{q}^{w_i w}(v) = \boldsymbol{q}^{w w_{i+1}}(v), & \text{if } v = w,\\ \boldsymbol{q}_n(v), & \text{if } v \in W_n. \end{cases}
\end{aligned}$$

For all runs $s, p \in \mathfrak{R}_n$, $s' \in \mathfrak{R}^{w_i w}$, $s'' \in \mathfrak{R}^{w w_{i+1}}$, such that $s(w_i) = s'(w_i)$, $s'(w) = s''(w)$, $s''(w_{i+1}) = p(w_{i+1})$, define the function $s \cup s' \cup s'' \cup p$ on W_n^d by taking, for all $v \in W_n^d$,

$$(s \cup s' \cup s'' \cup p)(v) = \begin{cases} s(v), & \text{if } \ v = w_j,\, j \le i, \\ s'(v) = s''(v), & \text{if } \ v = w, \\ p(v), & \text{if } \ v = w_j,\, i < j \le m. \end{cases}$$

Let $\mathfrak{R}_n^d$ be the set of all such functions. Elements in $\mathfrak{R}_n^d$ of the form $s \cup s' \cup s'' \cup s$, for some $s \in \mathfrak{R}_n$, are called *extensions of* s. We call an extension $s \cup s' \cup s'' \cup s$ *good*, if $s'(w) = s''(w) = x_s$; cf. **(ssb4)**. Observe that every $s \in \mathfrak{R}_n$ has a unique good extension in $\mathfrak{R}_n^d$.

For all $s, s' \in \mathfrak{R}_n^d$, define

$$s \lhd_n^d s' \qquad \text{iff} \qquad s(v) <_v s'(v) \ \text{ for all } v \in W_n^d.$$

In other words, we 'glue together' the blocks $\mathfrak{B}^{w_i w}$ and $\mathfrak{B}^{w w_{i+1}}$ at w, and then 'insert' the resulting piece into $\mathfrak{Q}_n$ between w_i and w_{i+1}. It can be readily checked that $\mathfrak{Q}_n^d = \langle \mathfrak{F}_n^d, \boldsymbol{q}_n^d, \mathfrak{R}_n^d, \lhd_n^d \rangle$ is a weak quasimodel. Moreover, the defect d in $\mathfrak{Q}_n^d$ is 'cured' in the sense that (by **(ssb4)**) the good extension r^+ of r is such that $\psi \in \boldsymbol{t}_w(r^+(w))$.

Case 2: d is an end-defect. This case is analogous to Case 1, but we have to use **(ssb3)** instead of **(ssb4)** for 'gluing together' $\mathfrak{Q}_n$ and a block $\mathfrak{B}^{w_m w}$ at w_m.

Next we turn the remaining defects in $\mathfrak{Q}_n$ to a subset D_n^d of the set of defects in $\mathfrak{Q}_n^d$ as follows. Suppose $\langle j, s, \Diamond_1 \chi \rangle$ is a defect in D_n different from d. Let s^+ be the good extension of s and let $k = j$ if $j \le i$ and $k = j + 1$ otherwise. If $\langle k, s^+, \Diamond_1 \chi \rangle$ is a defect in $\mathfrak{Q}_n^d$ then we put it into D_n^d. Clearly, $|D_n^d| \le |D_n| - 1$. If $D_n^d \ne \emptyset$ then we take a defect $d' \in D_n^d$, construct $\mathfrak{Q}_n^{dd'}$, and so on. When all the finitely many defects in D_n are cured, we obtain a weak quasimodel $\mathfrak{Q}_{n+1}$. Note that every run $r_n \in \mathfrak{R}_n$ has a unique extension $r_{n+1} \in \mathfrak{R}_{n+1}$ obtained by taking at every step the good extension of the previous run. We call this r_{n+1} the *good extension of* r_n *in* $\mathfrak{Q}_{n+1}$.

The limit quasimodel is defined by taking $\mathfrak{F} = \langle W, R \rangle$, where $W = \bigcup_{n<\omega} W_n$, $R = \bigcup_{n<\omega} R_n$ and $\boldsymbol{q} = \bigcup_{n<\omega} \boldsymbol{q}_n$. Then clearly $\mathfrak{F}$ is a strict linear order and $\langle \mathfrak{F}, \boldsymbol{q} \rangle$ is a basic structure for φ.

For every $i < \omega$ and every sequence of runs $\langle r_n \in \mathfrak{R}_n \mid n \ge i \rangle$ such that r_{n+1} is the good extension of r_n in $\mathfrak{Q}_{n+1}$ for all $n \ge i$, take $r = \bigcup \{ r_n \mid n \ge i \}$. Let $\mathfrak{R}$ be the set of such runs. For $r = \bigcup \{ r_n \mid n \ge i \}$ and $r' = \bigcup \{ r'_n \mid n \ge j \}$ in $\mathfrak{R}$, define

$$r \lhd r' \qquad \text{iff} \qquad r_n \lhd_n r'_n, \ \text{ for all } n \ge \max(i, j).$$

We show that $\mathfrak{R}$ and $\lhd$ satisfy **(qm3)** and **(qm4)**. Indeed, suppose that r and r' are of the above form and $r \lhd r'$. Take a $w \in W$. There is an $n \ge \max(i, j)$ such that $w \in W_n$. Then $r(w) = r_n(w)$, $r'(w) = r'_n(w)$ and $r_n \lhd_n r'_n$, which implies $r(w) <_w r'(w)$ by **(wq2′)**. For **(qm4)**, suppose that $r = \bigcup \{ r_n \mid n \ge i \}$ and $r(w) <_w x$ for some $x \in T_w$. Then there is an $n \ge i$ such that $w \in W_n$, and so $r(w) = r_n(w)$. Since $\mathfrak{Q}_n$ satisfies **(qm4)**, there is an $s_n \in \mathfrak{R}_n$ such that $s_n(w) = x$ and $r_n \lhd_n s_n$. Let $s = \bigcup \{ s_m \mid m \ge n \}$, where s_{m+1} is the good extension of s_m in $\mathfrak{Q}_{m+1}$ for all $m \ge n$. Then $s(w) = s_n(w) = x$, and it is not hard to see that, by **(ssb3)**, **(ssb4)** and **(wq2′)**, $r_m \lhd_m s_m$ hold for all $m \ge n$, from which $r \lhd s$.

Finally, we show that all the runs in $\mathfrak{R}$ are coherent and saturated. Indeed, suppose that $r = \bigcup \{ r_n \mid n \ge i \}$ and $\Diamond_1 \psi \in \boldsymbol{t}_w(r(w))$ for some $w \in W$. Then there is an $n \ge i$ such

that $w \in W_n$, and so $r(w) = r_n(w)$. If $\langle w, r_n, \Diamond_1\psi\rangle$ is not a defect in $\mathfrak{Q}_n$ then there is a $v \in W_n$ such that wRv, $r_n(v) = r(v)$ and $\psi \in \boldsymbol{t}_v(r_n(v))$. And if $\langle w, r_n, \Diamond_1\psi\rangle$ is a defect in $\mathfrak{Q}_n$ then it is cured in its good extension r_{n+1} in $\mathfrak{Q}_{n+1}$: there is $v \in W_{n+1}$ such that wRv, $r_{n+1}(v) = r(v)$ and $\psi \in \boldsymbol{t}_v(r_{n+1}(v))$. Conversely, assume that $\psi \in \boldsymbol{t}_w(r(w))$ and let vRw. Then there is an $n \geq i$ such that $v, w \in W_n$. Thus $r(w) = r_n(w)$, $r(v) = r_n(v)$ and vR_nw, and so $\Diamond_1\psi \in \boldsymbol{t}_v(r(v))$ follows by **(wq2)**.

Therefore, $\mathfrak{Q} = \langle \mathfrak{F}, \boldsymbol{q}, \mathfrak{R}, \lhd\rangle$ is a **K4.3** $\times$ **K**-quasimodel for φ, as required. ❑

Observe that the decision procedure given above is again non-elementary. In fact, no elementary decision procedure is known for **K4.3** $\times$ **K**. However, as quasistates in **K4.3** $\times$ **S5**-quasimodels are of double-exponential size, one can obtain a 2EXPTIME decision algorithm for **K4.3** $\times$ **S5** as follows. Take the set of all blocks for φ (a straightforward computation shows that the cardinality of this set is also at most double-exponential in the size of φ). Eliminate iteratively those blocks for which there are no 'noneliminated' blocks satisfying **(ssb3)** and **(ssb4)**. This elimination procedure stops after at most double-exponentially many steps. Now it is not hard to show that φ is satisfiable iff the set $\mathcal{S}$ of remaining blocks contains a block satisfying **(qm2)**.

Quasimodels and reductions to monadic second-order theories.

Here we give a second proof for the decidability of **K4.3** $\times$ **K** by showing that one can translate the statement "there exists a **K4.3** $\times$ **K**-quasimodel for φ based on some strict linear order $\mathfrak{F}$" into monadic second-order logic.

Fix some $\mathcal{ML}_2$-formula φ. For every $m \leq md(\varphi)$, below we will define a monadic second order formula qm^m_φ (in the language having a binary predicate constant $<$) in such a way that the following holds:

LEMMA 32. *For any strict linear order $\mathfrak{F}$, $\mathfrak{F} \models \mathsf{qm}^m_\varphi$ for some $m \leq md(\varphi)$ iff there exists a* **K4.3** $\times$ **K**-*quasimodel for φ based on $\mathfrak{F}$.*

Though the monadic second-order theory of all strict linear orders is undecidable, we can still use this lemma to deduce decidability of **K4.3** $\times$ **K** as follows. It is not hard to see, using Theorem 16, that it is enough to consider quasimodels that are based on *countable* strict linear orders. Now for every monadic second-order formula ψ and a monadic predicate variable P not occurring in ψ, define the relativisation ψ^P of ψ to P inductively by taking $\psi^P = \psi$ for atomic ψ, $(\neg\psi)^P = \neg\psi^P$, $(\psi_1 \wedge \psi_2)^P = \psi_1^P \wedge \psi_2^P$, $(\forall x\psi)^P = \forall x(P(x) \to \psi^P)$, and $(\forall Q\psi)^P = \forall Q\psi^P$. Obviously, for any sentence ψ and any strict linear order $\mathfrak{F}$, we have $\mathfrak{F} \models \exists P(\exists x P(x) \wedge \psi^P)$ iff $\mathfrak{F}' \models \psi$ for some (nonempty) suborder $\mathfrak{F}'$ of $\mathfrak{F}$—the intended interpretation of P is the domain of $\mathfrak{F}'$. As is well-known, any countable strict linear order is a suborder of $\langle \mathbb{Q}, <\rangle$. Let λ be the first-order sentence defining the class of all strict linear orders. Then qm^m_φ (assumed not to involve P) is satisfiable in some countable strict linear order $\mathfrak{F}$ iff the monadic second-order formula

$$\exists P \left(\exists x P(x) \wedge (\lambda \wedge \mathsf{qm}^m_\varphi)^P\right)$$

holds in $\langle \mathbb{Q}, <\rangle$. As the monadic second-order theory of $\langle \mathbb{Q}, <\rangle$ is known to be decidable (see [67]), this proves the decidability of **K4.3** $\times$ **K**.

In order to define the necessary monadic second order formulas qm^m_φ for each $m \leq md(\varphi)$, we require a number of auxiliary formulas. Denote by Σ_m the set of all quasistates for φ of depth m. Given a quasistate $\boldsymbol{q} = \langle\langle T_{\boldsymbol{q}}, <_{\boldsymbol{q}}\rangle, \boldsymbol{t}_{\boldsymbol{q}}\rangle$ from Σ_m and a point a in $T_{\boldsymbol{q}}$, we denote the depth of a by $d_{\boldsymbol{q}}(a)$.

Introduce a unary predicate variable $P_{\boldsymbol{q}}$ for each $\boldsymbol{q} \in \Sigma_m$ and a unary predicate variable R^k_ψ for each $\psi \in sub\,\varphi$ and each $k \leq m$. Given a type $\boldsymbol{t}$ for φ and $k \leq m$, let

$$\chi_{\boldsymbol{t}}(\overline{R^k}(x)) = \bigwedge_{\psi \in \boldsymbol{t}} R^k_\psi(x) \wedge \bigwedge_{\substack{\psi \notin \boldsymbol{t} \\ \psi \in sub\,\varphi}} \neg R^k_\psi(x),$$

saying that the type $\boldsymbol{t}$ at point x of depth k is defined with the help of

$$\overline{R^k}(x) = \left\langle R^k_\psi(x) \mid \psi \in sub\,\varphi \right\rangle.$$

For each $k \leq m$, let

$$\begin{aligned}\mathsf{run}_0(\overline{P}, \overline{R^k}) \;=\; & \forall x \bigwedge_{\boldsymbol{q} \in \Sigma_m} \big(P_{\boldsymbol{q}}(x) \to \\ & \bigvee_{\substack{a \in T_q \\ d_q(a)=k}} \chi_{\boldsymbol{t}_q(a)}(\overline{R^k}(x))\big) \;\wedge\; \forall x \bigwedge_{\Diamond_1 \psi \in sub\,\varphi} \left[R^k_{\Diamond_1 \psi}(x) \leftrightarrow \exists y\big(x < y \wedge R^k_\psi(y)\big)\right].\end{aligned}$$

This is intended to say that $\overline{R^k}$ defines a coherent and saturated k-run through a sequence of quasistates defined with the help of $\overline{P} = \langle P_{\boldsymbol{q}} \mid \boldsymbol{q} \in \Sigma_m \rangle$.

However, we have to refine this definition in order to ensure that condition **(qm4)** holds. To this end, we define, by 'backwards' induction on k, another formula $\mathsf{run}(\overline{P}, \overline{R^k})$ as follows. If $k = m$ (that is, we are at the 'leaf-level') then take $\mathsf{run}(\overline{P}, \overline{R^m}) = \mathsf{run}_0(\overline{P}, \overline{R^m})$.

Suppose, inductively, that for $k \leq m$ we have already defined $\mathsf{run}(\overline{P}, \overline{R^k})$. Then let $\mathsf{run}(\overline{P}, \overline{R^{k-1}})$ be the following formula:

$$\begin{aligned}& \mathsf{run}_0(\overline{P}, \overline{R^{k-1}}) \wedge \\ & \forall x \bigwedge_{\boldsymbol{q} \in \Sigma_m} \bigwedge_{\substack{a \in T_q \\ d_q(a)=k-1}} \Big[P_{\boldsymbol{q}}(x) \wedge \chi_{\boldsymbol{t}_q(a)}(\overline{R^{k-1}}(x)) \to \bigwedge_{\substack{b \in T_q \\ a <_q b}} \exists_{\psi \in sub\,\varphi} R^k_\psi \Big(\mathsf{run}(\overline{P}, \overline{R^k}) \wedge \chi_{\boldsymbol{t}_q(b)}(\overline{R^k}(x)) \wedge \\ & \qquad \forall z \bigwedge_{\boldsymbol{s} \in \Sigma_m} \bigwedge_{\substack{c \in T_s \\ d_s(c)=k-1}} \big(P_{\boldsymbol{s}}(z) \wedge \chi_{\boldsymbol{t}_s(c)}(\overline{R^{k-1}}(z)) \to \bigvee_{\substack{d \in T_s \\ c <_s d}} \chi_{\boldsymbol{t}_s(d)}(\overline{R^k}(z))\big)\Big)\Big].\end{aligned}$$

Finally, we define a monadic second-order sentence qm^m_φ by taking

$$\begin{aligned}\mathsf{qm}^m_\varphi = \exists_{\boldsymbol{q} \in \Sigma_m} P_{\boldsymbol{q}} \Big[& \forall x \bigvee_{\boldsymbol{q} \in \Sigma_m} \big(P_{\boldsymbol{q}}(x) \wedge \bigwedge_{\substack{\boldsymbol{q}' \in \Sigma_m \\ \boldsymbol{q} \neq \boldsymbol{q}'}} \neg P_{\boldsymbol{q}'}(x)\big) \;\wedge \\ & \bigvee_{\substack{\boldsymbol{s} \in \Sigma_m,\, a \in T_s \\ d_s(a)=0 \\ \varphi \in \boldsymbol{t}_s(a)}} \exists x \Big(P_{\boldsymbol{s}}(x) \wedge \exists_{\psi \in sub\,\varphi} R^0_\psi \;\big(\mathsf{run}(\overline{P}, \overline{R^0}) \wedge \chi_{\boldsymbol{t}_s(a)}(\overline{R^0}(x))\big)\Big)\Big].\end{aligned}$$

Evaluated in a strict linear order $\mathfrak{F} = \langle W, < \rangle$, the first line of qm^m_φ says that the sets $P_{\boldsymbol{q}} \subseteq W$ ($\boldsymbol{q} \in \Sigma_m$) form a partition of W. By defining the map $\boldsymbol{q} : W \to \Sigma_m$ as

$$\boldsymbol{q}(w) = \boldsymbol{q} \quad \text{iff} \quad w \in P_{\boldsymbol{q}}$$

and a relation $\lhd$ on the runs by taking $r \lhd r'$ iff r is defined by $\overline{R^{k-1}}$ and r' is defined by $\overline{R^k}$ for some $k \leq m$, we obtain a quasimodel $\mathfrak{Q} = \langle \mathfrak{F}, \boldsymbol{q}, \mathfrak{R}, \lhd \rangle$ for φ: the second line of qm_φ^m states condition **(qm2)**; conditions **(qm3)** and **(qm4)** are satisfied by the definitions of $\lhd$ and the formulas $\mathsf{run}(\overline{P}, \overline{R^k})$, respectively.

Lower complexity bounds.

The following general result was obtained by Marx [59]. It is proved by reducing the NEXPTIME-complete "$n \times n$ bounded tiling problem" to the satisfiability problem of the logics in question, see Chapter 3 of this handbook:

THEOREM 33. *Let L be a Kripke complete bimodal logic between* $\mathbf{K} \times \mathbf{K}$ *and* $\mathbf{S5} \times \mathbf{S5}$. *Then L is* coNEXPTIME*-hard.*

For products of 'linear' logics with **S5** (such as $\mathsf{Log}\{\langle \mathbb{N}, < \rangle\} \times \mathbf{S5}$, $\mathsf{Log}\{\langle \mathbb{Q}, < \rangle\} \times \mathbf{S5}$, $\mathbf{K4.3} \times \mathbf{S5}$) one can obtain an EXPSPACE lower bound by reducing the "2^n corridor tiling problem" to their satisfiability problem, see [23, Theorem 6.64].

Products of 'transitive' modal logics are usually undecidable

None of the techniques for proving decidability discussed above work if we consider two-dimensional products where both component logics are determined by *transitive* frames of unbounded 'cluster-depth' (such as $\mathbf{K4} \times \mathbf{K4}$). As we shall see below, these product logics are in fact undecidable, and often lack the 'abstract' fmp.

Given a transitive frame $\mathfrak{F} = \langle W, R \rangle$, a point $x \in W$ is said to be of *cluster-depth* $n < \omega$ in $\mathfrak{F}$ if there is a path $x = x_0 R x_1 R \dots R x_n$ of points from distinct clusters in $\mathfrak{F}$ (that is, $x_{i+1} R x_i$ does not hold for any $i < n$) and there is no such path of greater length. If for every $n < \omega$ there is a path of n points from distinct clusters starting from x, then we say that x is of *infinite cluster-depth*, or x is of *cluster-depth* ∞. The *cluster-depth of* $\mathfrak{F}$ is defined to be the supremum of the cluster-depths of its points (with $n < \infty$ for all $n < \omega$). For instance, $\mathfrak{F}$ is of infinite cluster-depth if it contains points of arbitrary finite cluster-depth. By the *cluster-depth* of a bimodal frame $\langle W, R_1, R_2 \rangle$ with transitive R_1, R_2 we understand the minimal cluster-depth of $\langle W, R_1 \rangle$ and $\langle W, R_2 \rangle$.

We remind the reader that a frame $\langle W, R \rangle$ is called *Noetherian* if there is no infinite strictly ascending chain $x_0 R x_1 R x_2 R \dots$ of points from W (i.e., no R-chain such that $x_i \neq x_{i+1}$, for all $i < \omega$).

THEOREM 34. (i) [28] *Let L_1 and L_2 be Kripke complete unimodal logics containing* **K4** *and such that both L_1 and L_2 have among their frames a rooted Noetherian linear order with an infinite descending chain of distinct points. Then all bimodal logics L in the interval*

$$[L_1, L_2] \subseteq L \subseteq L_1 \times L_2$$

lack the fmp.

(ii) [26] *If L is any Kripke complete bimodal logic containing* $\mathbf{K4} \times \mathbf{K4}$ *and having product frames of arbitrarily large finite or infinite cluster-depth, then L is undecidable.*

Note that as (by Theorem 21) $\mathbf{K4} \times \mathbf{K4} = [\mathbf{K4}, \mathbf{K4}]$, it is a simple and natural example for a finitely axiomatisable but undecidable modal logic.

Below we discuss the main points of the proof of Theorem 34. For more details, consult [26].

Lack of finite model property.

We will define a bimodal formula 'forcing' infinite [**K4**, **K4**]-frames. We want to 'get rid of' the clusters first: take two fresh propositional variables h and v, and define new modal operators by setting, for every bimodal formula ψ,

$$\begin{aligned}
\bar{\Diamond}_1 \psi &= \big[h \to \Diamond_1\big(\neg h \wedge (\psi \vee \Diamond_1\psi)\big)\big] \wedge \big[\neg h \to \Diamond_1\big(h \wedge (\psi \vee \Diamond_1\psi)\big)\big],\\
\bar{\Diamond}_2 \psi &= \big[v \to \Diamond_2\big(\neg v \wedge (\psi \vee \Diamond_2\psi)\big)\big] \wedge \big[\neg v \to \Diamond_2\big(v \wedge (\psi \vee \Diamond_2\psi)\big)\big],\\
\bar{\Box}_1 \psi &= \neg\bar{\Diamond}_1 \neg\psi, \qquad \text{and} \qquad \bar{\Box}_2 \psi = \neg\bar{\Diamond}_2 \neg\psi.
\end{aligned}$$

(Similar operators were used by Spaan [77] and by Reynolds and Zakharyaschev [70].)

Now define φ_∞ to be the conjunction of the following formulas:

$$\Box_1\Box_2\big((h \vee \Diamond_2 h \to \Box_2 h) \wedge (\neg h \vee \Diamond_2\neg h \to \Box_2\neg h)\big), \tag{9}$$

$$\Box_1\Box_2\big((v \vee \Diamond_1 v \to \Box_1 v) \wedge (\neg v \vee \Diamond_1\neg v \to \Box_1\neg v)\big), \tag{10}$$

$$\bar{\Diamond}_2\,\bar{\Diamond}_1\,(\bar{\Box}_2\,\bot \wedge \bar{\Box}_1\,\bot), \tag{11}$$

$$\bar{\Box}_1\,\bar{\Box}_2\,(\bar{\Box}_2\,\bot \wedge \bar{\Box}_1\,\bot \to d), \tag{12}$$

$$\bar{\Box}_2\,\bar{\Diamond}_1\,(\neg d \wedge \bar{\Box}_1\, d), \tag{13}$$

$$\bar{\Box}_1\,\bar{\Diamond}_2\,(d \wedge \bar{\Box}_2\,\neg d), \tag{14}$$

$$\bar{\Box}_1\,\bar{\Box}_2\,(d \to \bar{\Box}_1\,\bar{\Diamond}_2\, d), \tag{15}$$

$$\bar{\Box}_1\,\bar{\Box}_2\,(\neg d \to \bar{\Box}_2\,\bar{\Diamond}_1\,\neg d). \tag{16}$$

On the one hand, it is easy to see that φ is satisfiable in a product of two rooted Noetherian linear orders each of which contains an infinite descending chain of distinct points, see Fig. 4. Note that such a frame is *infinite*.

On the other hand, we show that φ_∞ cannot be satisfied in a *finite* frame for [**K4**, **K4**]. The idea behind the proof is that, though the points 'generated by' φ_∞ do not necessarily form a nice 'backward looking $\omega \times \omega$-grid' like on Fig. 4, yet each of them can be 'characterised' by a unique pair $\langle n, m\rangle$ of natural numbers.

To this end, suppose that φ_∞ is satisfied at the root r of a model $\mathfrak{M}$ based on a (not necessarily product) frame $\mathfrak{F} = \langle W, R_1, R_2\rangle$ for [**K4**, **K4**]. Then both R_1 and R_2 are transitive, they commute and satisfy the Church–Rosser property.

We define new ($\mathfrak{M}$-dependent) binary relations $\bar{R}_1$ and $\bar{R}_2$ on W by taking, for all $x, y \in W$,

$$\begin{aligned}
x\bar{R}_1 y \quad &\text{iff} \quad \exists z \in W\ \big[xR_1 z \text{ and } \big((\mathfrak{M}, x) \models h \iff (\mathfrak{M}, z) \models \neg h\big)\\
&\qquad\quad \text{and (either } z = y \text{ or } zR_1 y)\big],\\
x\bar{R}_2 y \quad &\text{iff} \quad \exists z \in W\ \big[xR_2 z \text{ and } \big((\mathfrak{M}, x) \models v \iff (\mathfrak{M}, z) \models \neg v\big)\\
&\qquad\quad \text{and (either } z = y \text{ or } zR_2 y)\big].
\end{aligned}$$

In other words, $x\bar{R}_1 y$ iff $xR_1 y$ and either x, y are of different 'horizontal colours' in the sense that h is true in precisely one of them, or x, y are of the same h-colour (i.e., $x \models h$ iff $y \models h$), but there is a point z of different h-colour such that $xR_1 zR_1 y$. Clearly, we always have $\bar{R}_i \subseteq R_i$ ($i = 1, 2$). It is not hard to see that, by (9)–(10), $\langle W, \bar{R}_1, \bar{R}_2\rangle$ is a

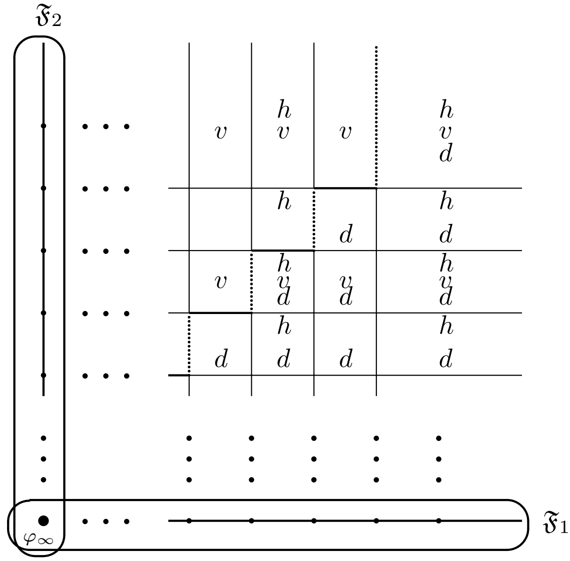

Figure 4. Satisfying φ_∞ in an infinite product frame.

(not necessarily rooted) frame for $[\mathbf{K4}, \mathbf{K4}]$, that is,

$$\text{both } \bar{R}_1 \text{ and } \bar{R}_2 \text{ are transitive,} \tag{tran}$$

$$\bar{R}_1 \text{ and } \bar{R}_2 \text{ commute, and} \tag{com}$$

$$\bar{R}_1 \text{ and } \bar{R}_2 \text{ are Church–Rosser.} \tag{chro}$$

Moreover, for all $x \in W$,

$$\begin{array}{lll}(\mathfrak{M}, x) \models \bar{\Diamond}_1 \psi & \text{iff} & \exists y \in W \ (x\bar{R}_1 y \text{ and } (\mathfrak{M}, y) \models \psi), \\ (\mathfrak{M}, x) \models \bar{\Diamond}_2 \psi & \text{iff} & \exists y \in W \ (x\bar{R}_2 y \text{ and } (\mathfrak{M}, y) \models \psi).\end{array}$$

We define inductively four infinite sequences

$$x_0, x_1, x_2, \ldots, \quad y_0, y_1, y_2, \ldots, \quad u_0, u_1, u_2, \ldots \quad \text{and} \quad v_0, v_1, v_2, \ldots$$

of points from W such that, for every $i < \omega$,

(gen1) $(\mathfrak{M}, x_i) \models d \wedge \bar{\Box}_2 \neg d$,

(gen2) $(\mathfrak{M}, y_i) \models \neg d \wedge \bar{\Box}_1 d$,

(gen3) $r\bar{R}_2 u_i$, $u_i \bar{R}_1 x_i$ and $u_i \bar{R}_1 y_i$,

(gen4) if $i > 0$ then $r\bar{R}_1 v_i$, $v_i \bar{R}_2 x_i$ and $v_i \bar{R}_2 y_{i-1}$,

see Fig. 5. (We do not claim at this point that, say, all the x_i are distinct.)

To begin with, by (11), there are u_0, x_0 such that $r\bar{R}_2 u_0 \bar{R}_1 x_0$ and

$$(\mathfrak{M}, x_0) \models \bar{\Box}_1 \bot \wedge \bar{\Box}_2 \bot. \tag{17}$$

By (12), $(\mathfrak{M}, x_0) \models d$. By (13), there is y_0 such that $u_0 \bar{R}_1 y_0$ and $(\mathfrak{M}, y_0) \models \neg d \wedge \bar{\Box}_1 d$. So **(gen1)**–**(gen3)** hold for $i = 0$.

Now suppose that, for some $n < \omega$, x_i and y_i with **(gen1)**–**(gen4)** have already been defined for all $i \leq n$. By **(gen3)** for $i = n$ and by (com), there is v_{n+1} such that $r \bar{R}_1 v_{n+1} \bar{R}_2 y_n$. So by (14), there is x_{n+1} such that $(\mathfrak{M}, x_{n+1}) \models d \wedge \bar{\Box}_2 \neg d$ and $v_{n+1} \bar{R}_2 x_{n+1}$. Now again by (com), there is u_{n+1} such that $r \bar{R}_2 u_{n+1} \bar{R}_1 x_{n+1}$. So, by (13), there is y_{n+1} such that $u_{n+1} \bar{R}_1 y_{n+1}$ and $(\mathfrak{M}, y_{n+1}) \models \neg d \wedge \bar{\Box}_1 d$, as required (see Fig. 5).

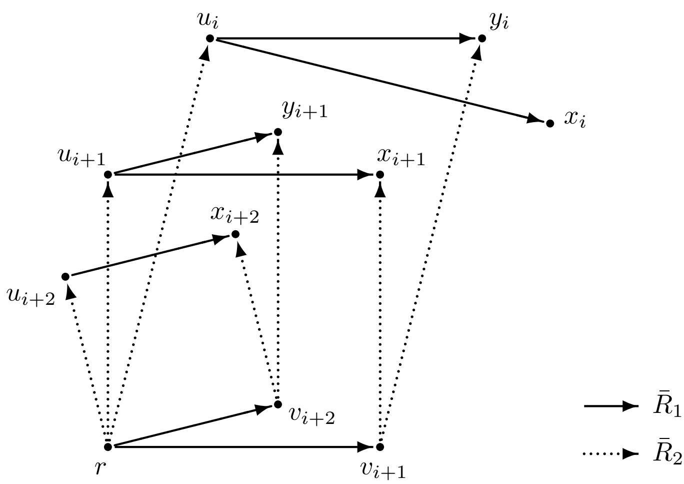

Figure 5. Generating the points x_i, y_i, u_i and v_i.

The following lemma is our basic tool in showing that all the x_n are different:

LEMMA 35. *For all $i, n < \omega$,*

(i) $(\mathfrak{M}, x_i) \models \bar{\Diamond}_1^n \top \leftrightarrow \bar{\Diamond}_2^n \top$,

(ii) $(\mathfrak{M}, y_i) \models \bar{\Diamond}_1^{n+1} \top \leftrightarrow \bar{\Diamond}_2^n \top$.

Proof. First, it is a straightforward consequence of (12), (16) and (com) that

$$\bar{\Box}_1 \bar{\Box}_2 (\neg d \to \bar{\Diamond}_1 \top) \tag{18}$$

holds in $\mathfrak{M}$. Further, it is not hard to show by induction on n that for all $n < \omega$,

$$\bar{\Box}_1 \bar{\Box}_2 (d \to \bar{\Box}_1^n \bar{\Diamond}_2^n d), \tag{19}$$

$$\bar{\Box}_1 \bar{\Box}_2 (\neg d \to \bar{\Box}_2^n \bar{\Diamond}_1^n \neg d). \tag{20}$$

are also true in $\mathfrak{M}$. Now to prove (i), suppose first that we have $(\mathfrak{M}, x_i) \models \bar{\Diamond}_1^n \top$. Then there is a point z such that $x_i \bar{R}_1^n z$. By **(gen1)**, $(\mathfrak{M}, x_i) \models d$. So, $(\mathfrak{M}, z) \models \bar{\Diamond}_2^n d$, by (19). Using (com), we find a point v such that $x_i \bar{R}_2^n v$ and $v \bar{R}_1^n u$, so $(\mathfrak{M}, x_i) \models \bar{\Diamond}_2^n \top$ follows. Conversely, suppose $(\mathfrak{M}, x_i) \models \bar{\Diamond}_2^n \top$, that is, there are points $z_1, \ldots, z_n$ such

that $x_i \bar{R}_2 z_1 \bar{R}_2 \dots \bar{R}_2 z_n$. By **(gen1)**, $(\mathfrak{M}, x_i) \models \bar{\Box}_2 \neg d$, and so $(\mathfrak{M}, z_1) \models \neg d$. Therefore, by (20) and (18), we have $(\mathfrak{M}, z_n) \models \bar{\Diamond}_1^n \top$, and then obtain $(\mathfrak{M}, x_i) \models \bar{\Diamond}_1^n \top$ using (com).

To show (ii), assume first that we have $(\mathfrak{M}, y_i) \models \bar{\Diamond}_2^n \top$. Then there is a point z such that $y_i \bar{R}_2^n z$. By **(gen2)**, $(\mathfrak{M}, y_i) \models \neg d$. So, by (20), $(\mathfrak{M}, z) \models \bar{\Diamond}_1^n \neg d$, and by (18), $(\mathfrak{M}, z) \models \bar{\Diamond}_1^{n+1} \top$. Now $(\mathfrak{M}, y_i) \models \bar{\Diamond}_1^{n+1} \top$ follows by (com). Conversely, suppose $(\mathfrak{M}, y_i) \models \bar{\Diamond}_1^{n+1} \top$, that is, there are points $z_1, \dots, z_n, z_{n+1}$ such that

$$y_i \bar{R}_1 z_1 \bar{R}_1 \dots \bar{R}_1 z_n \bar{R}_1 z_{n+1}.$$

By **(gen2)**, $(\mathfrak{M}, y_i) \models \bar{\Box}_1 d$, and so $(\mathfrak{M}, z_1) \models d$. Therefore, by (19), $(\mathfrak{M}, z_{n+1}) \models \bar{\Diamond}_2^n \top$. Finally, using (com) we obtain $(\mathfrak{M}, y_i) \models \bar{\Diamond}_2^n \top$. ❑

Now we can show that all the x_n are distinct as follows. For every formula ψ and $\Diamond \in \{\bar{\Diamond}_1, \bar{\Diamond}_2\}$, we introduce

$$\Diamond^{=\mathbf{n}}\psi \;=\; \Diamond^n \psi \wedge \Box^{n+1} \neg\psi,$$

meaning 'see ψ in n steps but not in $n+1$ steps.' Define the horizontal and vertical ranks $hr(x)$ and $vr(x)$ of a point x (in model $\mathfrak{M}$) by taking

$$hr(x) \;=\; \begin{cases} n, & \text{if } n < \omega \text{ and } (\mathfrak{M}, x) \models \bar{\Diamond}_1^{=\mathbf{n}} \top, \\ \infty, & \text{otherwise,} \end{cases}$$

$$vr(x) \;=\; \begin{cases} n, & \text{if } n < \omega \text{ and } (\mathfrak{M}, x) \models \bar{\Diamond}_2^{=\mathbf{n}} \top, \\ \infty, & \text{otherwise.} \end{cases}$$

The reader can readily check, using (com) and (chro), that if $x \bar{R}_1 y$ then $vr(x) = vr(y)$, and if $x \bar{R}_2 y$ then $hr(x) = hr(y)$.

We claim that, for all $n < \omega$,

$$vr(u_n) \;=\; n, \tag{21}$$

$$hr(v_n) \;=\; n, \tag{22}$$

$$hr(x_n) \;=\; vr(x_n) = n. \tag{23}$$

First we prove (21) by induction on n. For $n = 0$, it follows from the definition of x_0 (see (17)) and **(gen3)**. Suppose that (21) holds for some $n < \omega$. Then

$$\begin{aligned} vr(u_{n+1}) &\overset{\textbf{(gen3)}}{=} vr(x_{n+1}) \overset{\text{L.35(i)}}{=} hr(x_{n+1}) \\ &\overset{\textbf{(gen4)}}{=} hr(y_n) \overset{\text{L.35(ii)}}{=} vr(y_n) + 1 \overset{\textbf{(gen3)}}{=} vr(u_n) + 1 \overset{\text{(IH)}}{=} n + 1. \end{aligned}$$

Now (22) and (23) follow from (21) and

$$hr(v_n) \overset{\textbf{(gen4)}}{=} hr(x_n) \overset{\text{L.35(i)}}{=} vr(x_n) \overset{\textbf{(gen3)}}{=} vr(u_n).$$

Undecidability.

We discuss first how the 'diagonal points' x_n (with finite rank $hr(x_n) = vr(x_n) = n$) can be used not only to show the lack of fmp, but also to encode arbitrarily large finite parts of the '$\omega \times \omega$-grid' in frames for $[\mathbf{K4}, \mathbf{K4}]$. The enumeration of the points of $\omega \times \omega$

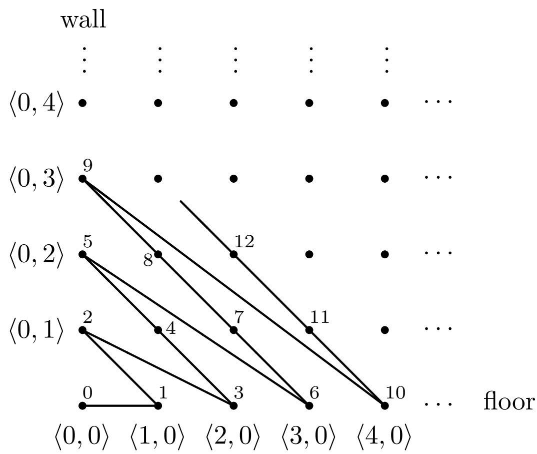

Figure 6. The enumeration *pair*.

we use below has been introduced in several papers dealing with undecidable multimodal logics; see, e.g., [36, 60, 70]. (Note that in all these cases either the language had *next-time operators* or all the frames were *linear*, neither is the case now.)

Let $pair : \omega \to \omega \times \omega$ be the function defined recursively by taking:

- $pair(0) = \langle 0, 0\rangle$,
- if $pair(n) = \langle 0, j\rangle$ then $pair(n+1) = \langle j+1, 0\rangle$,
- otherwise, if $pair(n) = \langle i+1, j\rangle$ then $pair(n+1) = \langle i, j+1\rangle$;

see Fig. 6. It is easy to see that *pair* is one-one and onto. Let $\sharp : \omega \times \omega \to \omega$ denote the inverse of the function *pair*. If $pair(n)$ is not on the wall (that is, the first coordinate of $pair(n)$ is different from 0) then define $left_n$ to be the $\sharp$ of the left neighbour of $pair(n)$. The reader can readily check the following important properties of these functions, for all $n > 0$:

(t1) If neither $pair(n)$ nor $pair(n-1)$ are on the wall then $left_n = left_{n-1} + 1$.

(t2) If $n > 1$ and $pair(n)$ is not on the wall, but $pair(n-1)$ is on the wall, then $n > 2$, $pair(n-2)$ is not on the wall, and $left_n = left_{n-2} + 1$.

(t3) $pair(n)$ is on the wall iff $pair(left_{n-1})$ is on the wall.

(t4) Either $pair(n)$ or $pair(n-1)$ is not on the wall.

We will require the following propositional variables:

- grid (marking the points of the grid),
- left (a pointer from n to $left_n$ when $pair(n)$ is not on the wall),
- wall (marking the wall, i.e., the pairs of the form $\langle 0, n\rangle$).

Let φ_{grid} be the conjunction of (9), (10) and the following formulas:

$$\bar{\Box}_1\,\bar{\Box}_2\left(\bar{\Box}_1\bot \rightarrow (\mathsf{grid} \leftrightarrow \bar{\Box}_2\bot)\right),$$
$$\bar{\Box}_1\,\bar{\Box}_2\,(\bar{\Box}_1\bot \wedge \mathsf{grid} \rightarrow \mathsf{wall}),$$
$$\bar{\Box}_1\,\bar{\Box}_2\,(\mathsf{wall} \rightarrow \mathsf{grid}),$$
$$\bar{\Box}_1\,\bar{\Box}_2\left(\bar{\Diamond}_1\mathsf{wall} \rightarrow \bar{\Box}_1(\mathsf{grid} \rightarrow \mathsf{wall})\right),$$
$$\bar{\Box}_1\,\bar{\Box}_2\left(\bar{\Diamond}_1\top \rightarrow (\mathsf{grid} \leftrightarrow \bar{\Diamond}_2^{=\mathbf{1}}\,\bar{\Diamond}_1^{=\mathbf{1}}\,\mathsf{grid})\right),$$
$$\bar{\Box}_1\,\bar{\Box}_2\left(\mathsf{grid} \wedge \bar{\Diamond}_1\top \rightarrow \left(\mathsf{wall} \leftrightarrow \bar{\Diamond}_2(\bar{\Diamond}_1^{=\mathbf{1}}\,\mathsf{left} \wedge \bar{\Diamond}_1\mathsf{wall})\right)\right),$$
$$\bar{\Box}_1\,\bar{\Box}_2\Big[\mathsf{left} \leftrightarrow \Big((\bar{\Diamond}_1^{=\mathbf{1}}\top \wedge \bar{\Box}_2\bot) \vee \left(\bar{\Diamond}_2(\bar{\Diamond}_1^{=\mathbf{2}}\,\mathsf{left} \wedge \bar{\Diamond}_1\mathsf{wall}) \wedge \bar{\Diamond}_2^{=\mathbf{1}}\,\bar{\Diamond}_1^{=\mathbf{2}}\,\mathsf{left}\right)$$
$$\vee \left(\bar{\Diamond}_2(\bar{\Diamond}_1^{=\mathbf{1}}\,\mathsf{left} \wedge \neg\bar{\Diamond}_1\mathsf{wall}) \wedge \bar{\Diamond}_2^{=\mathbf{1}}\,\bar{\Diamond}_1^{=\mathbf{1}}\,\mathsf{left}\right)\Big)\Big].$$

The following lemma, showing that φ_{grid} 'forces' the $\omega \times \omega$-grid onto 'diagonal points of finite rank', is proved in [26]:

LEMMA 36. *Suppose that $\mathfrak{M}$ is a model based on a rooted frame $\mathfrak{F} = \langle W, R_1, R_2\rangle$ for* $[\mathbf{K4}, \mathbf{K4}]$. *If $(\mathfrak{M}, r) \models \varphi_{grid}$ then the following hold, for all $n, m < \omega$ and all $x \in W$ such that $hr(x) = n$ and $vr(x) = m$:*

(i) $(\mathfrak{M}, x) \models \mathsf{grid}$ *iff* $n = m$,

(ii) $(\mathfrak{M}, x) \models \bar{\Diamond}_1^{=\mathbf{1}}\,\mathsf{left}$ *iff* $n > 0$, *$pair(n-1)$ is not on the wall and $m = left_{n-1}$,*

(iii) $(\mathfrak{M}, x) \models \mathsf{wall}$ *iff* $n = m$ *and $pair(n)$ is on the wall,*

(iv) $(\mathfrak{M}, x) \models \mathsf{left}$ *iff $pair(n)$ is not on the wall and $m = left_n$.*

Various undecidable problems can be 'represented' on the $\omega \times \omega$-grid, say, versions of the halting problems for Turing machines, register machines, etc., Post's correspondence problem, as well as infinite tiling problems.

Here we show as an example for reducing an undecidable tiling problem to the satisfiability problem for logics that (i) contain $[\mathbf{K4}, \mathbf{K4}]$ and (ii) have among their frames a product of two rooted Noetherian linear orders each of which contains an infinite descending chain of distinct points. (For other similar logics slight modifications of the proof might be necessary, see [26] for a general argument.)

A *tile type* is a 4-tuple of colours

$$t = \langle left(t), right(t), up(t), down(t)\rangle\,.$$

For a *finite* set T of tile types and a subset $X \subseteq \omega \times \omega$, we say that T *tiles* X if there exists a function (called a *tiling*) $\boldsymbol{\tau}$ from X to T such that, for all $\langle i, j\rangle \in X$,

- if $\langle i, j+1\rangle \in X$ then $up(\boldsymbol{\tau}(i,j)) = down(\boldsymbol{\tau}(i, j+1))$ and
- if $\langle i+1, j\rangle \in X$ then $right(\boldsymbol{\tau}(i,j)) = left(\boldsymbol{\tau}(i+1, j))$.

The following '*$\omega \times \omega$-tiling problem*' is undecidable (see [81, 9]): given a finite set T of tile types, decide whether T can tile $\omega \times \omega$.

Given a finite set T of tile types, we introduce a propositional variable t, for every $t \in T$. Let φ_T be the conjunction of the following formulas:

$$\bar{\Box}_1 \bar{\Box}_2 \,(\mathsf{grid} \leftrightarrow \bigvee_{t \in T} t),$$

$$\bar{\Box}_1 \bar{\Box}_2 \bigwedge_{t \neq t' \in T} \neg(t \wedge t'),$$

$$\bar{\Box}_1 \bar{\Box}_2 \bigwedge_{\substack{t,t' \in T \\ up(t') \neq down(t)}} \big(t \to \bar{\Box}_2 \,(\bar{\Diamond}_1^{=1} \,\mathsf{left} \to \neg \bar{\Diamond}_1 t')\big),$$

$$\bar{\Box}_1 \bar{\Box}_2 \bigwedge_{\substack{t,t' \in T \\ right(t') \neq left(t)}} \big(t \to \bar{\Box}_2 \,(\mathsf{left} \to \neg \bar{\Diamond}_1 t')\big).$$

For every $n < \omega$, let

$$plane_n = \{\langle i, j\rangle \mid \sharp(i,j) \leq n\}.$$

If formulas (9) and (10) are satisfied in a model $\mathfrak{M}$ based on a frame for $[\mathbf{K4}, \mathbf{K4}]$, then for all numbers $a, b < \omega$ and $x \in W$ with $hr(x) = a$ and $vr(x) = b$, there exists what we call a *perfect* $a \times b$*-rectangle starting at* x, that is, there are points $x_{i,j}$ (for $i \leq a$, $j \leq b$) such that

- $x = x_{a,b}$,
- $hr(x_{i,j}) = i$ and $vr(x_{i,j}) = j$,
- $x_{i,j} \bar{R}_1 x_{k,j}$ for $i > k$, and $x_{i,j} \bar{R}_2 x_{i,k}$ for $j > k$.

(Indeed, given x, take an a-long $\bar{R}_1$-path and a b-long $\bar{R}_2$-path starting from x, and then 'close them' under the Church-Rosser property.)

Now a straightforward induction on n shows the following:

LEMMA 37. *Let* $\mathfrak{M}$ *be a model that is based on a frame for* $[\mathbf{K4}, \mathbf{K4}]$ *with root* r *and suppose that* $(\mathfrak{M}, r) \models \varphi_{grid} \wedge \varphi_T$. *Then, for every* $n < \omega$, *every* $x \in W$ *such that* $hr(x) = vr(x) = n$, *and every perfect* $n \times n$*-rectangle* $x_{i,j}$ $(i \leq n,\ j \leq n)$ *starting at* x, *the function* $\tau : plane_n \to T$ *defined by*

$$\tau(i,j) = t \qquad \textit{iff} \qquad (\mathfrak{M}, x_{\sharp(i,j),\sharp(i,j)}) \models t$$

is a tiling of $plane_n$.

Now, using Lemma 37, it is straightforward to show that if $\varphi_\infty \wedge \varphi_{grid} \wedge \varphi_T$ is satisfiable in a frame for $[\mathbf{K4}, \mathbf{K4}]$ then T tiles $plane_n$, for all $n < \omega$. A standard compactness argument (or König's lemma) shows that if a given finite set T of tile types tiles $plane_n$ for every $n < \omega$, then it actually tiles the whole $\omega \times \omega$-grid. On the other hand, it is easy to see that if T tiles $\omega \times \omega$ then $\varphi_\infty \wedge \varphi_{grid} \wedge \varphi_T$ is satisfiable in a product of two rooted Noetherian linear orders each of which contains an infinite descending chain of distinct points.

With the help of some additional 'machinery', one can even reduce 'stronger' undecidable statements (like recurrent Turing machine and tiling problems) to the satisfiability

problem for certain products of 'transitive' logics. For instance, the following is shown in [26]:

THEOREM 38. *Let L_1 be any logic from the list*

$$\mathbf{K4},\ \mathbf{K4.1},\ \mathbf{K4.2},\ \mathbf{K4.3},\ \mathbf{S4},\ \mathbf{S4.1},\ \mathbf{S4.2},\ \mathbf{S4.3},$$
$$\mathbf{GL},\ \mathbf{GL.3},\ \mathbf{Grz},\ \mathbf{Grz.3},\ \mathsf{Log}\{\langle\omega,<\rangle\},\ \mathsf{Log}\{\langle\omega,\leq\rangle\},$$

and L_2 be any of

$$\mathsf{Log}\{\langle\omega,<\rangle\},\ \mathsf{Log}\{\langle\omega,\leq\rangle\},\ \mathbf{GL.3},\ \mathbf{Grz.3}.$$

Then any Kripke complete bimodal logic L in the interval

$$[L_1,L_2]\ \subseteq\ L\ \subseteq\ L_1\times L_2$$

is Π^1_1-hard.

We also obtain the following interesting corollary. As the commutator of two recursively axiomatisable logics is recursively axiomatisable by definition, Theorem 38 yields a number of *Kripke incomplete* commutators of Kripke complete and finitely axiomatisable logics:

COROLLARY 39. *Let L_1 and L_2 be like in Theorem 38. Then the commutator $[L_1,L_2]$ is Kripke incomplete.*

Higher dimensional decidable and undecidable products

Products of more than two modal logics are often undecidable and lack the fmp. Let us first discuss some exceptions.

It is not hard to see that any product $L_1\times\dots\times L_n$ of **Alt** and **K** logics has the *finite depth property*, that is, it is determined by some class of frames of finite depth. Indeed, suppose $\varphi\notin L_1\times\dots\times L_n$ for some $\mathcal{ML}_n$-formula φ. Then there are rooted frames $\mathfrak{F}_i$, $i=1,\dots,n$, such that $\mathfrak{F}_i\models L_i$ and φ is refuted at the root of $\mathfrak{F}_1\times\dots\times\mathfrak{F}_n$. By a standard unravelling argument, for each $i=1,\dots,n$, there is an intransitive tree $\mathfrak{T}_i$ and a p-morphism h_i from $\mathfrak{T}_i$ onto $\mathfrak{F}_i$. So we always have $\mathfrak{T}_i\models L_i$. Note that if $L_i=\mathbf{Alt}$ then the unravelling $\mathfrak{T}_i$ of $\mathfrak{F}_i$ is just a chain of irreflexive points. It is straightforward to check that the function h defined by

$$h(x_1,\dots,x_n)=\langle h_1(x_1),\dots,h_n(x_n)\rangle$$

is a p-morphism from $\mathfrak{T}_1\times\dots\times\mathfrak{T}_n$ onto $\mathfrak{F}_1\times\dots\times\mathfrak{F}_n$ (cf. Proposition 9). Now we prune all the trees $\mathfrak{T}_i$ down to the modal depth $md(\varphi)$ of φ. Clearly, the resulting product frame $\mathfrak{T}_1^-\times\dots\times\mathfrak{T}_n^-$ is of depth $n\cdot md(\varphi)$ and it is a frame for $L_1\times\dots\times L_n$. A straightforward induction on the stucture of φ shows that it refutes φ at its root.

As one can prove by a standard filtration argument that if an n-modal logic L has the finite depth property, then it has the fmp as well, we obtain the following theorem of Gabbay and Shehtman [24]:

THEOREM 40. *Any product of* **Alt** *and* **K** *logics has the fmp. In particular,* $\mathbf{K}^n$ *and* $\mathbf{Alt}^n$ *have the fmp, for any natural number $n\geq 2$.*

As a consequence of this theorem and Theorem 26 we have:

THEOREM 41. $\mathbf{Alt}^n$ *is decidable, for any natural number* $n \geq 2$.

In fact, it can be shown that $\mathbf{Alt}^n$ has the polynomial *product* fmp and it is coNP-complete.

On the other hand, the logic $\mathbf{K}^n$ is not so simple. Though it has the fmp, one cannot use it for a decision algorithm, as $\mathbf{K}^n$ is not only not finitely axiomatisable, but it is undecidable whether a finite n-frame is a frame for it (cf. Theorem 25). In fact, the following general result is shown in [42]:

THEOREM 42. *Let* $n \geq 3$ *and let* L *be any* n*-modal logic such that* $\mathbf{K}^n \subseteq L \subseteq \mathbf{S5}^n$. *Then* L *is undecidable and lacks the product fmp.*

The proof of this theorem (and that of Theorem 25) uses a reduction of a deep result of Hirsch and Hodkinson [40] saying that representability is undecidable for finite relation algebras.

Note that, unlike $\mathbf{K}^n$, logics like $\mathbf{K4}^n$ and $\mathbf{S5}^n$ do not even have the fmp (for $\mathbf{K4}^n$ this follows from Theorem 34, and for $\mathbf{S5}^n$ this was shown in [53]). The undecidability of $\mathbf{S5}^n$ was first shown by Maddux [58] in the algebraic framework of diagonal-free cylindric algebras. He used a reduction of the word problem of semigroups to prove the following general result:

THEOREM 43. *Any* n*-modal logic* L *in the interval*

$$[\mathbf{S5}, \mathbf{S5}, \ldots, \mathbf{S5}] \subseteq L \subseteq \mathbf{S5}^n$$

is undecidable whenever $n \geq 3$.

Another proof via the connection with first-order logic (see Section 3.2) that uses a reduction of the $\omega \times \omega$ tiling problem can be found in [23] (see also [47] for possible generalisations).

4 BETWEEN FUSIONS AND PRODUCTS

A natural idea for reducing the strong interaction between modal operators of product logics is to consider logics determined by (not necessarily generated) *subframes* of product frames. Worlds are still tuples, the relations still act coordinate-wise, but not all tuples of the Cartesian product are present, and so the commutativity and Church–Rosser properties do not necessarily hold. This kind of restriction on the 'domains' of modal operators is similar to 'relativisations' of the quantifiers in first-order logic and algebraic logic, where it indeed results in improving the bad algorithmic behaviour, cf. [63, 61].

This idea gives rise to the following combinations of logics. First, we choose a class of 'desirable' subframes of product frames. This can be any class: the class of all such subframes, the so-called 'locally cubic' frames, frames that 'expand' along one of the coordinates (see below for precise definitions), a class of frames satisfying some (modal or first-order) formulas, etc. Having chosen such a class $\mathcal{K}$, we then take the logic determined by those subframes of the appropriate product frames that belong to $\mathcal{K}$. Thus, each choice of $\mathcal{K}$ defines a new combination operator on logics:

DEFINITION 44. Let $n > 1$ be a natural number and $\mathcal{K}$ a class of subframes of n-ary product frames. Given Kripke complete (uni)modal logics $L_1, \ldots, L_n$ formulated in the language having $\Box_i$ $(i = 1, \ldots, n)$, the $\mathcal{K}$*-relativised product* $(L_1 \times \cdots \times L_n)^{\mathcal{K}}$ of $L_1, \ldots, L_n$

is defined by taking

$$(L_1 \times \cdots \times L_n)^{\mathcal{K}} = \mathsf{Log}\{\mathfrak{G} \in \mathcal{K} \mid \mathfrak{G} \subseteq \mathfrak{F}_1 \times \cdots \times \mathfrak{F}_n \text{ for some } \mathfrak{F}_i \in \mathsf{Fr}L_i,\ i = 1, \ldots, n\}.$$

Observe that if we choose $\mathcal{K}$ to be the class of all product frames $\mathfrak{F}_1 \times \cdots \times \mathfrak{F}_n$ such that $\mathfrak{F}_i \in \mathsf{Fr}L_i$, then the $\mathcal{K}$-relativised product of the L_i is just their usual product.

We discuss here in detail two kinds of 'relativised product' operators: arbitrary and expanding relativisations.

Arbitrary relativisations.

We begin by considering the combination operator determined by the class SF_n of *all* subframes of n-ary product frames. SF_n-relativised products of logics will be called *arbitrarily relativised products*. Since SF_n contains frames that do not satisfy commutativity and/or Church–Rosser properties,

$$(L_1 \times \cdots \times L_n)^{\mathsf{SF}_n} \subsetneq L_1 \times \cdots \times L_n.$$

On the other hand, unlike product logics, arbitrarily relativised products do not necessarily contain the fusion of their components. For example, consider the minimal deontic logic $\mathbf{D}$, which is known to be determined by the class of *serial* frames. The formula $\Diamond_2 \top$ clearly belongs to $\mathbf{K} \otimes \mathbf{D}$, but is refuted in any *finite* subframe of, say, $\langle \omega, < \rangle \times \langle \omega, < \rangle$, and so $\Diamond_2 \top \notin (\mathbf{K} \times \mathbf{D})^{\mathsf{SF}_2}$.

However, for a large class of natural logics, arbitrarily relativised products do contain the fusions. A Kripke complete modal logic L is called a *subframe logic* if the class of Kripke frames for L is closed under taking (not necessarily generated) subframes (see Chapter 7 of this handbook). Typical examples of subframe logics are modal logics whose classes of Kripke frames are definable by universal first-order formulas, such as $\mathbf{K}$, $\mathbf{Alt}$, $\mathbf{T}$, $\mathbf{K4}$, $\mathbf{S4}$, $\mathbf{S5}$, $\mathbf{K5}$, $\mathbf{K45}$, $\mathbf{S4.3}$, and $\mathbf{K4.3}$. Note, however, that subframe logics like $\mathbf{GL}$, $\mathbf{GL.3}$, $\mathbf{Grz}$ are not first-order definable. It is not hard to see the following:

PROPOSITION 45. *If $L_1, \ldots, L_n$ are subframe logics, then*

$$L_1 \otimes \cdots \otimes L_n \subseteq (L_1 \times \cdots \times L_n)^{\mathsf{SF}_n}.$$

As the following result of [54] shows, for many standard subframe logics the converse inclusion holds as well. Thus in several cases 'arbitrary relativisation' can be regarded as a 'many-dimensional' semantical characterisation of fusions of these logics.

THEOREM 46. *Let $L_i \in \{\mathbf{K}, \mathbf{T}, \mathbf{K4}, \mathbf{S4}, \mathbf{S5}, \mathbf{S4.3}\}$, for $i = 1, \ldots, n$. Then*

$$(L_1 \times \cdots \times L_n)^{\mathsf{SF}_n} = L_1 \otimes \cdots \otimes L_n.$$

The proof is based on the following lemma that can be proved by constructing the necessary p-morphism in a step-by-step manner, see [54]:

LEMMA 47. *Suppose that $L_i \in \{\mathbf{K}, \mathbf{T}, \mathbf{K4}, \mathbf{S4}, \mathbf{S5}, \mathbf{S4.3}\}$, $i = 1, \ldots, n$, and let $\mathfrak{G} = \langle W, S_1, \ldots, S_n \rangle$ be a countable rooted n-frame such that $\langle W, S_i \rangle \models L_i$ for all $i = 1, \ldots, n$. Then $\mathfrak{G}$ is a p-morphic image of a subframe of some product frame for $L_1 \times \cdots \times L_n$.*

It is not clear how far Theorem 46 can be generalised. It definitely does not hold for all subframe logics, not even for those of them that are characterised by universally

definable classes of frames. Take, for instance, the logic **K5** that is characterised by the class of Euclidean frames, i.e., frames $\langle W, R\rangle$ satisfying the universal (Horn) sentence

$$\forall x \forall y \forall u \left(R(u,x) \wedge R(u,y) \to R(x,y)\right).$$

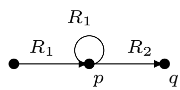
In particular, frames for **K5** have the property

$$\forall x \forall u \left(R(u,x) \to R(x,x)\right).$$

Now consider the formula

$$\varphi \;=\; \Diamond_1\big(p \wedge \Diamond_2(q \wedge \neg p)\big) \wedge \Box_1\Box_2(q \to \neg\Diamond_1 q).$$

It is clearly satisfiable in the following frame for $\mathbf{K5} \otimes \mathbf{K}$:



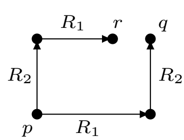
On the other hand, it is not hard to see that φ is not satisfiable in any subframe of a product frame for $\mathbf{K5} \times \mathbf{K}$. Therefore,

$$\mathbf{K5} \otimes \mathbf{K} \;\subsetneq\; (\mathbf{K5} \times \mathbf{K})^{\mathsf{SF}_2} \;\subsetneq\; \mathbf{K5} \times \mathbf{K}.$$

Other kinds of logics for which Theorem 46 does not hold are those having frames with a finite bound on their branching like **Alt**. The formula

$$\psi \;=\; p \wedge \Diamond_1\big(\neg p \wedge \Diamond_2 q\big) \wedge \Diamond_2\big(\neg p \wedge \Diamond_1 r\big) \wedge \Box_1\Box_2(q \to \neg r)$$

is clearly satisfiable in the $\mathbf{Alt} \otimes \mathbf{Alt}$-frame



On the other hand, it should be clear that ψ is not satisfiable in any subframe of a frame for $\mathbf{Alt} \times \mathbf{Alt}$. Thus,

$$\mathbf{Alt} \otimes \mathbf{Alt} \;\subsetneq\; (\mathbf{Alt} \times \mathbf{Alt})^{\mathsf{SF}_2} \;\subsetneq\; \mathbf{Alt} \times \mathbf{Alt}.$$

Expanding relativisations.

First-order modal and intuitionistic logics motivate our next combination operator. (To keep the notation simple, we concentrate on the $n = 2$ case only.)

DEFINITION 48. A 2-frame $\mathfrak{G} = \langle W, S_1, S_2\rangle$ is called an *expanding relativised product frame* if there exist frames $\mathfrak{F}_1 = \langle U_1, R_1\rangle$ and $\mathfrak{F}_2 = \langle U_2, R_2\rangle$ such that

- $\mathfrak{G}$ is a subframe of $\mathfrak{F}_1 \times \mathfrak{F}_2$, and
- for all $\langle w_1, w_2\rangle \in W$ and $u \in U_1$, if $w_1 R_1 u$ then $\langle u, w_2\rangle \in W$.

Define EX to be the class of all expanding relativised product frames. Given Kripke complete unimodal logics L_1 and L_2, the logic $(L_1 \times L_2)^{\mathsf{EX}}$ is called the *expanding relativised product* of L_1 and L_2.

Similarly to Proposition 45, if both L_1 and L_2 are subframe logics then $(L_1 \times L_2)^{\mathsf{EX}}$ is a (conservative) extension of both L_1 and L_2. Moreover, it is easy to see that every expanding relativised product frame satisfies the *left* commutativity and Church–Rosser properties (but not necessarily right commutativity). Now define the *e-commutator*

$$[L_1, L_2]^{\mathsf{EX}}$$

of L_1 *and* L_2 as the smallest bimodal logic containing L_1, L_2 and the axioms $\boldsymbol{com}^{\boldsymbol{l}}_{12}$ and $\boldsymbol{chr}_{12}$. Then clearly we have

$$[L_1, L_2]^{\mathsf{EX}} \subseteq (L_1 \times L_2)^{\mathsf{EX}}.$$

Similarly to Theorem 21, it can be shown that for some cases the e-commutator and the expanding relativised product coincide:

THEOREM 49. *Suppose* L_1 *and* L_2 *are Kripke complete unimodal logics such that* L_1 *is one of* **K**, **T**, **K4**, **S4**, **S5** *and* L_2 *is Horn axiomatisable. Then*

$$(L_1 \times L_2)^{\mathsf{EX}} = [L_1, L_2]^{\mathsf{EX}}.$$

No other general axiomatisation result for expanding relativised products is known.

As concerns decision problems, it is not hard to see that expanding relativised products are reducible to products. Indeed, let φ be an $\mathcal{ML}_2$-formula and e a propositional variable which does not occur in φ. Define by induction on the construction of φ an $\mathcal{ML}_2$-formula φ^e as follows:

$$\begin{array}{rclcrcl} p^e & = & p \quad (p \text{ a propositional variable}), & & & & \\ (\psi \wedge \chi)^e & = & \psi^e \wedge \chi^e, & & (\neg\psi)^e & = & \neg\psi^e, \\ (\Box_1\psi)^e & = & \Box_1\psi^e, & & (\Box_2\psi)^e & = & \Box_2(e \to \psi^e). \end{array}$$

By a structural induction on φ, one can easily prove the following:

PROPOSITION 50. *For all Kripke complete unimodal logics* L_1 *and* L_2 *and all* $\mathcal{ML}_2$*-formulas* φ*,*

$$\varphi \in (L_1 \times L_2)^{\mathsf{EX}} \quad \textit{iff} \quad \Big(e \wedge \Box_1^{\leq md(\varphi)}\Box_2^{\leq md(\varphi)}(e \to \Box_1 e)\Big) \to \varphi^e \in L_1 \times L_2.$$

As a consequence of this and the results in Section 3.4, we obtain that expanding relativised products are usually decidable if one of their components is an **S5**- or **K**-like logic.

On the other hand, as we saw in Section 3.4, products of 'transitive' logics with frames of arbitrarily large finite or infinite cluster-depth are undecidable. The following result of [27] shows that expanding relativised product logics with components having transitive frames of arbitrarily large finite cluster-depths can be *decidable*:

THEOREM 51. *If* $L_1, L_2 \in \{$**GL**, **Grz**, **GL.3**, **Grz.3**$\}$ *then* $(L_1 \times L_2)^{\mathsf{EX}}$ *is decidable.*

Here we discuss the main points of the proof for the case of $(\mathbf{GL}\times\mathbf{GL})^{\mathsf{EX}}$ only. For the other cases, as well as for more general results, consult [27].

We remind the reader that $\mathsf{Fr}\,\mathbf{GL}$ consists of all the irreflexive, transitive and Noetherian frames. Recall that the *depth* $d^{\mathfrak{F}}(x)$ of a point x in an irreflexive tree $\mathfrak{F}=\langle W,R\rangle$ is defined to be the R-distance of x from the root. More precisely, the depth of the root is 0, and the depth of immediate R-successors of a point of depth n is $n+1$. If for no $n<\omega$ the point x is of depth n, then we say that x is of *infinite depth.*

The first important step in the proof is to show that $(\mathbf{GL}\times\mathbf{GL})^{\mathsf{EX}}$ has the 'expanding' version of the product fmp:

LEMMA 52. *Given some $\mathcal{ML}_2$-formula φ, if φ is satisfiable in a frame for $(\mathbf{GL}\times\mathbf{GL})^{\mathsf{EX}}$ then φ is satisfiable in an expanding relativised product frame $\mathfrak{H}$ that is a subframe of a product of two finite trees $\mathfrak{G}_1$ and $\mathfrak{G}_2$. Moreover, $\mathfrak{G}_1=\langle U_1,S_1\rangle$ can be chosen such that, for every $x\in U_1$,*

- $|\{y \mid \langle x,y\rangle \text{ in } \mathfrak{H}\}| \le \big(|sub\,\varphi|+1\big)!^{\,d^{\mathfrak{G}_1}(x)+1}$, *and*
- *x has at most $|sub\,\varphi|\cdot\big(|sub\,\varphi|+1\big)!^{\,d^{\mathfrak{G}_1}(x)+1}$ immediate S_1-successors.*

Proof. By a standard unravelling argument one can show that every rooted frame for $\mathbf{GL}$ is a p-morphic image of a Noetherian tree-like frame. Moreover, similarly to Proposition 9, one can show that $(\mathbf{GL}\times\mathbf{GL})^{\mathsf{EX}}$ is determined by expanding relativised product frames that are subframes of products of two Noetherian tree-like frames. So we may assume that our formula φ is satisfied at the root $\langle r_1,r_2\rangle$ of some model $\mathfrak{M}=\langle\mathfrak{H},\mathfrak{V}\rangle$ that is based on an expanding relativised subframe $\mathfrak{F}=\langle W,R_1',R_2'\rangle$ of the product of two (possibly infinite) Noetherian tree-like frames $\mathfrak{F}_1=\langle W_1,R_1\rangle$ and $\mathfrak{F}_2=\langle W_2,R_2\rangle$.

For $i=1,2$, call a point x in W_i *R_i-maximal in a set $X\subseteq W_i$*, if $x\in X$ and there is no $x'\in X$ with xR_ix'. Now we take the closure U of the set $\{\langle r_1,r_2\rangle\}$ under the the following three rules:

- **$\Diamond_1$-rule:** if $\langle x,y\rangle\in U$, $(\mathfrak{M},\langle x,y\rangle)\models\Diamond_1\psi$, for some $\Diamond_1\psi\in sub\,\varphi$, and there is no $\langle x',y\rangle\in U$ such that xR_1x' and $(\mathfrak{M},\langle x',y\rangle)\models\psi$, then choose a point $x'\in W_1$ that is R_1-maximal in the set $\{z\mid xR_1z,\ \langle z,y\rangle\in W \text{ and } (\mathfrak{M},\langle z,y\rangle)\models\psi\}$ (such a point exists because $\mathfrak{F}_1$ is Noetherian), and set $U:=U\cup\{\langle x',y\rangle\}$.
- **$\Diamond_2$-rule:** if $\langle x,y\rangle\in U$, $(\mathfrak{M},\langle x,y\rangle)\models\Diamond_2\psi$, for some $\Diamond_2\psi\in sub\,\varphi$, and there is no $\langle x,y'\rangle\in U$ such that yR_2y' and $(\mathfrak{M},\langle x,y'\rangle)\models\psi$, then choose a point $y'\in W_2$ that is R_2-maximal in the set $\{z\mid yR_2z,\ \langle x,z\rangle\in W \text{ and } (\mathfrak{M},\langle x,z\rangle)\models\psi\}$ (such a point exists because $\mathfrak{F}_2$ is Noetherian), and set $U:=U\cup\{\langle x,y'\rangle\}$.
- **Square-rule:** if $\langle x,y\rangle\in U$, xR_1x' and $\langle x',y\rangle\notin U$, then set $U:=U\cup\{\langle x',y\rangle\}$.

Now let $S_i'=R_i'\cap(U\times U)$ $(i=1,2)$ and $\mathfrak{H}=\langle U,S_1',S_2'\rangle$. Take also $\mathfrak{G}_1=\langle U_1,S_1\rangle$ and $\mathfrak{G}_2=\langle U_2,S_2\rangle$, where $U_1=\{x\in W_1\mid \langle x,r_2\rangle\in U\}$, $U_2=\{y\in W_2\mid \exists x\in U_1\ \langle x,y\rangle\in U\}$, and $S_i=R_i\cap(U_i\times U_i)$ $(i=1,2)$. Then clearly, $\mathfrak{H}$ is an expanding relativised subframe of the product of Noetherian tree-like frames $\mathfrak{G}_1$ and $\mathfrak{G}_2$.

We show that $\mathfrak{G}_1$ and $\mathfrak{G}_2$ are in fact finite trees with the required bounds. First, we claim that

$$\text{if } x \text{ is of finite depth in } \mathfrak{G}_1, \text{ then } |\{y\mid\langle x,y\rangle\in U\}| \le \big(|sub\,\varphi|+1\big)!^{\,d^{\mathfrak{G}_1}(x)+1}. \tag{24}$$

Indeed, we can proceed by induction on n. If $n = 0$, then by applying the $\Diamond_2$-rule to the root $\langle r_1, r_2\rangle$ of $\mathfrak{H}$, we can obtain $\leq |sub\,\varphi|$ immediate S_2'-successors of the form $\langle r_1, y\rangle$. In view of maximality, at each of these points the number of formulas of the form $\Diamond_2\psi \in sub\,\varphi$ to which the $\Diamond_2$-rule still applies is $\leq |sub\,\varphi| - 1$. We proceed with the same kind of argument and finally get

$$|\{y \mid \langle x, y\rangle \in U\}| \;\;\leq\;\; 1+|sub\,\varphi|+|sub\,\varphi|\cdot(|sub\,\varphi|-1)+\cdots+|sub\,\varphi|\,! \;\leq\; (|sub\,\varphi|+1)\,!\,.$$

The induction step for y of depth $n+1$ is considered analogously. The only difference is that instead of one 'starting' point we should start applying the $\Diamond_2$-rule to all points of the form $\langle x, y\rangle$ such that $\langle z, y\rangle \in U$ for the unique point z with $d(z) = n$ and zS_1y, that is to $|\{y \mid \langle z, y\rangle \in U\}| \leq \big(|sub\,\varphi| + 1\big)!^{\,n+1}$ many points.

Next, we claim that every point x of finite depth in $\mathfrak{G}_1$ has $\leq |sub\,\varphi|\cdot\big(|sub\,\varphi|+1\big)!^{\,d(x)+1}$ immediate S_1-successors. Indeed, it follows from (24) and the fact that the $\Diamond_1$-rule can be applied at most $|sub\,\varphi|$ times to a point $\langle x, y\rangle$.

Finally, we claim that every point in $\mathfrak{G}_1$ is of finite depth, that is, $\mathfrak{G}_1$ is a tree. Indeed, since $\mathfrak{G}_1$ is Noetherian, we cannot have infinite ascending chains of distinct points in it. Suppose $\mathfrak{G}_1$ still contains a point x of infinite depth. This means that there is an infinite descending chain $\ldots S_1x_2S_1x_1S_1x$. Let z be an S_1-maximal point of finite depth such that zS_1x. By (24), $|\{y \mid \langle z, y\rangle \in U\}|$ is finite. Therefore, we may apply the $\Diamond_1$-rule to points of the form $\langle z, y\rangle$ finitely many times only, and so there exists an immediate S_1-successor z' of z located properly between z and x. But then $d(z') = d(z)+1$, and so the depth of z' is finite, which is a contradiction.

Therefore, $\mathfrak{G}_1$ is a Noetherian tree with finite branching. Therefore, by König's lemma, it must be finite. So $\mathfrak{G}_2$ is finite as well. This completes the proof of Lemma 52. ❑

We are now in a position to prove that $(\mathbf{GL}\times\mathbf{GL})^{\mathsf{EX}}$ is decidable. It is to be noted that the 'expanding product fmp' does not give decidability automatically because (i) Lemma 52 does not provide us with an effective upper bound for the size of a model refuting a given formula, nor (ii) do we know that $(\mathbf{GL}\times\mathbf{GL})^{\mathsf{EX}}$ is finitely axiomatisable.

Instead, we will use a version of Kruskal's tree theorem [50]. Given a finite set Σ, a *labelled Σ-tree* is a pair $\mathfrak{T} = \langle\langle T, <\rangle, l\rangle$, where $\langle T, <\rangle$ is a (transitive, irreflexive) tree and l is a function from T to Σ. Given two finite labelled Σ-trees $\mathfrak{T}_i = \langle\langle T_i, <_i\rangle, l_i\rangle$, $i = 1, 2$, we say that $\mathfrak{T}_1$ is *embeddable* into $\mathfrak{T}_2$ if there exists an injective map $\iota : T_1 \to T_2$ such that, for all $u, v \in T_1$,

- $u <_1 v$ iff $\iota(u) <_2 \iota(v)$,
- $l_2(\iota(u)) = l_1(u)$.

Now Kruskal's tree theorem says that for every infinite sequence $\mathfrak{T}_1, \mathfrak{T}_2, \ldots$ of finite labelled Σ-trees, there exist $i < j < \omega$ such that $\mathfrak{T}_i$ is embeddable into $\mathfrak{T}_j$.

In order to use this theorem, we again turn our models to *quasimodels*. The quasimodels used here are similar to the $L\times\mathbf{K}$-quasimodels of Section 3.4, but they do differ from them in two important aspects: (i) quasistates are now not intransitive, but *transitive* and *irreflexive* trees; (ii) runs are not total, but only *partial* functions over the underlying frame.

To be precise, given an $\mathcal{ML}_2$-formula φ, a *quasistate* for φ is a finite labelled (transitive, irreflexive) tree $\langle\langle T, <\rangle, \boldsymbol{t}\rangle$ where the label $\boldsymbol{t}(x)$ of each $x \in T$ is a type for φ, and $\langle\langle T, <\rangle, \boldsymbol{t}\rangle$ satisfies the $\Diamond_2$-saturation condition **(qm1)** of Section 3.4.

A *basic structure* for φ is a pair $\langle\mathfrak{F},\boldsymbol{q}\rangle$ such that $\mathfrak{F}=\langle W,R\rangle$ is a finite (transitive, irreflexive) tree and $\boldsymbol{q}$ a function associating with each $w\in W$ a quasistate $\boldsymbol{q}(w)=\langle\langle T_w,<_w\rangle,\boldsymbol{t}_w\rangle$ for φ. We call such a basic structure *small* if, for all $x,y\in W$,

(sm1) $|T_x|\leq\big(|sub\,\varphi|+1\big)!^{\,d^{\mathfrak{F}}(x)+1}$,

(sm2) x has at most $|sub\,\varphi|\cdot\big(|sub\,\varphi|+1\big)!^{\,d^{\mathfrak{F}}(x)+1}$ immediate R-successors in $\mathfrak{F}$, and

(sm3) if xRy and $x\neq y$ then $\boldsymbol{q}(x)$ is not embeddable into $\boldsymbol{q}(y)$.

For every $n<\omega$, let Q_n be the set of all small basic structures $\langle\mathfrak{F},\boldsymbol{q}\rangle$ such that $\mathfrak{F}$ is a finite (transitive, irreflexive) tree of depth n.

LEMMA 53. *There is an $n<\omega$ such that $Q_n=\emptyset$, and so the set of small basic structures for φ is finite and can be constructed effectively from φ.*

Proof. Suppose otherwise. Define a relation E on the set Q of all small basic structures as follows. For $\mathfrak{Q}=\langle\mathfrak{F},\boldsymbol{q}\rangle$, $\mathfrak{Q}'=\langle\mathfrak{F}',\boldsymbol{q}'\rangle$ in Q, set $\mathfrak{Q}E\mathfrak{Q}'$ iff $\mathfrak{F}$ is an 'initial subtree' of $\mathfrak{F}'$ and $\boldsymbol{q}$ coincides with $\boldsymbol{q}'$ on the points of $\mathfrak{F}$. Clearly, for every $\mathfrak{Q}'\in Q_{n+1}$, there is some $\mathfrak{Q}\in Q_n$ such that $\mathfrak{Q}E\mathfrak{Q}'$. Therefore, by König's infinity lemma, there is an infinite E-chain $\mathfrak{Q}_0E\mathfrak{Q}_1E\dots E\mathfrak{Q}_nE\dots$ in Q such that $\mathfrak{Q}_n\in Q_n$ for $n<\omega$. Since $\mathfrak{Q}_{n+1}$ is always an extension of $\mathfrak{Q}_n$, their union $\mathfrak{Q}=\bigcup_{n<\omega}\mathfrak{Q}_n$ is also a basic structure. Let $\mathfrak{Q}=\langle\mathfrak{F},\boldsymbol{q}\rangle$ and $\mathfrak{F}=\langle W,R\rangle$. Then $\mathfrak{F}$ is an infinite tree with finite branching. By König's lemma, it must have an infinite branch $x_0Rx_1R\dots$. Then, by Kruskal's theorem, there exist $i<j<\omega$ such that $\boldsymbol{q}(x_i)$ is embeddable into $\boldsymbol{q}(x_j)$. But x_i and x_j already belonged to the underlying tree of $\mathfrak{Q}_j$, contrary to $\mathfrak{Q}_j$ being in Q_j. ❏

A *run through* a basic structure $\langle\mathfrak{F},\boldsymbol{q}\rangle$ is a partial function r from W giving for each $w\in\operatorname{dom}r$ a point $r(w)\in T_w$ such that, for all $x\in W$, if $x\in\operatorname{dom}r$ and xRy then $y\in\operatorname{dom}r$. Coherent and saturated runs are defined as in Section 3.4. Finally, we call a triple $\langle\mathfrak{F},\boldsymbol{q},\mathcal{R}\rangle$ a $(\mathbf{GL}\times\mathbf{GL})^{\mathsf{EX}}$-*quasimodel* (for φ) if $\langle\mathfrak{F},\boldsymbol{q}\rangle$ is a basic structure and $\mathfrak{R}$ is a set of coherent and saturated runs through it, satisfying the following conditions (cf. **(qm2)**–**(qm4)** of Section 3.4):

(eqm2) $\varphi\in\boldsymbol{t}_{w_0}(x_0)$, where w_0 and x_0 are the roots of $\mathfrak{F}$ and $\langle T_{w_0},<_{w_0}\rangle$, respectively;

(eqm3) for all $r,r'\in\mathcal{R}$ and for all $x,y\in\operatorname{dom}r\cap\operatorname{dom}r'$, $w_{r(x)}<_x w_{r'(x)}$ iff $w_{r(y)}<_y w_{r'(y)}$;

(eqm4) for all $x\in W$ and $w\in T_x$ there is $r\in\mathcal{R}$ such that $r(x)=w$.

We call a quasimodel *small* if the underlying basic structure is small.

LEMMA 54. *φ is satisfiable in a frame for $(\mathbf{GL}\times\mathbf{GL})^{\mathsf{EX}}$ iff there is a small $(\mathbf{GL}\times\mathbf{GL})^{\mathsf{EX}}$-quasimodel for φ.*

Proof. Turning a quasimodel to a 'real' model is easy, so let us concentrate on the opposite direction. We may assume that φ is satisfied in a model $\mathfrak{M}=\langle\mathfrak{H},\mathfrak{V}\rangle$ based on an expanding relativised subframe $\mathfrak{H}$ of a product $\mathfrak{G}_1\times\mathfrak{G}_2$ satisfying the conditions of Lemma 52. We can turn $\mathfrak{M}$ to a $(\mathbf{GL}\times\mathbf{GL})^{\mathsf{EX}}$-quasimodel $\langle\mathfrak{G}_1,\boldsymbol{q},\mathcal{R}\rangle$ as follows. Suppose that $\mathfrak{G}_i=\langle U_i,S_i\rangle$, for $i=1,2$. For every $x\in U_1$, let $\boldsymbol{q}(x)=\langle\langle T_x,<_x\rangle,\boldsymbol{t}_x\rangle$, where

$$\begin{aligned} T_x &= \{y\in U_2 \mid \langle x,y\rangle \text{ in } \mathfrak{H}\}, &\qquad <_x &= S_2\cap(T_x\times T_x),\\ \boldsymbol{t}_x(y) &= \{\psi\in sub\,\varphi \mid (\mathfrak{M},\langle x,y\rangle)\models\psi\}. \end{aligned}$$

Finally, for every $y \in U_2$ define a run r_y through $\langle \mathfrak{G}_1, \boldsymbol{q} \rangle$ by taking

$$\operatorname{dom} r_y = \{x \in U_1 \mid \langle x, y \rangle \text{ in } \mathfrak{H}\}$$

and then $r_y(x) = y$, for every $x \in \operatorname{dom} r_y$. Put $\mathcal{R} = \{r_y \mid y \in U_2\}$. It is straightforward to check that $\langle \mathfrak{G}_1, \boldsymbol{q}, \mathcal{R} \rangle$ is indeed a $(\mathbf{GL} \times \mathbf{GL})^{\mathsf{EX}}$-quasimodel for φ. Moreover, by the assumption on $\mathfrak{M}$, the basic structure $\langle \mathfrak{G}_1, \boldsymbol{q} \rangle$ is finite. To show that we can turn it to a basic structure satisfying **(sm3)**, suppose that there are $x, y \in U_1$ such that xS_1y and $\boldsymbol{q}(x)$ is embeddable into $\boldsymbol{q}(y)$ by an embedding ι. Then we replace in $\mathfrak{G}_1$ the subtree generated by x with the subtree generated by y, thus obtaining some tree $\mathfrak{G}' = \langle U', S' \rangle$. Let $\boldsymbol{q}'$ be the restriction of $\boldsymbol{q}$ to U'. We define new runs through $\langle \mathfrak{G}', \boldsymbol{q}' \rangle$ by taking, for all $r, r' \in \mathcal{R}$ such that $x \in \operatorname{dom} r$, $y \in \operatorname{dom} r'$, $\iota(r(x)) = r'(y)$, and for all $z \in U'$, $z \in \operatorname{dom} r$,

$$(r + r')(z) \;=\; \begin{cases} r(z), & \text{if } zS_1x, \\ r'(z), & \text{if } z = y \text{ or } yS_1z. \end{cases}$$

Let $\mathcal{R}'$ be the collection of these new runs together with those runs from $\mathcal{R}$ that 'start at' a point z with yS_1z. It is straightforward to check that $\langle \mathfrak{G}', \boldsymbol{q}', \mathcal{R}' \rangle$ is a $(\mathbf{GL} \times \mathbf{GL})^{\mathsf{EX}}$-quasimodel for φ. Since $\mathfrak{G}_1$ is finite, after finitely many repetitions of this procedure the underlying basic structure will satisfy **(sm3)**. To comply with the cardinality conditions **(sm1)** and **(sm2)**, we can use the construction from the proof of Lemma 52. Then, again we can get rid of the embeddable pairs as above, and so on. As at each step the underlying tree can get only smaller, we end up with a small $(\mathbf{GL} \times \mathbf{GL})^{\mathsf{EX}}$-quasimodel for φ. ❑

Now we can describe the decision algorithm for $(\mathbf{GL} \times \mathbf{GL})^{\mathsf{EX}}$ as follows. Given a formula φ, by Lemma 53, we can effectively construct the set of all small basic structures for φ. Then for each such small basic structure, we check whether it is a $(\mathbf{GL} \times \mathbf{GL})^{\mathsf{EX}}$-quasimodel for φ. By Lemma 54, this way we find a quasimodel for φ iff φ is satisfiable in a frame for $(\mathbf{GL} \times \mathbf{GL})^{\mathsf{EX}}$.

Observe that this decision procedure does not give an even primitive recursive complexity bound. In fact, using a reduction of the reachability problem for *lossy channel systems* (known to be non-primitive recursive by Schnoebelen [73]), it is shown in [27] that there is no primitive recursive decision algorithm for $(\mathbf{GL} \times \mathbf{GL})^{\mathsf{EX}}$.

Other expanding relativised products can even be more complex. The results in [46] suggest that logics like $(\mathsf{Log}\{\langle \mathbb{N}, < \rangle\} \times \mathsf{Log}\{\langle \mathbb{N}, < \rangle\})^{\mathsf{EX}}$ or $(\mathsf{Log}\{\langle \mathbb{N}, < \rangle\} \times \mathbf{S4})^{\mathsf{EX}}$ are undecidable. However, nothing is known about the decision problem of products 'expanding along' branching transitive frames with infinite ascending chains, such as $(\mathbf{K4} \times \mathbf{K4})^{\mathsf{EX}}$ or $(\mathbf{S4} \times \mathbf{S4.3})^{\mathsf{EX}}$. Note that these logics do not have the 'expanding product fmp'.

Another open direction of research is to study the decision problem for the finitely axiomatisable logics obtained by adding either only one of the commutativity axioms or the Church–Rosser axioms to decidable fusions.

5 OTHER COMBINATIONS

Of course, even within the constraints of the combination principles **(C1)**–**(C3)** formulated in the introduction, there are infinitely many ways of combining modal logics. Though much research have been done on multimodal logics, very little of it can be

regarded as systematic investigation into properties of some combination method. Moreover, the 'global analysis'—as explained in Chapter 7 of this handbook for the unimodal case—of multimodal logics is still in its infancy. (In fact, most of the investigations into fusions and products can be considered as the first detailed case studies.) The translation of [49] of multimodal logics into unimodal ones is not helpful either in the combination context, as it makes the information about the 'components' virtually disappear.

Releasing (parts of) the criteria **(C2)** and **(C3)** allows us to treat more 'multi-aspect' approaches to modal logic as combinations. The possibilities are again endless, below we discuss a rather ad hoc list of examples. Many more ideas that are relevant to combining modal logics can be found in the 'combining systems' literature, see e.g. the series 'Frontiers of Combining Systems (FroCoS)' [8, 14, 45, 2].

Interaction operators. Interaction between the components can be handled not only by adding interaction axioms, but also by enriching the language with 'dimension-connecting' connectives.

Perhaps the simplest and most natural operations of this sort are the *diagonal constants* d_{ij}. Given two natural numbers i and j with $1 \leq i, j \leq n$, the truth-relation for the constant d_{ij} in models over (subframes of) n-ary product frames is defined as follows:

$$(\mathfrak{M}, \langle u_1, \dots, u_n \rangle) \models \mathsf{d}_{ij} \quad \text{iff} \quad u_i = u_j.$$

The set of n-tuples satisfying d_{ij} is usually called the (i, j)-*diagonal element*. The main reason for introducing such constants has been to give a 'modal treatment' of equality of classical first-order logic, see Section 3.2 above. Modal algebras for the product logic $\mathbf{S5}^n$ extended with diagonal elements are called *representable cylindric algebras* and are extensively studied in the algebraic logic literature; see e.g. [39, 41] and the references therein.

Another natural way of connecting dimensions is via so-called 'jump' modalities. Given a function $\pi : \{1, \dots, n\} \to \{1, \dots, n\}$ (such a map can be called a *jump*), define the truth-relation for the unary modal operator s_π in models over (subframes of) product frames as follows:

$$(\mathfrak{M}, \langle u_1, \dots, u_n \rangle) \models \mathsf{s}_\pi \varphi \quad \text{iff} \quad (\mathfrak{M}, \langle u_{\pi(1)}, \dots, u_{\pi(n)} \rangle) \models \varphi.$$

These modal operators are often called (*generalised*) *substitutions*, since by taking

$$P(x_{\pi(1)-1}, \dots, x_{\pi(n)-1})^\bullet = \mathsf{s}_\pi P(x_0, \dots, x_{n-1}) \qquad (P \text{ an atomic formula})$$

one can extend the translation $^\bullet$ of Section 3.2 above from formulas with a fixed order of the variables to arbitrary first-order formulas. Note that in cubic universal product $\mathbf{S5}^n$-frames certain substitutions are expressible with the help of the boxes and the diagonal constants [39]. Various versions of modal algebras corresponding to products of $\mathbf{S5}$ logics with substitutions and with or without diagonal constants (e.g., *polyadic* and *substitution algebras*) are introduced by Halmos [33, 34] and Pinter [64, 65] and have been studied in the algebraic logic literature ever since.

Valuation restrictions. One may try to loosen the strong interaction between the components of product logics by imposing restrictions on possible valuations in models over (subframes of) product frames. In general, the resulting formalisms will not be closed under the rule of Substitution, and so do not satisfy **(C2)**.

DEFINITION 55. Let $\mathfrak{M}_1 = \langle \mathfrak{F}_1, \mathfrak{V}_1 \rangle$ and $\mathfrak{M}_2 = \langle \mathfrak{F}_2, \mathfrak{V}_2 \rangle$ be Kripke models that are based on respective frames $\mathfrak{F}_1 = \langle W_1, R_1 \rangle$ and $\mathfrak{F}_2 = \langle W_2, R_2 \rangle$, and let $\Phi(x_1, x_2)$ be a formula in the first-order language $\mathcal{L}$ having two unary predicate symbols V_1, V_2 and two binary predicate symbols. Then a model

$$\mathfrak{M}^\Phi = \left\langle \mathfrak{F}_1 \times \mathfrak{F}_2, \mathfrak{V}^\Phi \right\rangle$$

is said to be a Φ-*flat product of* $\mathfrak{M}_1$ *and* $\mathfrak{M}_2$ if, for all propositional variables p and all $u_1 \in W_1$, $u_2 \in W_2$,

$$\langle u_1, u_2 \rangle \in \mathfrak{V}^\Phi(p) \quad \text{iff} \quad I_p \models \Phi[u_1, u_2],$$

where I_p is the first-order $\mathcal{L}$-structure $I_p = \langle W_1 \cup W_2, \mathfrak{V}_1(p), \mathfrak{V}_2(p), R_1, R_2 \rangle$. The valuations in flat-product models are called *flat valuations.*

If Φ is a Boolean combination of $V_1(x_1)$ and $V_2(x_2)$ then we say that $\mathfrak{M}^\Phi$ is a *Boolean-flat model.*

Boolean-flat models are introduced and studied in [21, 37]. Various special cases of flat valuations are discussed for many-dimensional temporal logics in [21, 22] and for temporal arrow logics in [61]. Satisfiability in Boolean-flat models can be reduced to satisfiability in the component models, as the following 'flat product decomposition theorem' of Gabbay and Shehtman [25, 23] shows:

THEOREM 56. *Let $\mathfrak{M}^\Phi$ be a Boolean-flat product of models $\mathfrak{M}_1$ and $\mathfrak{M}_2$. Then for every $\mathcal{ML}_2$-formula φ, there are a finite set I_φ and unimodal formulas $\varphi_i^{\mathbf{1}}$ (with $\Box_1$) and $\varphi_i^{\mathbf{2}}$ (with $\Box_2$), $i \in I_\varphi$, such that, for all worlds $\langle u_1, u_2 \rangle$ in $\mathfrak{M}^\Phi$,*

$$(\mathfrak{M}^\Phi, \langle u_1, u_2 \rangle) \models \varphi \qquad \textit{iff} \qquad \exists i \in I_\varphi \big((\mathfrak{M}_1, u_1) \models \varphi_i^{\mathbf{1}} \textit{ and } (\mathfrak{M}_2, u_2) \models \varphi_i^{\mathbf{2}} \big).$$

Modalising one logic with another. Another possibility is to take some combination method satisfying **(C1)**–**(C3)** and then consider a *fragment* of the full modal language only. The general methodology of 'temporalising' a logic, introduced by Finger and Gabbay [17], results in such a combination when applied to two modal logics:

DEFINITION 57. The set of *modalised formulas* is the smallest set Γ of $\mathcal{ML}_2$-formulas such that:

- if φ is an $\mathcal{ML}_1$-formula then $\varphi \in \Gamma$,
- Γ is closed under Boolean combinations,
- if $\varphi \in \Gamma$ then $\Diamond_2 \varphi \in \Gamma$ and $\Box_2 \varphi \in \Gamma$.

We will evaluate modalised formulas in *modalised models.* These are structures of the form $\mathfrak{M} = \langle \mathfrak{F}, f \rangle$, where $\mathfrak{F} = \langle W, R \rangle$ is a frame and f is a function mapping each $w \in W$ to a pair $f(w) = \langle \mathfrak{M}_w, x_w \rangle$ with $\mathfrak{M}_w$ being a Kripke model and x_w a world in it. The *truth-relation* '$\mathfrak{M}, w \models \varphi$' for modalised formulas φ and worlds w in $\mathfrak{F}$ is defined inductively as follows:

- $\mathfrak{M}, w \models \psi$ iff $(\mathfrak{M}_w, x_w) \models \psi$, whenever ψ is an $\mathcal{ML}_1$-formula,
- $\mathfrak{M}, w \models \neg\psi$ iff $\mathfrak{M}, w \not\models \psi$,
- $\mathfrak{M}, w \models \psi \wedge \chi$ iff $\mathfrak{M}, w \models \psi$ and $\mathfrak{M}, w \models \chi$,

- $\mathfrak{M}, w \models \Diamond_2\psi$ iff there is $v \in W$ such that wRv and $\mathfrak{M}, v \models \psi$.

We say that φ *is true in* $\mathfrak{M}$ if $\mathfrak{M}, w \models \varphi$ for all $w \in W$.

Now let L_1 and L_2 be two Kripke complete unimodal logics formulated in the language $\mathcal{ML}_1$ in such a way that they have different modal operators (say, $\Diamond_1, \Box_1$ and $\Diamond_2, \Box_2$, respectively). The *modalisation of* L_1 *with* L_2 is the set $L_2[L_1]$ of modalised formulas that are true in all modalised models $\mathfrak{M} = \langle \mathfrak{F}, f \rangle$ where

- $\mathfrak{F}$ is a frame for L_2, and
- for all w in $\mathfrak{F}$, the underlying frame of $\mathfrak{M}_w$ is a frame for L_1.

It is not hard to see that $L_2[L_1]$ is a decidable subset of all $\mathcal{ML}_2$-formulas, whenever L_1 and L_2 are both decidable. In fact, this is a consequence of Theorem 5, as $L_2[L_1]$ is a fragment of the fusion of L_1 and L_2 in the sense that $L_2[L_1]$ is the set of all modalised formulas in $L_1 \otimes L_2$ (cf. the proof of Theorem 3).

$\mathcal{E}$-connections. This combination method is introduced by Kutz *et al.* [56, 55] in the more general setting of 'abstract description systems.' When applied to modal logics, this method takes disjoint Kripke models for each component and connects their domains via 'link relations.' These 'connections' then also appear explicitly in the language.

DEFINITION 58. Suppose that we have n 'copies' of the unimodal language $\mathcal{ML}_1$ in such a way that their sets of propositional variables are disjoint (say, $p_0^i, p_1^i, \dots$ for the ith copy) and their modal operators are disjoint as well (say, $\Box_i$ and $\Diamond_i$ for the ith copy). Let J be a non-empty set and take an $n-1$-ary new connective ${}^i\langle E_j \rangle$, for each $j \in J$, $i = 1, \dots, n$. Then the *n-ary $\mathcal{E}$-connection language* $\mathcal{EL}_n^J$ is defined as follows. *$\mathcal{EL}_n^J$-formulas* are partitioned into n sets, each one containing the so-called *i-formulas* for some $i = 1, \dots, n$. For all $i = 1, \dots, n$, the sets of i-formulas are defined by simultaneous induction:

- the propositional variables $p_0^i, p_1^i, \dots$ are i-formulas,
- the set of i-formulas is closed under the Boolean connectives and the modal operators $\Box_i$ and $\Diamond_i$,
- if φ_k is a k-formula, for each $k = 1, \dots, i-1, i+1, \dots, n$, then
$$ {}^i\langle E_j \rangle (\varphi_1, \dots, \varphi_{i-1}, \varphi_{i+1}, \dots, \varphi_n) $$
is an i-formula, for every $j \in J$.

$\mathcal{EL}_n^J$-formulas are evaluated in *$\mathcal{EL}_n^J$-models.* These are structures of the form
$$ \mathfrak{M} = \left\langle \mathfrak{M}_1, \dots, \mathfrak{M}_n, E_j^{\mathfrak{M}} \right\rangle_{j \in J}, $$
where the $\mathfrak{M}_i = \langle \langle W_i, R_i \rangle, \mathfrak{V}_i \rangle$ are (unimodal) Kripke models and $E_j^{\mathfrak{M}} \subseteq W_1 \times \dots \times W_n$, for each $j \in J$. The *truth-relation* '$\mathfrak{M}, w \models \varphi$' for i-formulas φ and worlds w in $\mathfrak{M}_i$ is defined inductively as follows, simultaneously for $i = 1, \dots, n$:

- $\mathfrak{M}, w \models p_k^i$ iff $w \in \mathfrak{V}_i(p_k^i)$,
- $\mathfrak{M}, w \models \neg\psi$ iff $\mathfrak{M}, w \not\models \psi$,

- $\mathfrak{M}, w \models \psi \wedge \chi$ iff $\mathfrak{M}, w \models \psi$ and $\mathfrak{M}, w \models \chi$,
- $\mathfrak{M}, w \models \Diamond_i \psi$ iff there is $v \in W_i$ such that wR_iv and $\mathfrak{M}, v \models \psi$,
- $\mathfrak{M}, w \models {}^i\langle E_j \rangle (\psi_1, \ldots, \psi_{i-1}, \psi_{i+1}, \ldots, \psi_n)$ iff for all $k = 1, \ldots, i-1, i+1, \ldots, n$ there are $v_k \in W_k$ such that $\mathfrak{M}, v_k \models \psi_k$ and $\langle v_1, \ldots, v_{i-1}, w, v_{i+1}, \ldots, v_n \rangle \in E_j^{\mathfrak{M}}$.

We say that an i-formula φ *is true in* $\mathfrak{M}$ if $\mathfrak{M}, w \models \varphi$ for all $w \in W_i$.

Now let $L_1, \ldots, L_n$ be unimodal logics formulated in n 'almost disjoint' copies of $\mathcal{ML}_1$ as described above, and let J be a non-empty set. The *basic $\mathcal{E}$-connection*

$$\mathcal{EC}^J(L_1, \ldots, L_n)$$

of $L_1, \ldots, L_n$ is the set of all *$\mathcal{EL}_n^J$-formulas* that are true in all $\mathcal{EL}_n^J$-models $\mathfrak{M} = \langle \mathfrak{M}_1, \ldots, \mathfrak{M}_n, E_j^{\mathfrak{M}} \rangle_{j \in J}$ where $\mathfrak{M}_i$ is a model for L_i, for $i = 1, \ldots, n$.

The following theorem on the transfer of decidability is proved in [55] in the more general setting of 'abstract desription systems:'

THEOREM 59. *If $L_1, \ldots, L_n$ are all decidable unimodal modal logics, then the basic $\mathcal{E}$-connection $\mathcal{EC}^J(L_1, \ldots, L_n)$ is decidable.*

Intuively, the decision procedure for, say, $\mathcal{EC}^{\{0\}}(L_1, L_2)$ works as follows. As usual, we can consider satisfiability instead of validity. To check whether there exists a model $\mathfrak{M} = \langle \mathfrak{M}_1, \mathfrak{M}_2, E_0 \rangle$ and a world w in $\mathfrak{M}_i$ such that $\mathfrak{M}, w \models \varphi$ for a given i-formula φ, the algorithm non-deterministically 'guesses'

- the 1-types that are realised in $\mathfrak{M}_1$ and the 2-types that are realised in $\mathfrak{M}_2$ (where a *k-type* is a set of k-formulas that are true at a world of $\mathfrak{M}_k$), and
- a binary relation e between the guessed sets of 1-types and 2-types.

Then it checks whether the guessed sets satisfy a collection of 'integrity conditions.' This check involves satisfiability tests of certain sets of k-formulas constructed from φ, for $k = 1, 2$—here we exploit that L_1 and L_2 are decidable. If the integrity conditions are satisfied, then it is possible to construct a model satisfying φ using models of the constructed sets of k-formulas. If the integrity conditions are not satisfied then φ is not satisfiable. This algorithm also provides an upper bound for the satisfiability problem for $\mathcal{EC}^J(L_1, \ldots, L_n)$: the time complexity is non-deterministic and one exponent higher than the maximal time complexity of the component procedures.

ACKNOWLEDGEMENTS

The work on this chapter was partially supported by U.K. EPSRC grants GR/S63175/01 and GR/S61973/01. I am grateful to Carsten Lutz for his thorough reading of the manuscript and for his constructive comments and suggestions. Thanks are also due to Frank Wolter for his suggestions.

1 INTRODUCTION

Formal modal logic is mostly mathematical in its methods, regardless of area of application. This Handbook presents a wide variety of mathematical techniques developed over decades of studying the intricate details of modal logic. Also included among relatively recent general purpose sources on the mathematics of modal logic are monographs [57, 75, 99, 114, 153] and a survey paper [115]. For that matter, the applications of mathematics in modal logic are overwhelming, while those in the dual category, the uses of modal logic in mathematics, are less numerous.

Mathematics normally finds a proper language and level of abstraction for the study of its objects. Propositional modal logic offers a new paradigm of applying logical methods: instead of using the traditional languages with quantification (first-order or higher-order) to describe a structure, look for an appropriate quantifier-free language with additional logic operators (modalities) that represent the phenomenon at hand. In a number of prominent cases, we end up with a logic-based language which is much richer than Boolean logic, and yet, unlike universal languages with quantification, does not fall under the scope of classical undecidability limitations. Modal logic often offers better decidability and complexity results than the rival first-order logic.

We adopt a strict approach as to what constitutes an application of modal logic in mathematics, i.e., we limit our attention to mathematical objects which existed independently of modal logic, rather than those developed for the needs of modal logic itself. This requirement is not by any means sufficient; after all, any class of binary relations in mathematics specifies some propositional modal logic which, however, does not automatically make these connections worthy of study. We consider only the cases in which a mathematical modality-like notion was developed and studied by mathematicians to the extent that the modal logical language and methods became pertinent. Neither is this requirement necessary; for example, elaborate algebraic models originally developed for the needs of logic (e.g., modal logic) are now deeply embedded into the corresponding field of mathematics and may well be regarded as a contribution of modal logic to mathematics. Fortunately, algebraic models for modal logic have been covered in Chapter 6 of this Handbook. Moreover, the present author has not been quite pedantic in carrying out even this imperfect approach; such important issues as topos models and the connection between modal logic and Grothendieck topology on categories were barely mentioned in this survey. Some of these topics were considered in Chapter 9 of this Handbook.

There are two major ideas that dominate the landscape of modal logic application in mathematics: Gödel's provability semantics and Tarski's topological semantics.

Gödel's use of modal logic to describe provability in the 1930s gave the first exact semantics of modality. This approach led to a comprehensive provability semantics for a broad class of modal logics, including the major ones: K, T, $\mathsf{K4}$, $\mathsf{S4}$, $\mathsf{S5}$, GL, Grz, and others. It also proved vital for such applications as the Brouwer-Heyting-Kolmogorov (intended) provability semantics for intuitionistic logic, for introducing justification into formal epistemology and tackling its logical omniscience problem, for introducing self-reference into combinatory logic and lambda-calculi, etc.

Another major use of modal logic in mathematics is the topological semantics suggested by Tarski and developed by Tarski and McKinsey in the 1940s. Here modal logic provides a natural high-level language for describing topology in a point-free manner. In addition to its natural mathematical appeal, this approach has evolved into an active

research area with applications in dynamic systems, control systems, spatio-temporal reasoning, etc.

There has also been significant research activity in applying modal logic to set theory, which can be traced back to Solovay's work of the 1970s. We devote Section 7 to this issue.

The reader might perceive a certain bias towards provability logic in this survey. A possible explanation is that Gödel's provability semantics of modal logic is the oldest and arguably the most well-established tradition of applying modal logic to mathematics. It is perhaps more essential for proof theory and foundations than other applications of modal logic for the corresponding object areas of mathematics. This observation is not intended to discount other interpretations of modal logic considered here; we hope that this survey gives a fair assessment of their beauty and vast potential.

Among other recent surveys in this area, we recommend the article 'Provability logic' by Verbrugge in the Stanford Encyclopedia of Philosophy

`http://plato.stanford.edu/entries/logic-provability/`,

the handbook chapter 'Provability Logic' [25], and the forthcoming collection 'The Logic of Space' edited by Aiello, van Benthem, and Pratt-Hartmann.

2 SOME HISTORY

In his 1933 paper [109], Gödel chose the language of propositional modal logic to describe the basic logical laws of provability. According to his approach, $\Box F$ should be interpreted informally as

$$F \textit{ is provable},$$

and the classical modal logic $\mathsf{S4}$ provides a system of plausible postulates for provability. Gödel's goal was to provide an exact interpretation of intuitionistic propositional logic within a classical modal logic of provability, hence giving classical meaning to the basic intuitionistic logical system.

This line of research attracted a great deal of attention in mathematics and eventually led to two distinct models of provability based on modal logics:

1. the Provability Logic GL, which was shown by Solovay to be the logic of Gödel's formal provability predicate;

2. Gödel's original logic $\mathsf{S4}$, which was shown by Artemov to be a forgetful projection of the Logic of Proofs LP.

These two models complement each other and cover a wide range of applications, from traditional proof theory to formal verification and epistemology.

The use of modal logic in topology was initially motivated by Kuratowski's axioms for topological spaces, which were recast in the manner of modal logic by Tarski in the late 1930s. Under this interpretation, the Boolean components were treated in the usual set theoretical way as subsets of a given topological set, whereas $\Box$ was interpreted as

the interior operator.

In their seminal paper of 1944 [187], McKinsey and Tarski proved that S4 was the logic of any separable dense-in-itself metric space, in particular the real topological space $\mathbb{R}^n$, for each $n = 1, 2, 3, \ldots$. Among other known topological operators on sets,

the derived set operator,

regarded as the modality $\Diamond$, has been given a complete axiomatization in works by Esakia and Shehtman. The modal logic of topology developed into an area of research that included modal studies of other operators in topological spaces, modal logic of metric spaces, dynamic topological logic, spatio-temporal reasoning, etc., with applications outside the original mathematical core.

It was perhaps Solovay who initiated research in the application of modal logic to set theory in 1976 when he gave a complete axiomatization of such modalities as

true in all transitive models of ZF

and

true in all universes.

Hamkins and Löwe recently found a complete axiom system of the modality

true in all forcing extensions.

Studies of connections between infinitary modal logic and set theory initiated by Barwise and Moss in 1996 culminated in Baltag's Structural Theory of Sets STS, which considered

the canonical model of infinitary modal logic as the set theoretical universe.

3 TWO MODELS OF PROVABILITY

According to Brouwer, truth in intuitionistic mathematics means the existence of a proof. An axiom system for intuitionistic logic was suggested by Heyting in 1930; its full description may be found in the fundamental monographs [132, 149, 246]. By IPC, we infer Heyting's intuitionistic propositional calculus. In 1931–34, Heyting and Kolmogorov gave an informal description of the intended proof-based semantics for intuitionistic logic [130, 131, 132, 150], which is now referred to as the *Brouwer-Heyting-Kolmogorov* (*BHK*) *semantics*. According to the *BHK*-conditions, a formula is 'true' if it has a proof. Furthermore, a proof of a compound statement is connected to proofs of its parts in the following way:

- a proof of $A \wedge B$ consists of a proof of proposition A and a proof of proposition B,
- a proof of $A \vee B$ is given by presenting either a proof of A or a proof of B,
- a proof of $A \rightarrow B$ is a construction transforming proofs of A into proofs of B,
- falsehood $\perp$ is a proposition which has no proof; $\neg A$ is shorthand for $A \rightarrow \perp$.

From a foundational point of view, it did not make much sense to understand the above 'proofs' as proofs in an intuitionistic system which those conditions were supposed to

specify. So in 1933 ([109]), Gödel took the first step towards developing an exact semantics for intuitionism based on **classical provability**. Gödel considered the classical modal logic S4 to be a calculus describing properties of provability in classical mathematics:

1. *Axioms and rules of classical propositional logic*,
2. $\Box(F\to G)\to(\Box F\to\Box G)$,
3. $\Box F\to F$,
4. $\Box F\to\Box\Box F$,
5. *Rule of necessitation*: $\dfrac{\vdash F}{\vdash \Box F}$.

Based on Brouwer's understanding of logical truth as provability, Gödel defined a translation $tr(F)$ of the propositional formula F in the intuitionistic language into the language of classical modal logic, i.e., $tr(F)$ was obtained by prefixing every subformula of F with the provability modality $\Box$. Informally speaking, when the usual procedure of determining classical truth of a formula is applied to $tr(F)$, it will test the provability (not the truth) of each of F's subformulas in agreement with Brouwer's ideas.

> Gödel's treatment of provability as modality in [109] has an interesting prehistory. In his letter to Gödel [263] of January 12, 1931, von Neumann actually used formal provability as a modal-like operator B and gave a shorter, modal-style derivation of the second Gödel's incompleteness theorem. Von Neumann freely used such modal logic features as the transitivity axiom $B(a) \to B(B(a))$, equivalent substitution, and the fact that the modality commutes with the conjunction '$\wedge$.' Even earlier, in 1928, Orlov published the paper [205] in Russian, in which he considered an informal modal-like operator of provability, introduced modal postulates (ii)–(v), and described the translation $tr(F)$ from propositional formulas to modal formulas. On the other hand, Orlov chose to base his modal system on a type of relevance logic; his system fell short of S4.

From Gödel's results in [109], and the McKinsey-Tarski work on topological semantics for modal logic [188], it follows that the translation $tr(F)$ provides a proper embedding of the intuitionistic logic IPC into S4, i.e., an embedding of IPC into classical logic extended by the provability operator.

THEOREM 1 (Gödel, McKinsey, Tarski). IPC *proves* F $\Leftrightarrow$ S4 *proves* $tr(F)$.

Still, Gödel's original goal of defining IPC in terms of classical provability was not reached, since the connection of S4 to the usual mathematical notion of provability was not established. Moreover, Gödel noticed that the straightforward idea of interpreting modality $\Box F$ as F *is provable in a given formal system* T contradicted Gödel's second incompleteness theorem (cf. [62, 65, 90, 126, 240] for basic information concerning proof and provability predicates, as well as Gödel's incompleteness theorems).

Indeed, $\Box(\Box F \rightarrow F)$ can be derived in $\mathsf{S4}$ by the rule of necessitation from the axiom $\Box F \rightarrow F$. On the other hand, interpreting modality $\Box$ as the predicate $\mathsf{Provable}_T(\cdot)$ of formal provability in theory T and F as contradiction, i.e., $0 = 1$, converts this formula into a false statement that the consistency of T is internally provable in T:

$$\mathsf{Provable}_T\left(\ulcorner \mathit{Consis(T)} \urcorner\right) .$$

To see this, it suffices to notice that the following formulas are provably equivalent in T:

$$\mathsf{Provable}_T(\ulcorner 0=1 \urcorner) \rightarrow (0=1) \ , \quad \neg\mathsf{Provable}_T(\ulcorner 0=1 \urcorner) \ , \quad \mathit{Consis(T)} \ .$$

Here $\ulcorner\varphi\urcorner$ stands for the Gödel number of φ. Below we will omit Gödel number notation whenever it is safe, e.g., we will write $\mathsf{Provable}(\varphi)$ and $\mathsf{Proof}(n, \varphi)$ instead of $\mathsf{Provable}(\ulcorner\varphi\urcorner)$ and $\mathsf{Proof}(n, \ulcorner\varphi\urcorner)$.

The situation after Gödel's paper [109] can be described by the following figure where '$\hookrightarrow$' denotes a proper embedding:

$$\mathsf{IPC} \ \hookrightarrow \ \mathsf{S4} \ \hookrightarrow \ ? \ \hookrightarrow \ \mathit{CLASSICAL\ PROOFS}\ .$$

In a public lecture in Vienna in 1938 [110], Gödel suggested using the format of explicit proofs *t is a proof of F* for interpreting his provability calculus $\mathsf{S4}$, though he did not give a complete set of principles of the resulting logic of proofs. Unfortunately, Gödel's work [110] remained unpublished until 1995, when the Gödelian logic of proofs had already been axiomatized and supplied with completeness theorems connecting it to both $\mathsf{S4}$ and classical proofs.

The provability semantics of $\mathsf{S4}$ was discussed in [62, 65, 70, 111, 158, 169, 176, 191, 197, 199, 200, 221, 222]. These works constitute a remarkable contribution to this area (cf. Section 4), however, they neither found the Gödelian logic of proofs nor provided $\mathsf{S4}$ with a provability interpretation capable of modeling the *BHK* semantics for intuitionistic logic. Comprehensive surveys of work on provability semantics for $\mathsf{S4}$ may be found in [16, 21, 25].

The Logic of Proofs LP was first reported in 1994 at a seminar in Amsterdam and at a conference in Münster. Complete proofs of the main theorems of the realizability of $\mathsf{S4}$ in LP, and about the completeness of LP with respect to the standard provability semantics were published in the technical report [14] in 1995. The foundational picture now is

$$\mathsf{IPC} \ \hookrightarrow \ \mathsf{S4} \ \hookrightarrow \ \mathsf{LP} \ \hookrightarrow \ \mathit{CLASSICAL\ PROOFS}\ .$$

The correspondence between intuitionistic and modal logics induced by Gödel's translation $tr(F)$ has been studied by Blok, Dummett, Esakia, Flagg, H. Friedman, Grzegorczyk, Kuznetsov, Lemmon, Maksimova, McKinsey, Muravitsky, Rybakov, Shavrukov, Tarski, and many others. A detailed survey of modal companions of intermediate (or superintuitionistic) logics is given in [74]; a brief one is in [75], Sections 9.6 and 9.8.

Gödel's 1933 paper [109] on a modal logic of provability left two natural open problems:

(A) Find a precise provability semantics for the modal logic $\mathsf{S4}$, which appeared to be 'a provability calculus without a provability semantics.'

(B) Find a modal logic of Gödel's predicate of formal provability $\mathsf{Provable}(x)$, which appeared to be 'a provability semantics without a calculus.'

The solution to problem (A) was obtained by Artemov through the Logic of Proofs LP (see above and Section 5).

Problem (B) was solved in 1976 by Solovay, who showed that the modal logic GL (a.k.a. G, L, K4.W, PRL) axiomatized all propositional properties of the provability predicate $\mathsf{Provable}(F)$ ([62, 65, 147, 241, 242]).

The provability logic GL is given by the following list of postulates:

1. *Axioms and rules of classical propositional logic*,
2. $\Box(F\to G)\to(\Box F\to\Box G)$,
3. $\Box(\Box F\to F)\to\Box F$,
4. $\Box F\to\Box\Box F$,
5. *Rule of necessitation*: $\dfrac{\vdash F}{\vdash \Box F}$.

Models (A) and (B) have quite different expressive capabilities. The logic GL formalizes Gödel's second incompleteness theorem $\neg\Box(\neg\Box\bot)$, Löb's theorem $\Box(\Box F\to F)\to\Box F$, and a number of other meaningful provability principles. However, proofs as objects are not present in this model. LP naturally contains typed λ-calculus, modal logic, and modal λ-calculus ([18, 19]). On the other hand, model (A) cannot express Gödel's incompleteness theorem.

Provability models (A) and (B) complement each other by addressing different areas of application. The provability logic GL finds applications in traditional proof theory (cf. Subsection 4.11). The Logic of Proofs LP targets areas of typed theories and programming languages, foundations of verification, formal epistemology, etc. (cf. Subsection 5.7)

4 PROVABILITY LOGIC

A significant step towards finding a modal logic of formal provability was made by Löb who formulated in [180], on the basis of previous work by Hilbert and Bernays from 1939 (see [133]), a number of natural modal-style properties of the formal provability predicate and observed that these properties were sufficient to prove Gödel's second incompleteness theorem. These properties, known as the *Hilbert-Bernays-Löb derivability conditions*, essentially coincide with postulates (2), (4), and (5) of the above formulation of GL, i.e., with the modal logic K4. Moreover, Löb found an important strengthening of the Gödel theorem. He established the validity of the following *Löb Rule* about formal provability:

$$\frac{\vdash \Box F\to F}{\vdash F} \; .$$

It was later noticed in (cf. [182]) that this rule can be formalized in arithmetic, which gave a valid law of formal provability known as *Löb's principle*:

$$\Box(\Box F\to F)\to\Box F \; .$$

This principle provided the last axiom of the provability logic GL, named after Gödel and Löb. Neither Gödel nor Löb formulated the logic explicitly, though they established the validity of the underlying arithmetical principles. Presumably, it was Smiley, whose work [238] on the foundations of ethics was the first to consider GL a modal logic.

Significant progress in the general understanding of the formalization of metamathematics, particularly in [90], inspired Kripke, Boolos, de Jongh, and others to look into the problem of modal axiomatization of the logic of provability. More specifically, the effort was concentrated on establishing GL's completeness with respect to the formal provability interpretation. Independently, a similar problem in an algebraic context was considered by Magari and his school in Italy (see [184]). A comprehensive account of these early developments in provability logic can be found in [66].

H. Friedman formulated the question of decidability of the letterless fragment of provability logic as his Problem 35 in [97]. This question, which happened to be much easier than the general case, was immediately answered by a number of people including Boolos [60], van Benthem, Bernardi, and Montagna. This result was apparently known to von Neumann as early as 1931 [263].

4.1 Solovay's completeness theorem

The modal logic of Gödel's predicate of formal provability $\mathsf{Provable}(x)$ was found in 1976 by Solovay.

Let $*$ be a mapping from the set of propositional letters to the set of arithmetical sentences. We call such a mapping an (arithmetical) *interpretation*. Given a standard provability predicate $\mathsf{Provable}(x)$ in Peano arithmetic PA, we can extend the interpretation $*$ to all modal formulas as follows:

- $\bot^* = \bot$; $\top^* = \top$;
- $*$ commutes with all Boolean connectives;
- $(\Box G)^* = \mathsf{Provable}(G^*)$.

The Hilbert-Bernays-Löb derivability conditions, together with the validity of Löb's principle, essentially mean that GL is sound with respect to the arithmetical interpretation.

PROPOSITION 2. *If* $\mathsf{GL} \vdash X$*, then for all interpretations* $*$, $\mathsf{PA} \vdash X^*$*.*

Solovay in [242] established that GL is also complete with respect to the arithmetical interpretation. Solovay also showed that the set of modal formulas expressing universally *true* principles of provability was axiomatized by a decidable extension of GL, which is usually denoted by S. The system S has the axioms

- all theorems of GL (a decidable set),
- $\Box X \rightarrow X$,

and *modus ponens* as the sole rule of inference.

THEOREM 3 (Solovay [242]).

(1) $\mathsf{GL} \vdash X$ *iff for all interpretations* $*$, $\mathsf{PA} \vdash X^*$*;*

(2) $\mathsf{S} \vdash X$ *iff for all interpretations* $*$, X^* *is true.*

For the proof of this theorem in [242], Solovay invented an elegant technique of embedding Kripke models into arithmetic. Variants and generalizations of this construction have been applied to obtain arithmetical completeness results for various logics with provability and interpretability semantics. An inspection of Solovay's construction shows that it works for all natural formal theories containing a rather weak *elementary arithmetic* EA (cf [25], section 3.1). Such robustness allows us to claim that GL is indeed a universal propositional logic of formal provability.

Whether or not Solovay's theorem can be extended to bounded arithmetic theories such as S^1_2 or S_2 remains an intriguing open question. Interesting partial results here were obtained by Berarducci and Verbrugge in [53].

Solovay's results and methods opened a new page in the development of provability logic. Several groups of researchers in the USA (Solovay, Boolos, Smoryński), the Netherlands (D. de Jongh, Visser), Italy (Magari, Montagna, Sambin, Valentini), and USSR (Artemov and his students), have started to work intensively in this area. An early textbook by Boolos [62], followed by Smoryński's [241], played an important educational role.

The following uniform version of Solovay's Theorem 3.1 was established independently by Artemov, Avron, Boolos, Montagna, and Visser [7, 8, 37, 63, 194, 253]:

there is an arithmetical interpretation $*$ *such that for each modal formula* X, $\mathsf{PA} \vdash X^*$ *iff* $\mathsf{GL} \vdash X$.

The main thrust of the research efforts in the wake of Solovay's Theorem was in the direction of generalizing Solovay's results to more expressive languages. Some of the problems that have received prominent attention are covered below.

4.2 Fixed point theorem

As an important early result on the application of modal logic to the study of the concept of provability in formal systems, a theorem stands out that was found independently by de Jongh and Sambin, who established that GL has the fixed point property (see [62, 65, 240, 241]). The de Jongh-Sambin fixed point theorem is a striking reproduction of Gödel's fixed point lemma in a propositional language free of coding, self-substitution functions, etc.

A modal formula $F(p)$ is said to be *modalized in* p if every occurrence of the sentence letter p in $F(p)$ is within the scope of $\Box$.

THEOREM 4 (de Jongh, Sambin). *For every modal formula* $F(p)$ *modalized in the sentence letter* p*, there is a modal formula* H *containing only sentence letters from* F*, not containing* p*, and such that* GL *proves*

$$H \ \leftrightarrow \ F(H) \ .$$

Moreover, any two solutions to this fixed-point equation with respect to F *are provably equivalent in* GL.

The uniqueness segment was also established by Bernardi in [54].

The proof actually provided an efficient algorithm that, given F, calculates its fixed point H. Here are some examples of F's and their fixed points H.

Modal formula $F(p)$	Its fixed point H
$\Box p$	$\top$
$\Box\neg p$	$\Box\bot$
$\neg\Box p$	$\neg\Box\bot$
$\neg\Box\neg p$	$\bot$
$q \wedge \Box p$	$q \wedge \Box q$

Perhaps the most famous fixed point of the above sort is given by the second Gödel incompleteness theorem. Indeed, consider $\neg\Box p$ as $F(p)$. By the above table, the corresponding fixed point H is $\neg\Box\bot$. Hence GL proves

(1) $\neg\Box\bot \rightarrow \neg\Box(\neg\Box\bot)$.

Since the arithmetical interpretation of $\neg\Box\bot$ for a given theory T is the consistency formula *Consis(T)*, this yields that (1) represents the formalized second Gödel incompleteness theorem:

if T is consistent, then T does not prove its consistency

and that this theorem is provable in T.

The fixed point theorem for GL allowed van Benthem [248] and then Visser [262] to interpret the modal μ-calculus in GL. Together with van Benthem's observation that GL is faithfully interpretable in μ-calculus [248], this relates two originally disjoint research areas.

4.3 First-order provability logics

The natural problem of axiomatizing first-order provability logic was first introduced by Boolos in [62, 64] as the major open question in this area. A straightforward conjecture that the first-order version of GL axiomatizes first-order provability logic was shown to be false by Montagna [196]. A final negative solution was given in papers by Artemov [9] and Vardanyan [252].

THEOREM 5 (Artemov, Vardanyan). *First-order provability logic is not recursively axiomatizable.*

In particular, Artemov showed that the set of the first-order modal formulas that are true under any arithmetical interpretation is not arithmetical. This proof used Tennenbaum's well-known theorem about the uniqueness of the recursive model of Peano arithmetic. Vardanyan showed that the set of first-order modal formulas that are provable in PA under any interpretation is Π^0_2-complete, thus not effectively axiomatizable. Independently but somewhat later, similar results were obtained by McGee in his Ph.D. thesis; they were never published.

Even more dramatically, [11] showed that first-order provability logics are sensitive to a particular formalization of the provability predicate and thus are not robustly defined.

The material on first-order provability logic is extensively covered in a textbook [65] and in a survey [147].

4.4 Intuitionistic provability logic

The question of generalizing Solovay's results from classical theories to intuitionistic ones, such as Heyting arithmetic HA, proved to be remarkably difficult. Visser in [253] found

a number of nontrivial principles of the provability logic of HA. Similar observations were independently made by Gargov and Gavrilenko. In [255], a characterization and a decision algorithm for the letterless fragment of the provability logic of HA were obtained, thus solving an intuitionistic analog of Friedman's 35th problem.

THEOREM 6 (Visser [255]). *The letterless fragment of the provability logic of* HA *is decidable.*

Some significant further results were obtained in [79, 135, 136, 137, 255, 258, 260, 261], but the general problem of axiomatizing the provability logic of HA remains a major open question.

4.5 Classification of provability logics

Solovay's theorems naturally led to the notion of *provability logic for a given theory T relative to a metatheory U*, which was suggested by Artemov in [7, 8] and Visser in [253]. This logic, denoted $\boldsymbol{PL}_T(U)$, is defined as the set of all propositional principles of provability in T that can be established by means of U. In particular, GL is the provability logic $\boldsymbol{PL}_T(U)$ with $U = T = \mathsf{PA}$, and Solovay's provability logic S from Theorem 3.2 corresponds to $T = \mathsf{PA}$ and U's being the set of all true sentences of arithmetic. The problem of describing all provability logics for a given theory T relative to a metatheory U, where T and U range over extensions of Peano arithmetic, has become known as the *classification problem for provability logics*. Each of these logics extends GL, hence can be represented in the form $\mathsf{GL}X$ which is GL with additional axioms X and modus ponens as the sole rule of inference. Within this notational convention, $\mathsf{S}{=}\mathsf{GL}\{\Box p \to p\}$. Consider sentences $F_n = \Box^{n+1}\bot \to \Box^n\bot$, for $n \in \omega$. In [8, 10, 254], the following three families of provability logics were found:

$$\mathsf{GL}_\alpha = \mathsf{GL}\{F_n \mid n \in \alpha\},\ \text{ where } \alpha \subseteq \omega\ ;$$

$$\mathsf{GL}^-_\beta = \mathsf{GL}\{\bigvee_{n \notin \beta} \neg F_n\},\ \text{ where } \beta \text{ is a confinite subset of } \omega\ ;$$

$$\mathsf{S}_\beta = \mathsf{S} \cap \mathsf{GL}^-_\beta,\ \text{ where } \beta \text{ is a confinite subset of } \omega\ .$$

The families GL_α, GL^-_β and S_β are ordered by inclusion of their indices, and $\mathsf{GL}_\beta \subset \mathsf{S}_\beta \subset \mathsf{GL}^-_\beta$, for cofinite β.

In [10], the classification problem was reduced to finding all provability logics in the interval between GL_ω and S. In [143], Japaridze found a new provability logic Dzh in this interval,

$$\mathsf{Dzh} = \mathsf{GL}\{\neg\Box\bot, \Box(\Box p \vee \Box q) \to (\Box p \vee \Box q)\}\ .$$

He showed that Dzh is the provability logic of PA relative to $\mathsf{PA}+$ *formalized ω-consistency of* PA. This discovery produced one more provability logic series,

$$\mathsf{Dzh}_\beta = \mathsf{Dzh} \cap \mathsf{GL}^-_\beta,\ \text{ where } \beta \text{ is a confinite subset of } \omega\ ,$$

with $\mathsf{GL}_\beta \subset \mathsf{Dzh}_\beta \subset \mathsf{S}_\beta \subset \mathsf{GL}^-_\beta$, for cofinite β.

The classification was completed by Beklemishev who showed in [42] that no more provability logics exist.

THEOREM 7 (Beklemishev [42]). *All provability logics occur in* GL_α, GL^-_β, S_β, *and* Dzh_β, *for* $\alpha, \beta \subseteq \omega$, *and* β *cofinite.*

The proof of Theorem 7 produced yet another provability interpretation of Dzh which was shown to be the provability logic of any Σ_1-sound but not sound theory relative to the set of all true sentences of arithmetic. For more details, see [25, 42, 50].

4.6 Provability logics with additional operators

Solovay's theorems have been generalized to various extensions of the propositional language by additional operators having arithmetical interpretations.

The most straightforward generalization is obtained by simultaneously considering several provability operators corresponding to different theories. Already in the simplest case of *bimodal provability logic*, the axiomatization of such logics turns out to be very difficult. The bimodal logics for many natural pairs of theories have been characterized in [43, 44, 73, 143, 241]. However, the general classification problem for bimodal provability logics for pairs of recursively enumerable extensions of PA remains a major open question.

Bimodal logic has been used to study relationships between provability and interesting related concepts such as the Mostowski operator, and Rosser, Feferman, and Parikh provabilities (see [179, 225, 226, 241, 256]). In a number of cases, Solovay-style arithmetical completeness theorems have been obtained. These results have their origin in an important paper by Guaspari and Solovay [123] (see also [241]). They consider an extension of the propositional modal language by a *witness comparison* operator allowing the formalization of Rosser-style arguments from his well-known proof of the incompleteness theorem [218]. Similar logics have since been used in [71, 72, 78], e.g., in the study of the speed-up of proofs.

4.7 Generalized provability predicates

A natural generalization of the provability predicate is given by the notion of n-*provability* which is, by definition, a provability predicate in the set of all true arithmetical Π_n-sentences. For $n = 0$, this concept coincides with the usual notion of provability. As was observed in [241], the logic of each individual n-provability predicate coincides with GL. A joint logic of n-provability predicates for $n = 0, 1, 2, \ldots$ contains the modalities $[0]$, $[1]$, $[2]$, etc. The arithmetical interpretation of a formula in this language is defined as usual, except that now we require, for each $n \in \omega$, that $[n]$ be interpreted as n-provability.

The system GLP introduced by Japaridze [143, 144] is given by the following axioms and rules of inference.

1. *Axioms of* GL *for each operator* $[n]$,
2. $[m]\phi \rightarrow [n]\phi$, *for* $m \leq n$,
3. $\langle m\rangle\phi \rightarrow [n]\langle m\rangle\phi$, *for* $m < n$,
4. *Rule modus ponens*,
5. *Rule* $\phi \vdash [n]\phi$.

THEOREM 8 (Japaridze). GLP *is sound and complete with respect to the n-provability interpretation.*

Originally, Japaridze established in [143, 144] the completeness of GLP for an interpretation of modalities $[n]$ as the provability in arithmetic using not more than n nested applications of the ω-rule. Later, Ignatiev in [141] observed that Japaridze's theorem holds for the n-provability interpretation. Ignatiev also found normal forms for letterless formulas in GLP which play a significant role in Section 4.11 (where only the soundness of GLP is essential).

4.8 Interpretability and conservativity logics

Interpretability is one of the central concepts of mathematics and logic. A theory X is interpretable in Y iff the language of X can be translated into the language of Y in such a way that Y proves the translation of every theorem of X. For example, Peano arithmetic PA is interpretable in Zermelo-Fraenkel set theory ZF. The importance of this concept lies in its ability to compare theories of different mathematical character in different languages, e.g., set theory and arithmetic. The notion of interpretability was given a mathematical shape by Tarski in 1953 in [245]. There is not much known about interpretability in general. The modal logic approach provides insights into the structure of interpretability in special situations when X and Y are finite propositional-style extensions of a base theory containing a certain sufficient amount of arithmetic.

Visser, following Švejdar [243], introduced a binary modality $A \rhd B$ to stand for the arithmetization of the statement

the theory $T + A$ interprets $T + B$.

Interpretations here are understood in the standard sense of Tarski, and are limited to theories T containing a sufficient amount of arithmetic, and to propositional A's and B's. This new modality emulates provability $\Box F$ by $\neg F \rhd \bot$, and thus is more expressive than the ordinary $\Box$. The resulting *interpretability logic* substantially depends on the basis theory T.

The following logic IL is the collection of some basic interpretability principles valid in all reasonable theories: axioms and rules of GL plus

- $\Box(A \to B) \to A \rhd B$,
- $(A \rhd B \wedge B \rhd C) \to A \rhd C$,
- $(A \rhd C \wedge B \rhd C) \to (A \vee B) \rhd C$,
- $A \rhd B \to (\Diamond A \to \Diamond B)$,
- $\Diamond A \rhd A$.

(We assume here that the interpretability modality '$\rhd$' binds stronger than the Boolean connectives.)

For two important classes of theories T, the interpretability logic has been characterized axiomatically.

Let ILP be IL augmented by the principle

$$A \rhd B \rightarrow \Box(A \rhd B) .$$

THEOREM 9 (Visser [257]). *The interpretability logic of a finitely axiomatizable theory satisfying some natural conditions is* ILP.

In particular, the class of theories covered by this theorem includes the arithmetical theories $\mathsf{I}\Sigma_n$ for all $n = 1, 2, 3, \ldots$, the second-order arithmetic ACA_0, and the von Neumann-Gödel-Bernays theory GB of sets and classes.

Let ILM be IL augmented by Montagna's principle

$$A \rhd B \rightarrow (A \wedge \Box C) \rhd (B \wedge \Box C) .$$

The following theorem was established independently in [224] and [52].

THEOREM 10 (Shavrkurov, Berarducci). *The interpretability logic of essentially reflexive theories satisfying some natural conditions is* ILM.

In particular, this theorem states that ILM is the interpretability logic for Peano arithmetic PA and Zermelo-Fraenkel set theory ZF.

An axiomatization of the minimal interpretability logic, i.e., of the set of interpretability principles that hold over all reasonable arithmetical theories, is not known. Important progress in this area has been made by Goris and Joosten, who have found new universal interpretability principles (cf. [120, 148]). Yet more new interpretability principles have been found recently by Goris; they were discovered using the Kripke semantics and later shown sound for arithmetic.

The $\rhd$ modality has a related *conservativity* interpretation, which leads to the conservativity logics studied in [124, 125, 140]. Logics of *interpolability* and of *tolerance*, introduced by Ignatiev and Japaridze [80, 81, 142], have a related arithmetical interpretation, but a format which is different from that of interpretability logics; see [147] for an overview.

An excellent survey of interpretability logic is given in [259]; see also [147].

4.9 Magari algebras and propositional second-order provability logic

An algebraic approach to provability logic was initiated by Magari and his students [183, 184, 194, 195]. The *provability algebra* of a theory T, also called the *Magari algebra of* T, is defined as the set of T-sentences factorized modulo provable equivalence in T and equipped with the usual Boolean operations together with the provability operator mapping a sentence F to $\mathsf{Provable}_T(F)$.

Using the notion of provability algebra, one can impart a provability semantics to a representative subclass of propositional second-order modal formulas, i.e., modal formulas with quantifiers over arithmetical sentences. These are just first-order formulas over the provability algebra. For several years, the questions of decidability of the propositional second-order provability logic and of the first-order theory of the provability algebra of PA remained open (cf. [24]). Shavrukov in [227] provided a negative solution to both of these questions.

THEOREM 11 (Shavrukov [227]). *The first-order theory of the provability algebra of* PA *is mutually interpretable with the set of all true arithmetical formulas.*

This result was proved by one of the most ingenious extensions of Solovay's techniques.

4.10 'True and Provable' modality

A gap between the provability logic GL and S4 can be bridged to some extent by using the *strong provability* modality $\boxdot F$ which is interpreted as

$$(\boxdot F)^* = F^* \wedge \mathsf{Provable}(F^*) \ .$$

The reflexivity principle

$$\boxdot F \rightarrow F$$

is then vacuously provable, hence the strong provability modality is S4-compliant.

This approach has been explored in [61, 111, 170], where it was shown independently that the arithmetically complete modal logic of strong provability coincides with Grzegorczyk's logic Grz, which is the extension of S4 by the axiom

$$\Box(\Box(F \rightarrow \Box F) \rightarrow F) \rightarrow F \ .$$

The modality of strong provability has been further studied in [202, 203]; it played a significant role in introducing justification into formal epistemology (cf. [30, 31, 32]), as well as in the topological semantics for modal logic (cf. surveys [86, 100]).

Strong provability plays a certain foundational role: it provides an exact provability-based model for intuitionistic logic IPC. Indeed, by Grzegorczyk's result from [122], Gödel's translation *tr* specifies an exact embedding of IPC into Grz (cf. Theorem 1):

$$\mathsf{IPC}\ \textit{proves}\ F \quad \Leftrightarrow \quad \mathsf{Grz}\ \textit{proves}\ tr(F)\ .$$

However, the foundational significance of this reduction for intuitionistic logic is somewhat limited by a nonconstructive meaning of strong provability as 'classically true and formally provable,' which seems incompatible with the intended intuitionistic semantics. The aforementioned embedding does not bring us closer to the *BHK* semantics for IPC either. For more discussion on these matters, see [12, 16, 171].

4.11 Applications

The methods of modal provability logic are applicable to the study of fragments of Peano arithmetic.

Using provability logic methods, Beklemishev in [45] answered a well-known question: what kind of computable functions could be proved to be total in the fragment of PA where induction is restricted to Π_2-formulas without parameters? He showed that these functions coincide with those that are primitive recursive. In general, provability logic analysis substantially clarified the behavior of parameter-free induction schemata.

Later results [46, 48] revealed a deeper connection between provability logic and traditional proof-theoretic questions, such as consistency proofs, ordinal analysis, and independent combinatorial principles. In [48], Beklemishev gave an alternative proof of

Gentzen's famous theorem on the proof of the consistency of PA by transfinite induction up to the ordinal ϵ_0.

In [47] (cf. also surveys [25, 49]), Beklemishev suggested a simple PA-independent combinatorial principle called *the Worm Principle*, which is derived from Japaridze's polymodal extension GLP of provability logic (cf. Section 4.7). Finite words in the alphabet of natural numbers will be called *worms.* The Worm Principle asserts the termination of any sequence $w_0, w_1, w_2, \ldots$ of worms inductively constructed according to the following two rules. Suppose $w_m = x_0 \ldots x_n$, then

1. if $x_n = 0$, then $w_{m+1} := x_0 \ldots x_{n-1}$ (the head of the worm is cut away);
2. if $x_n > 0$, set $k := \max\{i < n : x_i < x_n\}$ and let $w_{m+1} = x_0 \ldots x_k(x_{k+1} \ldots x_{n-1}(x_n - 1))^{m+1}$ (the head of the worm decreases by one, and the part after position k is appended to the worm m times).

Clearly, the emerging sequence of worms is fully determined by the initial worm w_0. For example, consider a worm $w_0 = 2031$. Then the sequence looks as follows:

$w_0 = 2031$
$w_1 = 203030$
$w_2 = 20303$
$w_3 = 20302222$
$w_4 = 2030222122212221222122221$
$w_5 = 2030(22212221222122212220)^6$
$\ldots$

THEOREM 12 (Beklemishev [47]).

(1) *For any initial worm w_0, there is an m such that w_m is empty.*

(2) *The previous statement is unprovable in Peano arithmetic* PA. *In fact, Statement 1 is equivalent to the 1-consistency of* PA.

For other PA-independent principles, cf. [244].

Japaridze used a technique from the area of Provability Logic to investigate fundamental connections between provability, computability, and truth in his work on Computability Logic [145, 146].

The Logic of Proofs (Section 5) with its applications also emerged from studies in Provability Logic.

5 LOGIC OF PROOFS

The source of difficulties in provability interpretation of modality lies in the implicit nature of the existential quantifier $\exists$. Consider, for instance, the reflection principle in PA, i.e., all formulas of type $\mathsf{Provable}(F) \to F$. By Gödel's second incompleteness theorem, this principle is not provable in PA, since the consistency formula $\mathsf{Con}(\mathsf{PA})$ coincides with a special case of the reflection principle, namely $\mathsf{Provable}(\bot) \to \bot$. The formula $\mathsf{Provable}(F)$ is $\exists x \mathsf{Proof}(x, F)$ where $\mathsf{Proof}(x, y)$ is Gödel's *proof predicate*

$$x \textit{ is (a code of) a proof of a formula (having code) } y\,.$$

Assuming $\mathsf{Provable}(F)$ does not yield pointing to any specific proof of F, since this x may be a nonstandard natural number which is not a code of any actual derivation in PA.

For proofs represented by explicit terms, the picture is very different. The principle of *explicit reflection* $\mathsf{Proof}(p, F) \rightarrow F$ is provable in PA for each specific derivation p. Indeed, if $\mathsf{Proof}(p, F)$ holds, then F is evidently provable in PA, and so is the formula $\mathsf{Proof}(p, F) \rightarrow F$. Otherwise, if $\mathsf{Proof}(p, F)$ does not hold, then $\neg\mathsf{Proof}(p, F)$ is true and provable, therefore $\mathsf{Proof}(p, F) \rightarrow F$ is also provable.

This observation suggests a remedy: representing proofs by terms t in the proof formula $\mathsf{Proof}(t, F)$ instead of implicit representation of proofs by existential quantifiers in the provability formula $\exists x \mathsf{Proof}(x, F)$. As we have already mentioned, Gödel suggested using the format of explicit proof terms for the interpretation of $\mathsf{S4}$ as early as 1938, but that paper remained unpublished until 1995 ([110]). Independently, the study of explicit modal logics was initiated in [14, 33, 34, 35, 247]. The Logic of Proofs may be regarded an instance of Gabbay's Labelled Deductive Systems (cf. [98]).

Proof polynomials are terms built from *proof variables* $x, y, z, \ldots$ and *proof constants* $a, b, c, \ldots$ by means of three operations: *application* '$\cdot$' (binary), *union* '$+$' (binary), and *proof checker* '!' (unary). The language of *Logic of Proofs* LP is the language of classical propositional logic supplemented by a new rule for building formulas, namely for each proof polynomial p and formula F, there is a new formula $p{:}F$ denoting 'p is a proof of F.' It is also possible to read this language type-theoretically: formulas become types, and $p{:}F$ denotes 'term p has type F.' We assume also that '$t{:}$' and '$\neg$' bind stronger than '$\wedge, \vee$' which, in turn, bind stronger than '$\rightarrow$.'

Axioms and inference rules of LP:

1. *Axioms of classical propositional logic*
2. $t{:}(F \rightarrow G) \ \rightarrow \ (s{:}F \rightarrow (t \cdot s){:}G)$ (*application*)
3. $t{:}F \rightarrow F$ (*reflection*)
4. $t{:}F \ \rightarrow\, !t{:}(t{:}F)$ (*proof checker*)
5. $s{:}F \rightarrow (s+t){:}F, \quad t{:}F \rightarrow (s+t){:}F$ (*sum*)
6. *Rule modus ponens*
7. $\vdash c{:}A$, *where* A *is from* 1-5, *and* c *is a proof constant* (*constant specification*)

As one can see from the principles of LP, constants denote proofs of axioms. The application operation corresponds to the internalized *modus ponens* rule: for each s and t, a proof $s \cdot t$ is a proof of all formulas G such that s is a proof of $F \rightarrow G$ and t is a proof of F for some F. The sum '$s + t$' of proofs s and t is a proof which proves everything that either s or t does. Finally, '!' is interpreted as a universal program for checking the correctness of proofs, which given a proof t, produces a proof that t proves F ([14, 16]). In [17], it was noted that proof polynomials represent the whole set of possible operations on proofs for a propositional language. It was shown that any operation on proofs which is invariant with respect to a choice of a normal proof system and which can be specified in a propositional language can be realized by a proof polynomial.

In what follows, '$\vdash$' denotes derivability in LP unless stated otherwise. By a *constant specification* $\mathcal{CS}$, we mean a set of formulas $\{c_1{:}A_1, c_2{:}A_2, \ldots\}$ where each A_i is an axiom from 1–5 of LP, and each c_i is a proof constant. By default, with each derivation in LP,

we associate a constant specification $\mathcal{CS}$ introduced in this derivation by the use of the rule of constant specification.

One of the basic properties of LP is its capability of internalizing its own derivations. The weak form of this property yields the following admissible rule for LP ([14, 16]):

$$\textit{if} \vdash F,\ \textit{then} \vdash p{:}F\ \textit{for some proof polynomial}\ p\ .$$

This rule is a translation of the well-known necessitation rule of modal logic

$$\frac{\vdash F}{\vdash \Box F}$$

into the language of explicit proofs. The following more general *internalization rule* holds for LP: *if*

$$A_1, \ldots, A_n \vdash B\ ,$$

then it is possible to construct a proof polynomial $t(x_1, \ldots, x_n)$ *such that*

$$x_1{:}A_1, \ldots, x_n{:}A_n \vdash t(x_1, \ldots, x_n){:}B$$

One might notice that the Curry-Howard isomorphism covers only a simple instance of the proof internalization property where all of $A_1, \ldots, A_n, B$ are purely propositional formulas containing no proof terms. For the Curry-Howard isomorphism basics, see, e.g., [108].

The decidability of LP was established by Mkrtychev in [193]. Kuznets in [168] obtained an upper bound Σ_2^p on the satisfiability problem for LP-formulas in Mkrtychev models (cf. Section 5.3). This bound was lower than the known upper bound *PSPACE* on the satisfiability problem in $\mathsf{S4}$ (under the assumption that $\Sigma_2^p \neq \mathit{PSPACE}$). A possible explanation of why LP wins in complexity over $\mathsf{S4}$ is that the satisfiability test for LP is somewhat similar to type checking, i.e., checking the correctness of assigning types (formulas) to terms (proofs), which is known to be relatively easy in classical cases.

Milnikel in [190] established Π_2^p-completeness of LP for some natural classes of constant specifications, including so-called injective ones, when each constant denotes a proof of not more than one axiom. Π_2^p-hardness for the whole LP remains on open problem.

N. Krupski in [159] established the disjunctive property for LP:

$$\textit{if}\ \mathsf{LP} \vdash s{:}F \vee t{:}G,\ \textit{then}\ \mathsf{LP} \vdash s{:}F\ \textit{or}\ \mathsf{LP} \vdash t{:}G.$$

5.1 Arithmetical completeness

The Logic of Proofs LP is sound and complete with respect to the natural provability semantics. By a *proof system* we mean a provably in PA decidable predicate $\mathsf{Proof}(x, y)$ that enumerates all theorems of PA, i.e.,

$$\mathsf{PA} \vdash \varphi \quad \text{iff} \quad \mathsf{Proof}(n, \varphi)\ \text{ holds for some } n\ ,$$

together with computable functions $\mathbf{m}(x, y)$, $\mathbf{a}(x, y)$ and $\mathbf{c}(x)$ which satisfy identities for '$\cdot$,' '$+$,' and '!' respectively, i.e., for all arithmetical formulas φ, ψ and all natural numbers k, n the following holds:

$$\mathsf{Proof}(k, \varphi \to \psi) \wedge \mathsf{Proof}(n, \varphi) \to \mathsf{Prf}(\mathbf{m}(k, n), \psi)$$

$\mathsf{Proof}(k,\varphi)\rightarrow\mathsf{Proof}(\mathbf{a}(k,n),\varphi),\qquad \mathsf{Proof}(n,\varphi)\rightarrow\mathsf{Proof}(\mathbf{a}(k,n),\varphi)$
$\mathsf{Proof}(k,\varphi)\rightarrow\mathsf{Proof}(\mathbf{c}(k),\mathsf{Proof}(k,\varphi))$.

The class of proof systems includes the Gödelian proof predicate in PA

x is a Gödel number of a derivation in PA *containing a formula with a Gödel number y*

with obvious choice of operations $\mathbf{m}(x,y)$, $\mathbf{a}(x,y)$ and $\mathbf{c}(x)$. In particular, $\mathbf{a}(n,m)$ is the concatenation of proofs n and m, and $\mathbf{c}$ is a computable function that given a Gödel number of a proof n, returns the Gödel number $\mathbf{c}(n)$ of a proof, containing formulas $\mathsf{Proof}(n,\varphi)$ for all φ's such that $\mathsf{Proof}(n,\varphi)$ holds.

An arithmetical interpretation $*$ is determined by a choice of proof system as well as an interpretation of proof variables and constants by numerals (denoting proofs), and propositional variables by arithmetical sentences. Boolean connectives are understood in the same way in LP and PA, and a formula $p{:}F$ is interpreted as an arithmetical formula $\mathsf{Proof}(p^*,F^*)$.

> This kind of provability semantics is referred to as *call-by-value semantics*; it was introduced in [15] and used in [16, 18, 29, 119, 270]. A more sophisticated *call-by-name semantics* of the language of LP was introduced in [14] and used in [160, 161, 235, 269]. Under the call-by-name semantics, proof polynomials are interpreted as Gödel numbers of definable provably recursive arithmetical terms. Call-by-value interpretations may be regarded as a special case of call-by-name interpretations since numerals are definable provably recursive arithmetical terms.

For a given constant specification $\mathcal{CS}$, an interpretation $*$ is called a *$\mathcal{CS}$-interpretation* if all formulas from $\mathcal{CS}$ are true under a given $*$. The following arithmetical completeness theorem has been established in [14] for the call-by-name semantics and in [15] for the call-by-value semantics (see also articles [16, 18]):

THEOREM 13 (Artemov [14, 15]). *A formula F is derivable in* LP *with a given constant specification $\mathcal{CS}$ iff* $\mathsf{PA}\vdash F^*$, *for any $\mathcal{CS}$-interpretation $*$.*

This theorem stands if one replaces '$\mathsf{PA}\vdash F^*$' by 'F^* holds in the standard model of arithmetic.'

In his recent paper [119], Goris showed that LP is sound and complete with respect to the call-by-value semantics of proofs in Buss's weak arithmetic S^1_2, thus showing that proof polynomials can be realized by *PTIME*-computable operations on proofs. Note that the corresponding question for the Provability Logic GL remains a major open problem.

The logic of single-conclusion proofs was described by V. Krupski in [160, 161]. This system does not correspond to any normal modal logic.

5.2 Realization Theorem

Another major feature of the Logic of Proofs is its ability to realize all S4-derivable formulas by restoring corresponding proof polynomials inside all occurrences of modality. This fact may be expressed by the following realization theorem ([14, 16]). By a *forgetful projection* of an LP-formula F, we understand a modal formula obtained by replacing all assertions $t{:}(\cdot)$ in F by $\Box(\cdot)$.

THEOREM 14 (Artemov [14]). *$\mathsf{S4}$ is the forgetful projection of LP.*

That the forgetful projection of LP is $\mathsf{S4}$-compliant is a straightforward observation. The converse has been established in [14, 16] by presenting an algorithm which substitutes proof polynomials for all occurrences of modalities in a given cut-free Gentzen-style $\mathsf{S4}$-derivation of a formula F, thereby producing a formula F^r derivable in LP. The original realization algorithms from [14, 16] were exponential. Brezhnev and Kuznets in [69] offered a realization algorithm of $\mathsf{S4}$ into LP which is polynomial in the size of a cut-free derivation in $\mathsf{S4}$. The lengths of realizing proof polynomials can be kept quadratic in the length of the original cut-free $\mathsf{S4}$-derivation.

Here is an example of an $\mathsf{S4}$-derivation realized as an LP-derivation in the style of Theorem 14. There are two columns in the table below. The first is a Hilbert-style $\mathsf{S4}$-derivation of a modal formula $\Box A \vee \Box B \rightarrow \Box(\Box A \vee B)$. The second column displays corresponding steps of an LP-derivation resulted in an LP-proof of a formula

$$x{:}A \vee y{:}B \rightarrow (a{\cdot}!x + b{\cdot}y){:}(x{:}A \vee B)$$

with constant specification

$$\{\ a{:}(x{:}A \rightarrow x{:}A \vee B),\quad b{:}(B \rightarrow x{:}A \vee B)\ \}\ .$$

	Derivation in $\mathsf{S4}$	Derivation in LP
1.	$\Box A \rightarrow \Box A \vee B$	$x{:}A \rightarrow x{:}A \vee B$
2.	$\Box(\Box A \rightarrow \Box A \vee B)$	$a{:}(x{:}A \rightarrow x{:}A \vee B)$
3.	$\Box\Box A \rightarrow \Box(\Box A \vee B)$	$!x{:}x{:}A \rightarrow (a{\cdot}!x){:}(x{:}A \vee B)$
4.	$\Box A \rightarrow \Box\Box A$	$x{:}A \rightarrow !x{:}x{:}A$
5.	$\Box A \rightarrow \Box(\Box A \vee B)$	$x{:}A \rightarrow (a{\cdot}!x){:}(x{:}A \vee B)$
$5'$.		$(a{\cdot}!x){:}(x{:}A \vee B) \rightarrow (a{\cdot}!x + b{\cdot}y){:}(x{:}A \vee B)$
$5''$.		$x{:}A \rightarrow (a{\cdot}!x + b{\cdot}y){:}(x{:}A \vee B)$
6.	$B \rightarrow \Box A \vee B$	$B \rightarrow x{:}A \vee B$
7.	$\Box(B \rightarrow \Box A \vee B)$	$b{:}(B \rightarrow x{:}A \vee B)$
8.	$\Box B \rightarrow \Box(\Box A \vee B)$	$y{:}B \rightarrow (b{\cdot}y){:}(x{:}A \vee B)$
$8'$.		$(b{\cdot}y){:}(x{:}A \vee B) \rightarrow (a{\cdot}!x + b{\cdot}y){:}(x{:}A \vee B)$
$8''$.		$y{:}B \rightarrow (a{\cdot}!x + b{\cdot}y){:}(x{:}A \vee B)$
9.	$\Box A \vee \Box B \rightarrow \Box(\Box A \vee B)$	$x{:}A \vee y{:}B \rightarrow (a{\cdot}!x + b{\cdot}y){:}(x{:}A \vee B)$

Extra steps $5'$, $5''$, $8'$, and $8''$ are needed in the LP case to reconcile different internalized proofs of the same formula: $(a{\cdot}!x){:}(x{:}A \vee B)$ and $(b{\cdot}y){:}(x{:}A \vee B)$. The resulting realization respects Skolem' idea that negative occurrences of existential quantifiers (here over proofs hidden in the modality of provability) are realized by free variables whereas positive occurrences are realized by functions of those variables.

Switching from the provability format to the language of specific witnesses reveals hidden self-referentiality of modal logic, i.e., the necessity of using proof assertions of the form $t{:}F(t)$, where t occurs in the very formula $F(t)$ of which it is a proof. A recent result by Kuznets in [69] shows that self-referentiality is an intrinsic feature of the modal logic approach to provability in general.

THEOREM 15 (Kuznets [69]). *Self-referential constant specifications of the sort $c{:}A(c)$ are necessary for realization of the modal logic $\mathsf{S4}$ in the Logic of Proofs LP.*

In particular, the $\mathsf{S4}$-theorem

$$\neg\Box\neg(S \to \Box S)$$

cannot be realized in LP without self-referential constant specifications of the sort $c{:}A(c)$.

Systems of proof polynomials for other classical modal logics K, $\mathsf{K4}$, D, $\mathsf{D4}$, T were described in [67, 68]. The case of $\mathsf{S5} = \mathsf{S4} + (\neg\Box F \to \Box\neg\Box F)$ was special because of the presence of negative information about proofs and its connections to formal epistemology. The paper by Artemov, Kazakov, and Shapiro [29] introduced a system of proof terms for $\mathsf{S5}$, and established realizability of the logic $\mathsf{S5}$ by these terms, decidability, and completeness of the resulting logic of proofs.

5.3 Fitting Models

The main idea of epistemic semantics for LP can be traced back to Mkrtychev and Fitting. It consists of augmenting Boolean or Kripke models with an *evidence function*, which assigns 'admissible evidence' terms to a statement before deciding its truth value.

Fitting models are defined as follows. A *frame* is a structure (W, R), where W is a non-empty set of *possible worlds* and R is a binary reflexive and transitive *evidence accessibility* relation on W. Given a frame (W, R), a *possible evidence function* $\mathcal{E}$ is a mapping from worlds and proof polynomials to sets of formulas. We can read $F \in \mathcal{E}(u, t)$ as

'F is one of the formulas for which t serves as possible evidence in world u.'

An *evidence function* is a possible evidence function which respects the intended meanings of the operations on proof polynomials, i.e., for all proof polynomials s and t, for all formulas F and G, and for all $u, v \in W$, each of the following hold:

1. *Monotonicity*: uRv implies $\mathcal{E}(u,t) \subseteq \mathcal{E}(v,t)$;
2. *Closure*:
   - *Application*: $F \to G \in \mathcal{E}(u,s)$ and $F \in \mathcal{E}(u,t)$ implies $G \in \mathcal{E}(u, s\cdot t)$;
   - *Inspection*: $F \in \mathcal{E}(u,t)$ implies $t{:}F \in \mathcal{E}(u, !t)$;
   - *Sum*: $\mathcal{E}(u,s) \cup \mathcal{E}(u,t) \subseteq \mathcal{E}(u, s+t)$.

A model is a structure $\mathcal{M} = (W, R, \mathcal{E}, \Vdash)$ where (W, R) is a frame, $\mathcal{E}$ is an evidence function on (W, R), and $\Vdash$ is an arbitrary mapping from sentence variables to subsets of W. Given a model $\mathcal{M} = (W, R, \mathcal{E}, \Vdash)$, the forcing relation $\Vdash$ is extended from sentence variables to all formulas by the following rules. For each $u \in W$:

1. $\Vdash$ respects connectives ($u \Vdash F \wedge G$ iff $u \Vdash F$ and $u \Vdash G$, $u \Vdash \neg F$ iff $u \nVdash F$, etc.);
2. $u \Vdash t{:}F$ iff $F \in \mathcal{E}(u,t)$ and $v \Vdash F$ for every $v \in W$ with uRv.

We consider the modality $\Box$, associated with the evidence accessibility relation R. In this terms, the last item of the above definition can be recast as

$2'$. $u \Vdash t{:}F$ iff $u \Vdash \Box F$ and t is an admissible evidence for F at u.

Mkrtychev models are Fitting models with singleton W's. LP was shown to be sound and complete with respect to both Mkrtychev models ([193]) and Fitting models ([91, 93]). Fitting models were adapted for multi-agent epistemic setting in [20, 30, 32, 92] and became the standard semantics for justification logics.

5.4 Joint logics of proofs and provability

The problem of finding a joint logic of proofs and provability has been a natural next step, since there are principles that can only be formulated in a mixed language of formal provability and explicit proofs. For example, the modal principle of negative introspection $\neg\Box F \rightarrow \Box\neg\Box F$ is not valid in the provability semantics; neither is a purely explicit version of negative introspection $\neg(x:F) \rightarrow t(x):\neg(x:F)$. However, a mixed explicit-implicit principle $\neg(t{:}F) \rightarrow \Box\neg(t{:}F)$ is valid in the standard provability semantics.

The complete joint system of provability and explicit proofs without operations on proof terms, system B, was found in [13]. This system describes those principles that have a pure logical character and do not depend on any specific operations of proofs.

The postulates of B consist of those of GL together with the following new principles:

- A1. $t{:}F \rightarrow F$,
- A2. $t{:}F \rightarrow \Box t{:}F$,
- A3. $\neg t{:}F \rightarrow \Box\neg t{:}F$,
- RR. *Rule of reflection:* $\dfrac{\vdash \Box F}{\vdash F}$.

THEOREM 16 (Artemov [13]). B *is sound and complete with respect to the semantics of proofs and provability in Peano arithmetic.*

The problem of joining two models of provability, GL and LP, into one model can be specified as that of finding an arithmetically complete logic containing postulates of both GL and LP and closed under internalization.

The first solution to this problem was offered by Yavorskaya (Sidon) who found an arithmetically complete system of provability and explicit proofs, LPP, containing both GL and LP (cf. [235, 269]). Along with natural extensions of principles and operations from GL and LP, LPP contains additional operations '$\Uparrow$' and '$\Downarrow$' which were used to secure the internalization property of LPP. The operation '$\Uparrow$' given a proof t of F, returns a proof $\Uparrow t$ of $\mathsf{Provable}(F)$. The operation '$\Downarrow$' takes a proof t of $\mathsf{Provable}(F)$ and returns a proof $\Downarrow t$ of F. The set of postulates of LPP consists of those of GL and LP together with A2, A3, and RR from B, plus two new principles:

- A4. $t{:}F \rightarrow (\Uparrow t){:}\Box F$,
- A5. $t{:}\Box F \rightarrow (\Downarrow t){:}F$.

Finally, Nogina in [30, 201] noticed that operations '$\Uparrow$' and '$\Downarrow$' along with A4 and A5 are in certain sense redundant and offered a simpler system, GLA, which is an arithmetically complete logic in a joint language of GL and LP, containing postulates of both GL and LP, and closed under internalization. The system GLA is presented in [30, 201] by the set of postulates of GL and LP augmented by the principles:

- $t{:}F \to \Box F$,
- $\neg t{:}F \to \Box \neg t{:}F$,
- $t{:}\Box F \to F$.

and *Rule of reflection* RR.

THEOREM 17.

(1) (Yavorskaya (Sidon) [235, 269]). LPP *is sound and complete with respect to the semantics of proofs and provability in Peano arithmetic.*

(2) (Nogina [30, 201]). GLA *is sound and complete with respect to the semantics of proofs and provability in Peano arithmetic.*

It was the system GLA, which served in [30, 32] as a prototype of justification logics (cf. Subsection 5.7).

5.5 Quantified logics of proofs

The arithmetical provability semantics for the logic of proofs may be naturally generalized to first-order language and to the language of LP with quantifiers over proofs. Both possibilities of enhancing the expressive power of LP were investigated and in both cases, axiomatizability questions have been answered negatively.

THEOREM 18.

(1) (Artemov, Yavorskaya (Sidon) [36]). *The first-order logic of proofs is not recursively enumerable.*

(2) (Yavorsky [271]). *The logic of proofs with quantifiers over proofs is not recursively enumerable.*

An interesting decidable fragment of the first-order logic of the standard proof predicate was found in [270].

5.6 Intuitionistic logic of proofs

The problem of building the intuitionistic logic of proofs has two distinct parts. Firstly, one has to answer the question about the propositional logical principles that axiomatize HA-tautologies in the propositional language enriched by atoms *u is a proof of F* without operations on proof terms, i.e. when u is a variable. The resulting basic logic of proofs reflects purely logical principles of the chosen format. Secondly, one has to pick systems of operations on proofs and study the corresponding intuitionistic logics of proofs. The first of the above problems was solved by Artemov and Iemhoff in [27] where the *Basic Intuitionistic Logic of Proofs*, iBLP, was introduced and found to be arithmetically complete with respect to the semantics of proofs in HA. The paper essentially uses technique and results by de Jongh [77], Smoryński [239], de Jongh and Visser's work on a basis for admissible rules in IPC (circa 1991, cf. [137]), Artemov & Strassen [33] and Artemov [13], Ghilardi [106, 107], Iemhoff [136, 138, 139].

The completeness proof presented in [27] is also interesting because it is the first result in this area for constructive theories; the corresponding problem for the provability logic of Heyting arithmetic HA is still open (Section 4.4).

5.7 Applications

Here we will list some conceptual applications of the Logic of Proofs.

1. *Existential semantics for modal logic.* Proof polynomials and LP represent an exact *existential semantics* for mainstream modal logic. Initially, Gödel regarded the modality $\Box F$ as the provability assertion, i.e.,

there exists a proof for F.

Thus, according to Gödel, modality is an informal Σ_1-sentence, i.e., the one which consists of an existential quantifier (here over proofs) followed by a decidable condition. Such an understanding of modality is typical of 'naive' semantics for a wide range of epistemic and provability logics. Nonetheless, before LP was discovered, major modal logics lacked a mathematical semantics of an existential character. The exception to the rule is the arithmetical provability interpretation for the Provability Logic GL, which still cannot be extended to the major modal logics S4 and S5.

Almost 30 years after the first work by Gödel on the subject, a semantics of a *universal* character was discovered for modal logic, namely Kripke semantics. Modality in that semantics is read informally as the sentence:

in each possible situation, F holds.

Such a reading of modality naturally appears in dynamic and temporal logics aimed at describing computational processes, states of which usually form a (possibly branching) Kripke structure. Universal semantics has been playing a prominent role in modal logic. However, it is not the only possible semantical tool in the study and application of modality. The existential semantics of realizability by proof polynomials can also be useful for foundations and application of modal logic. For more discussion on the existential semantics for modal logic, see [22].

2. *Justification Logic.* A major area of application of the Logic of Proofs is epistemology. The books [89, 189] serve as an excellent introduction to the mathematical logic of knowledge.

Plato's celebrated tripartite definition of knowledge as *justified true belief* is generally regarded in mainstream epistemology as a set of necessary conditions for the possession of knowledge. Due to Hintikka, the 'true belief' components have been fairly formalized by means of modal logic and its possible worlds semantics. The remaining 'justification' condition has received much attention in epistemology (cf., for example, [59, 105, 116, 129, 174, 177, 178, 204]), but lacked formal representation. The issue of finding a formal epistemic logic with justification has also been discussed in [247]. Such a logic contains assertions of the form $\Box F$ (*F is known*), along with those of the form $t{:}F$ (*t is a justification for F*). Justification was introduced into formal epistemology in [20, 30, 31, 32] by combining Hintikka-style epistemic modal logic with justification calculi arising from the Logic of Proofs LP. The generic name for this kind of systems is *Justification Logic*.

3. *Logical omniscience problem.* The traditional Hintikka-style modal logic approach to knowledge has the well-known defect of *logical omniscience*, which is an unrealistic feature that an agent knows all logical consequences of his/her assumptions ([87, 88, 134, 198, 206, 207]). Justification Logic addresses the issue of logical omniscience in a natural way. The paper [28] suggests looking at the logical omniscience as a complexity issue

and offers the following Logical Omniscience Test (LOT): an epistemic system E is not logically omniscient if for any valid in E knowledge assertion $\mathcal{A}$ of type '*F is known*' there is a proof of F in E, the complexity of which is bounded by some polynomial in the length of $\mathcal{A}$. The usual epistemic modal logics are logically omniscient (modulo some common complexity assumptions). On the other hand, Justification Logic is logically omniscient w.r.t. the usual (implicit) knowledge and are not logically omniscient w.r.t. the evidence-based knowledge.

4. *Justified Knowledge.* Justification Logic was used in [20, 23] to offer a new approach to *common knowledge*. A modal operator $J\varphi$ for *justified knowledge* introduced in [20, 23] is defined as a forgetful projection of justification assertions $t{:}\varphi$. Hence the intended meaning of $J\varphi$ is

there is an access to an explicit evidence for φ .

In particular, justified knowledge J was shown in [5, 20, 23] to provide a lighter, constructive version of common knowledge and can be used as such in solving specific problems.

6 MODAL LOGIC OF SPACE

The application of modal logic to topology has a rather long history. The idea of a simple 'algebraic calculus' suitable for proving some topological theorems dates back to Kuratowski [163]. A somewhat similar idea was proposed earlier by Riesz in [216]. A. Robinson in [217] put the problem of developing a topological model theory in the same manner as the classical first-order model theory. Classical first-order logic is insufficient for topology because here one usually deals both with points and sets, hence some fragments of second-order logic should be involved. Topological model theory in this style was developed in [95, 96].

The modal logic approach to topology lies within the same mathematical tradition. Modal calculi can also be interpreted in certain weak fragments of second-order logic. However, modal logics of interest are usually decidable and have a good mathematical structure with respect to both model theory and proof theory. All these features bring into topology some specific logical tools and results.

The use of modal logic in topology was initially motivated by Kuratowski's axioms. Let $\mathcal{T} = \langle \boldsymbol{X}, \mathbb{I} \rangle$ be a topological space, where $\boldsymbol{X}$ is a set of points and $\mathbb{I}$ the interior operation. In terms of the interior ($\mathbb{I}$) and Boolean operations, modal topological principles look as follows:

A1. $\mathbb{I}(Y \cap Z) = \mathbb{I}Y \cap \mathbb{I}Z$;
A2. $\mathbb{I}Y = \mathbb{I}\mathbb{I}Y$;
A3. $\mathbb{I}Y \subseteq Y$;
A4. $\mathbb{I}\boldsymbol{X} = \boldsymbol{X}$

Here Y, Z are subsets of $\boldsymbol{X}$. These axioms can be viewed as identities in the language of Boolean algebras with an extra functional symbol $\mathbb{I}$. They define the variety of so-called *topo-Boolean algebras* (a.k.a. *interior algebras* or *closure algebras*, the latter used by McKinsey and Tarski), and in an obvious way every topological space $\mathcal{T}$ corresponds to a topo-Boolean algebra, which is the powerset of $\mathcal{T}$ with the interior (or closure) operation acting on the subsets of $\mathcal{T}$. The above axioms can also be written as propositional modal formulas: Boolean operations should be replaced by the corresponding propositional

connectives, and $\mathbb{I}$ with the modal connective $\Box$. Thus we obtain the following modal axiom schemes:

A1. $\Box(A \wedge B) = \Box A \wedge \Box B$,

A2. $\Box A \to \Box\Box A$,

A3. $\Box A \to A$,

A4. $\Box\top$,

which are the well-known postulates of $\mathsf{S4}$. This property, noticed in the late 1930s by Tarski, and independently by Stone and Tang, is rather surprising because Lewis' original motivation of $\mathsf{S4}$ was purely logical, and Gödel's provability interpretation of $\mathsf{S4}$ was also of a logical character.

The topological interpretation can be modified to fit other modal logics, namely, one can consider *neighborhood frames*. By definition, such a frame $\mathcal{F} = (\boldsymbol{X}, \mathbb{I})$ is a set $\boldsymbol{X}$ together with an operation $\mathbb{I}$ on its subsets. Then U is called a neighborhood of x if $x \in \mathbb{I}U$. Given a valuation φ which sends proposition letters to subsets of X, we can extend it to all modal formulas as follows:

$\varphi(\neg A) = \boldsymbol{X} \setminus \varphi(A)$,

$\varphi(A \wedge B) = \varphi(A) \cap \varphi(B)$,

$\varphi(A \vee B) = \varphi(A) \cup \varphi(B)$,

$\varphi(\Box A) = \mathbb{I}\varphi(A)$.

The same definition can be given in terms of a forcing relation (or the truth at a point): a formula A is called true at w under interpretation φ if $w \in \varphi(A)$; this is also denoted by $w \Vdash A$. Now the above conditions for extending φ can be written as follows:

$w \Vdash \neg A$ iff $w \nVdash A$,

$w \Vdash A \wedge B$ iff ($w \Vdash A$ and $w \Vdash B$),

$w \Vdash A \vee B$ iff ($w \Vdash A$ or $w \Vdash B$),

$w \Vdash \Box A$ iff $\{y \mid y \Vdash A\}$ is a neighborhood of w.

So $\Box A$ can be read as A *is locally true* [220]. A formula A is called valid in $\mathcal{F}$ (notation: $\mathcal{F} \Vdash A$) if $\varphi(A) = \boldsymbol{X}$ for any valuation φ.

The set $\mathbf{L}(\mathcal{F}) := \{A \mid \mathcal{F} \Vdash A\}$ is called the modal logic of $\mathcal{F}$. Logics of this form are called neighborhood (N-) complete. All well-known modal logics are N-complete. Moreover, they can be presented as logics of familiar topological spaces.

The following theorem is a classical result in this area:

THEOREM 19 (McKinsey, Tarski [187]). *Let $\mathcal{M}$ be a separable dense-in-itself metric space. Then $\mathbf{L}(\mathcal{M}) = \mathsf{S4}$.*

In particular, $\mathbf{L}(\mathbb{R}^n) = \mathsf{S4}$, for each $n = 1, 2, 3, \ldots$.

A simplified proof of topological completeness of $\mathsf{S4}$ with respect to the Cantor space was obtained in [192]. Simplified proofs of completeness of $\mathsf{S4}$ with respect to the real line $\mathbb{R}$ were given in [56, 237].

However, there exist N-incomplete modal logics, even among the extensions of $\mathsf{S4}$. Such examples can be found in [103, 104, 228, 233]. This fact is perhaps counter to the naive intuition: it turns out that there exist systems of topo-Boolean identities that do not correspond to any particular topo-Boolean algebra of a topological space — every such algebra satisfies some other identities that are non-derivable from the original system. This is indeed an incompleteness phenomenon at the level of propositional modal logic akin to those in arithmetical theories.

Kripke semantics can be regarded as a particular case of neighborhood semantics. In fact, given a Kripke frame (W, R), one can build the neighborhood frame $\mathbf{N}(W, R) = (W, \mathbb{I})$ where $\mathbb{I}U := \{x \mid R(x) \subseteq U\}$, so that validities in these two frames are the same. Hence, Kripke-completeness implies N-completeness. The converse is not true; there exist topological spaces with Kripke-incomplete modal logics [103, 104, 228, 233].

For topological semantics of first-order modal logic, see Chapter 9 this Handbook. Modal logics of product topologies were studied in [181, 219, 251]. Gabelaia's master's thesis [100] is a very informative source on modal logic and topology.

6.1 Other operators in topological spaces

The modality $\Box$ can be interpreted in topological spaces not only as the interior, but in some other natural ways. There are other known topological operators on sets that are not expressible in terms of Boolean operation and interior, e.g., taking the derived set $d(X)$ which is the set of all limit points of X [164]. It turns out that the corresponding 'derivational modal logics' of natural classes of topological spaces are not among the most popular modal logics, with one noticeable exception: the derivational modal logic of Cantor's scattered topological spaces turned out to be the Provability Logic GL.

DEFINITION 20. Let C be a class of topological spaces. We understand by $\mathbf{Ld}(C)$ the *derivational modal logic of* C, i.e., the set of propositional formulas with the modality $\Diamond$ interpreted as the derived set operator d that hold in all $\mathcal{T}$'s from C. By $\mathsf{wK4}$ ('weak $\mathsf{K4}$') we understand the modal logic $\mathsf{K} + (p \wedge \Box p) \to \Box\Box p$, and by $\mathsf{D4}$ the logic $\mathsf{K4} + \neg\Box\bot$.

By the modality $\Box^+ F$, we mean $F \wedge \Box F$.

THEOREM 21.

(1) (Esakia [83, 85, 86]). $\mathsf{wK4}$ *is the derivational logic of the class of all topological spaces.*

(2) (Shehtman [230]). *For* $n > 1$, $\mathbf{Ld}(\mathbb{R}^n) = \mathsf{D4} + \Box[(p \wedge \Box p) \vee (\neg p \wedge \Box \neg p)] \to \Box p \vee \Box \neg p$.

(3) (Shehtman [232]). $\mathbf{Ld}(\mathbb{R}) = \mathsf{D4} + \Box(\Box^+ F_1 \vee \Box^+ F_2 \vee \Box^+ F_3) \to (\Box\neg F_1 \vee \Box\neg F_2 \vee \Box\neg F_3)$, *where*

$$F_i = p_i \wedge \bigwedge_{j \neq i} \neg p_j \ .$$

Note that the derivational modal logics of $\mathbb{R}$ and $\mathbb{R}^n$ for $n > 1$ are different. Shehtman in [230] also found that derivational modal logics of $\mathbb{Q}$, Cantor's discontinuum $\mathcal{C}$, as well as any 0-dimensional separable dense-in-itself metric space are all equal to $\mathsf{D4}$. Further results on axiomatization and definability of derivational logics can be found in [55].

A topological space is called *scattered* if it has no dense-in-itself non-empty subsets. Let α be an ordinal. We view α as a topological space with its interval topology. Then it is known that every ordinal α is a scattered space ([186]).

THEOREM 22.

(1) (Esakia [84, 86]). GL *is the derivational logic of the class of all scattered spaces.*

(2) (Abashidze [1], Blass [58]). GL *is the derivational logic of* α, *for any specific ordinal* $\alpha \geq \omega^\omega$.

These theorems demonstrate that Gödel's consistency operator *Con(F)*, stating that

F is consistent with Peano arithmetic ,

and Cantor's topological derived set operator d on scattered spaces have the same set of propositional identities.

6.2 Adding the universal modality

Topological spaces may be considered Boolean algebras with several extra operations, and this leads to different polymodal logics. The basic modal language can be expanded by other modal connectives. For example, one can add the universal modality $[\forall]$, with the following interpretation:

$$w \Vdash [\forall]A \quad \text{iff} \quad x \Vdash A \quad \text{holds for any } x \in \boldsymbol{X}\,.$$

The new language is more expressive: in fact, the formula

$$(\mathrm{AC}) \;:=\; [\forall](\Box p \vee \Box\neg p) \to [\forall]p \vee [\forall]\neg p$$

is valid exactly in connected spaces, but connectedness cannot be expressed in the basic language. Moreover, the following analogs of the classical McKinsey–Tarski Theorem 19 hold. Let

$\mathsf{S4U} = \mathsf{S4}(\text{for } \Box) + \mathsf{S5}(\text{for } [\forall]) + [\forall]p \to \Box p$,

$\mathsf{S4UC} = \mathsf{S4U} + (\mathrm{AC})$.

Let also $\mathbf{LU}(C)$ denote the logic of a class C in the expanded language with $\Box$ and $[\forall]$.

THEOREM 23.

(1) (Goranko, Passy [117]). $\mathsf{S4U} = \mathbf{LU}$ *(all topological spaces).*

(2) (Shehtman [231]). *If $\mathcal{X}$ is a separable dense-in-itself metric space, then*

$$\mathbf{LU}(\mathcal{X}) = \mathsf{S4UC}\,.$$

Some refinement of Shehtman's result (2) can be found in [250] and Chapter 9 of this Handbook. It was shown in [117, 231] that S4U and S4UC have the finite model property, and so they are decidable. As for complexity, S4U is known to be *PSPACE*-complete [6].

An interesting feature is that many *mereotopological relations* between spatial regions (such as 'X is disconnected from Y' or 'X is a (non)tangential proper part of Y') arising in geographical information systems and qualitative spatial representation and reasoning can be expressed within S4U. For example, spatial regions of the *region connection calculus* RCC-8 [51, 82, 211, 212] are interpreted as regular closed subsets of a topological space, and hence can be represented by S4U-formulas of the form $\Diamond\Box X$. The binary relations of RCC-8 can be captured using the universal modality, for instance, $[\forall](\Diamond\Box X \to \Diamond\Box Y)$ says that region X is a part of region Y. RCC-8 is *NP*-complete whereas the satisfiability problem for BRCC-8 (RCC-8 with Boolean operations on regions) in the Euclidean spaces is *PSPACE*-complete, that is, of the same complexity as S4U itself ([101, 266]).

6.3 Modal logic of metric spaces

The first paper on modal logic for metric spaces was, perhaps, the McKinsey and Tarski paper [187], though there were no special modalities for distances there. First-order modal logics for metric spaces were considered in [121]. Modal logics containing specific metric modalities

- $\exists^{<a}$ (or $\exists^{\leq a}$) for 'somewhere in the sphere of radius a excluding (or including) the boundary,' where a is a positive rational number;
- $\exists^{<a}_{>b}$ for 'somewhere at distance d with $b < d < a$,' where $b < a$ are positive rational numbers,

were introduced and studied in [166, 267, 268]. In particular, Wolter and Zakharyaschev in [268] introduced the *modal logic of metric and topology*, MT, in the language containing $\Box$ and $[\forall]$, along with the metric modalities $\exists^{<a}$ and $\exists^{\leq a}$.

THEOREM 24 (Wolter, Zakharyaschev [268]).
(1) MT *is decidable and EXPTIME-complete over arbitrary metric spaces.*
(2) MT *is decidable over the one-dimensional Euclidean space* $\mathbb{R}$*.*
(3) MT *over* $\mathbb{R}^2$ *with the Euclidean metric is undecidable.*

For a survey of other results and further research directions cf. [165].

6.4 Modal logic of dynamic topology

One more class of natural mathematical objects, the *topological dynamic systems*, became a subject of modal logic studies. Two independently working groups can be credited for its origin in 1997: one at Stanford (Kremer, Mints, and Rybakov), and one at Cornell (Artemov, Davoren, and Nerode). We will start by observing the results of the latter, since their approach was more general.

The basic model under consideration is a topological dynamic system $\langle \mathcal{T}, f\rangle$ consisting of a topological space $\mathcal{T} = \langle \boldsymbol{X}, \mathbb{I}\rangle$ and a total function f mapping $\boldsymbol{X}$ to $\boldsymbol{X}$. The corresponding bimodal logic consists of good old S4 with its standard topological interpretation in $\langle \boldsymbol{X}, \mathbb{I}\rangle$, together with a unary modality $\bigcirc$ similar to the one called *the next* or *tomorrow* in temporal logic. A temporal logic was first introduced in [208, 209, 210, 264, 265].

The interpretation of the Boolean connectives is set theoretical in $\boldsymbol{X}$, $\Box$ is interpreted as the interior operation $\mathbb{I}$ on $\mathcal{T}$, and $\bigcirc Y$ is interpreted as $f^{-1}Y$, i.e., the inverse image of Y with respect to f. Hence, the interpretation of $\bigcirc$ reflects the idea of the 'next' temporal operator: $\bigcirc Y$ is the set of points of $\boldsymbol{X}$ which will land in Y 'tomorrow,' after f acts on them once.

DEFINITION 25. The basic system S4F of the dynamic topological logic is S4 together with two temporal principles:

$\bigcirc(A \rightarrow B) \rightarrow (\bigcirc A \rightarrow \bigcirc B)$,
$\bigcirc(\neg A) \leftrightarrow \neg\bigcirc A$,
and the Rule of necessitation for $\bigcirc$: $\dfrac{\vdash A}{\vdash \bigcirc A}$.

The expressive power of S4F suffices to capture the Hoare implication $A \rightarrow \bigcirc B$, stating that with a precondition A after action f, the condition B will hold. One of the main motivations for the authors of [26] to introduce and study dynamic topological logic was to devise a logic tool for analysis of classical and hybrid control systems, where the control function is not necessarily continuous. This line of work has been pursued by Davoren in her dissertation [76], and in subsequent works.

Dynamic systems with continuous function f have been given special treatment. The bimodal language of dynamic topological logic naturally expresses continuity via the principle

$$\textbf{Cont}: \qquad \bigcirc\Box A \to \Box\bigcirc A,$$

reflecting the definition of a continuous mapping as one where an inverse image of an open set is open. Consider the logic

$$\mathsf{S4C} = \mathsf{S4F} + \textbf{Cont} \ .$$

THEOREM 26 (Artemov, Davoren, Nerode [26]).
(1) S4F *is sound and complete with respect to the class of all dynamic systems* $\langle \mathcal{T}, f\rangle$,
(2) S4C *is sound and complete with respect to the class of all dynamic systems* $\langle \mathcal{T}, f\rangle$ *where* f *is continuous on* $\mathcal{T}$.

In addition, S4F and S4C enjoy cut-elimination and the finite model property w.r.t. the corresponding class of Kripke models.

It follows from the proof that S4C is also sound and complete w.r.t. continuous dynamic systems with Alexandrov spaces (the topological equivalents of Kripke frames). Slavnov in [236] and independently Kremer and van Benthem (cf. [156, 237]) showed that the analog of the McKinsey-Tarski completeness theorem does not hold here: S4C is not complete with respect to the real topology over $\mathbb{R}$. In [237], the following weaker form of the McKinsey-Tarski theorem for S4C was established by Slavnov:

if F *is not provable in* S4C*, then* F *has a countermodel in* $\mathbb{R}^n$ *for an appropriate* n .

There is no complete axiomatization known for continuous dynamic systems over $\mathbb{R}^n$ for any specific n.

Dynamic systems $\langle \mathcal{T}, f\rangle$ with continuous f became a starting point for [154, 155, 157]. Consider the logic

$$\mathsf{S4}\bigcirc = \mathsf{S4C} + \Box\bigcirc A \to \bigcirc\Box A \ .$$

THEOREM 27 (Kremer, Mints, Rybakov [156, 157]). S4$\bigcirc$ *is sound and complete w.r.t. the following classes of dynamic systems* $\langle \mathcal{T}, f\rangle$*:*
(a) f *is a homeomorphism;*
(b) $\mathcal{T}$ *is an Alexandrov space,* f *is a homeomorphism;*
(c) $\mathcal{T}$ *is a real topology* $\mathbb{R}^n$*,* f *is a homeomorphism;*
(d) $\mathcal{T}$ *is a unit ball* $\mathcal{B}^n$*,* f *is a measure preserving homeomorphism.*

As was shown in [156], S4$\bigcirc$ has the finite model property, hence it is decidable.

The systems S4F, S4C, and S4$\bigcirc$ (along with so-called *temporal-over-topological fragment* of the dynamic topological logic from [156]), basically exhaust the list of known axiomatizability results in dynamic topology. The papers [76, 155, 157] in addition to $\Box$ and $\bigcirc$, consider the S4-type modality *henceforth*, $*$, to be borrowed from temporal logic, with an apparent goal of capturing some asymptotic behavior of the function f in a dynamic system $\langle \mathcal{T}, f\rangle$. The formal topological interpretation φ of $*B$ is

$$\varphi(*B) = \bigcap_{n\geq 0} f^{-n}\varphi(B) \ ,$$

which specifies the set of points $X \subseteq \varphi(B)$ that never leave $\varphi(B)$ under f, f^2, f^3, etc. The dual of $*$ is the modality $\sharp$, such that $\sharp B$ is interpreted as

$$\varphi(\sharp B) = \bigcup_{n \geq 0} f^{-n}\varphi(B) ,$$

which gives the set of points X that are either in $\varphi(B)$, or reach $\varphi(B)$ under at least one of the iterations f, f^2, f^3, etc. This third modality $*$ considerably extends the expressive power of the dynamic topological logic, making it closer to applications in dynamic systems and control theory. However, this expressive power seems to ruin good algorithmic behavior of dynamic topological logic, as is shown in the following theorem.

THEOREM 28 (Konev, Kontchakov, Wolter, Zakharyaschev [151]). *Let $\mathcal{M}$ be one of the following classes of dynamic systems $\langle \mathcal{T}, f\rangle$:*

(a) *f is a homeomorphism;*
(b) *$\mathcal{T}$ is the class of all Alexandrov spaces, f is a homeomorphism;*
(c) *$\mathcal{T}$ is a real topology $\mathbb{R}^n$, f is a homeomorphism;*
(d) *$\mathcal{T}$ is a unit ball $\mathcal{B}^n$, f is a measure preserving homeomorphism.*

Then the set of valid formulas in the language with $\{\Box, \bigcirc, *\}$ that are valid in $\mathcal{M}$ is not recursively enumerable. All these logics are different.

The proof is by reduction of the Post correspondence problem.

In addition, [151] considers logics for dynamic systems $\langle \mathcal{T}, f\rangle$, where $\mathcal{T}$ is a metric space and f an isometric function. The modal operator for topological interior $\Box$ is replaced by distance operators of the form $\exists^{\leq a}$ 'somewhere in the ball of radius a,' for a positive rational a. In contrast to the topological case, the resulting logic turns out to be decidable, but not bounded in time by any elementary function.

A follow-up paper [102] showed (using more general results on products of modal logics with expanding domains) that the dynamic topological logic interpreted in topological spaces with *continuous* functions was decidable if the number of function iterations was assumed to be *finite*, however, not in primitive recursive time. The decidability proof was based on Kruskal's tree theorem, and the proof of non-primitive recursiveness was established by reduction of the reachability problem for lossy channel systems. Note that the dynamic topological logics interpreted in topological spaces with finite iterations of homeomorphisms are not recursively enumerable.

Quite recently, by encoding the ω-reachability problem for lossy channel systems it was shown in [152] that the dynamic topological logic over some natural spaces with continuous functions is undecidable.

THEOREM 29 (Konev, Kontchakov, Wolter, Zakharyaschev [152]). *The set of formulas in the language with $\{\Box, \bigcirc, *\}$ that are valid in any of the following classes:*

(a) *all continuous dynamic systems $\langle \mathcal{T}, f\rangle$,*
(b) *continuous dynamic systems $\langle \mathcal{T}, f\rangle$ where $\mathcal{T}$ is the class of all Alexandrov spaces,*
(c) *continuous dynamic systems $\langle \mathcal{T}, f\rangle$ where $\mathcal{T}$ is a real topology $\mathbb{R}^n$, is undecidable. All these logics are different.*

This gives a solution to one of the major open problems in the area.

The remaining challenging open questions here are:

1. the decidability and axiomatizability of the dynamic topological logic in the language with $\{\Box, \bigcirc\}$ for the class of continuous dynamic systems over real topological spaces $\mathbb{R}_n$ for fixed $n = 1, 2, 3, \ldots$;

2. the axiomatizability of the dynamic topological logic in the language with $\{\Box, \bigcirc, *\}$ for the class of all continuous dynamic systems.

6.5 Other geometric notions

A number of other fundamental geometrical notions have been connected to corresponding extensions of modal logic in [2, 3, 4]. The paper [3] considered different topological and geometric structures such as connectedness, affine structure, convexity, etc., and proposed a number of languages extending the usual modal language in order to describe these structures. Some authors studied modal logics of such geometric notions as incidence, parallelism, orthogonality, and such structures as projective and affine planes. Precise references and details can be found, e.g., in [38].

The *logic of comparative similarity*, CSL, with the sole metric operator $\leftleftarrows$ for '*closer*' was introduced and investigated in [234]: $X \leftleftarrows Y$ is the set of all points of a given metric space that are closer to set X than to set Y. Despite its apparent simplicity, this langauge is quite impressive. In particular, the topological interior and closure operators as well as the universal modality can be expressed in terms of $\leftleftarrows$.

In all, the above papers contributed to making spatial and spatio-temporal reasoning a lively and actively developing area. Once again, we will refer the reader to the forthcoming collection 'The Logic of Space,' edited by Aiello, van Benthem, and Pratt-Hartmann.

6.6 Modal logic of spacetime

The Minkowski spacetime, together with the causal ($\prec$) and chronological ($\preceq$) accessibility relations, constitute Kripke-style frames which naturally have corresponding modal logics. Knowing such modal logics provide additional understanding of Minkowski's spacetime that forms the basis of Einstein's special theory of relativity. The mathematical problem of finding modal logics for chronological future modality was solved by Goldblatt [112] and Shehtman [229]; the modal logic of the chronological relation $\preceq$ turned out to be $\mathsf{S4.2}{=}\mathsf{S4}{+}\Diamond\Box F \to \Box\Diamond F$. A similar problem for causal future modality was solved by Shapirovsky and Shehtman in [223].

6.7 Topoi

Yet another incarnation of the topological semantics is given by interpreting intuitionistic modality in Grothendieck topology on a category and sheaf theory. Such an interpretation was suggested by Lawvere [173]; a relevant axiomatic system was suggested by Goldblatt in [113]. See the survey [115] and Chapter 9 of this Handbook for exact formulations and discussion. For a different connection between modalities and topos theory relying on geometric morphisms, also see Chapter 9 of this Handbook. An interesting topos-theoretic approach to modality can be found in the works of Reyes and his collaborators [172, 185, 213, 214, 215].

6.8 Universal algebra

A new research thrust in which using modal logic on classical mathematical structures makes a good sense was suggested by Goranko and Vakarelov in [118]. They have devel-

oped a uniform approach to axiomatizing various classes of traditional algebraic structures in modal logic, using the fact that difference modality is naturally definable there.

7 MODALITIES IN SET THEORY

We start with two theorems by Solovay, both published in [65], Chapter 13. These theorems gave a modal characterization of the notions of truth in all transitive models of ZF and truth in all models V_κ, where κ is inaccessible.

Let φ be a function that assigns to each propositional letter a sentence of the language of set theory. For each modal formula A, we define its interpretation, $\varphi(A)$ as follows: φ commutes with Boolean connectives, and $\varphi(\Box A)$ is the sentence of ZF that translates '$\varphi(A)$ holds in all transitive models of ZF.'

Let I be the system of modal logic that results when the principle

$$\Box(\Box A \to \Box B) \vee \Box(\Box B \to (A \wedge \Box A))$$

is added to GL as a new axiom schema.

A *universe* is a set V_κ, where κ is inaccessible. All such V_κ's are models of ZF (cf. [162]). Let ψ be defined as φ before, except that we now define $\psi(\Box A)$ as the sentence of ZF that translates '$\psi(A)$ holds in all universes.' Let J be GL plus the principle

$$\Box(\Box A \to B) \vee \Box((B \wedge \Box B) \to A)\ .$$

THEOREM 30 (Solovay, cf. [65]).

(1) $\mathsf{I} \vdash A$ *iff* $\mathsf{ZF} \vdash \varphi(A)$*, for all* φ *that translate* $\Box A$ *as 'A holds in all transitive models of* ZF*.'*

(2) $\mathsf{J} \vdash A$ *iff* $\mathsf{ZF} \vdash \psi(A)$*, for all* ψ *that translate* $\Box A$ *as 'A holds in all universes.'*

A strong connection between modal logic and non-well-founded sets has been provided by Barwise and Moss in [41] and Baltag in [39, 40]. Suppose one takes ordinary modal logic over some fixed set of atomic sentences and then considers the full infinitary propositional language generated by this. The resulting language has conjunctions and disjunctions of all sets of sentences, and this itself is a proper class of sentences. In addition to this, one can also consider the language with Boolean combinations of at most κ sentences, where κ is a cardinal number. A *pointed model* is a Kripke model with a distinguished point. Bisimulations between pointed models are ordinary bisimulations which relate the distinguished points. Barwise and Moss proved that for every pointed graph (X, x), there is a single sentence $\phi_{X,x}$ which characterizes (X, x) in the sense that for all (Y, y), $(Y, y) \models \phi_{X,x}$ iff (Y, y) is bisimilar to (X, x). The countable case of the Barwise-Moss result had been proved earlier in [249]. It also has roots in infinitary model theory: the Scott sentences there are essentially the same as the characterizing sentences for modal logic. The reason why these results are of interest in non-well-founded set theory is that one way to think about non-well-founded sets is as equivalence classes of pointed models, where the equivalence relation is just the maximum bisimulation. Incidentally, the presence of atomic sentences in the various modal logics then corresponds to the presence of *urelements* in the various set theories.

Viewing the canonical model as a structure for set theory will not give anything like a model of standard ZF because it would have a universal set. However, one can use the

model to obtain a new set theory. This is what Baltag did in [39, 40]. His system STS (Structural Theory of Sets) contains a strengthening of Aczel's AFA axiom, expressed in terms of modal descriptions. Baltag's axiom SAFA, Super-Antifoundation, implies that every maximally consistent class in the infinitary modal logic characterizes some set. STS also has applications to paradoxes and to the 'large/small' distinction in set theory.

Fitting and Smullyan's book [94] is a development of forcing used in independence results, presented in the language of modal logic. The authors use modal terms to explicate many of the combinatorial issues in forcing. Forcing is not usually presented in this way, although it seems quite natural to do so, and they explore a number of affinities between modal logic and forcing.

The paper [58] by Blass presents a set theoretical interpretation of possibility and necessity, based on infinite combinatorics. This is set theoretically meaty, and the focus is on consistency results for infinite combinatorics.

Hamkins' paper [127] introduces the forcing interpretation of modal logic. The focus of the paper, however, is on the Maximality Principle, and it does not use much modal logic beyond observing that the Maximality Principle is equivalent to S5 under the forcing interpretation. The Ph.D. dissertation of Hamkins' student Leibman [175] explores the forcing interpretation of modal logic a bit further. In a recent paper [128] by Hamkins and Löwe, it was proved that the ZFC-provable modal validities for this interpretation are exactly S4.2. There are a large number of open questions in this area.

ACKNOWLEDGEMENTS

We would like to thank Lev Beklemishev, Guram Bezhanishvili, Silvio Ghilardi, Valentin Goranko, Evan Goris, Joel Hamkins, Giorgi Japaridze, Roman Kontchakov, Larry Moss, Elena Nogina, Valentin Shehtman, Johan van Benthem, Rineke Verbrugge, and Michael Zakharyaschev for many valuable suggestions and contributions. Special thanks to Karen Kletter for proofreading and editing this paper.

1 INTRODUCTION

This chapter describes an automata-theoretic approach to temporal reasoning. The basic idea underlying this approach is that for any temporal formula we can construct a finite-state automaton that accepts the computations that satisfy the formula. For linear temporal logics the automaton runs on infinite words while for branching temporal logics the automaton runs on infinite trees. The simple combinatorial structures that emerge from the automata-theoretic approach decouple the logical and algorithmic components of temporal reasoning and yield clear and asymptotically optimal algorithms.

Temporal logics, which are modal logics geared towards the description of the temporal ordering of events, have been adopted as a powerful tool for specifying behavior concurrent programs and for verifying that such programs meet their specifications [47, 57]. One of the most significant developments in this area is the discovery of algorithmic methods for verifying temporal logic properties of *finite-state* programs [15, 44, 60, 81].

(A state of a program is a complete description of its status, including the assignment of values to variables, the value of the program counter, which points to the instruction currently being executed, and the like. Finite-state programs have finitely many possible states, which means that the variables range over finite domains and recursion, if allowed, is bounded in depth.) This derives its significance from the fact that many synchronization, coordination and communication protocols can be modeled as finite-state programs [46, 63]. Finite-state programs can be modeled by transition systems where each state has a bounded description, and hence can be characterized by a fixed number of Boolean atomic propositions. This means that a finite-state program can be viewed as a finite *propositional Kripke structure* and that its properties can be specified using *propositional* temporal logic. Thus, to verify the correctness of the program with respect to a desired behavior, one only has to check that the program, modeled as a finite Kripke structure, is a model of (satisfies) the propositional temporal logic formula that specifies that behavior. Hence the name *model checking* for the verification methods derived from this viewpoint. An extensive survey of model checking can be found in [16, 37]. Model checking is an *algorithmic* approach to program verification. It is different from the *deductive approach*, in which in which a person, perhaps aided by computers, use deductive techniques to prove that a program satisfy its specification [48].

We distinguish between two types of temporal logics: linear and branching (see [43] and general discussion of temporal structures in Chapter 11 of this handbook). In linear temporal logics, each moment in time has a unique possible future, while in branching temporal logics, each moment in time may split into several possible futures. (For an extensive discussion of various temporal logics, see [22].) For both types of temporal logics, a close and fruitful connection with the theory of automata on infinite structures has been developed. The basic idea is to associate with each temporal logic formula a finite automaton on infinite structures that accepts the computations that satisfy the formula. For linear temporal logic the structures are infinite words [66, 45, 68, 83], while for branching temporal logic the structures are infinite trees [30, 69, 21, 26, 82]. This enables the reduction of temporal logic decision problems, such as satisfiability and model checking, to known automata-theoretic problems, such as nonemptiness, yielding clean and asymptotically optimal algorithms. This reduction is the subject matter of this chapter. (See also Chapter 11 for a general discussion of temporal reasoning and Chapters 4 and 7 for discussions of modal reasoning.)

Initially, the translations in the literature from temporal logic formulas to automata used *nondeterministic* automata (cf. [34, 82, 83]). These translations have two disadvantages. First, the translation itself is rather nontrivial; For example, in [82, 83] the translations go through a series of ad-hoc intermediate representations in an attempt to simplify the translation. Second, for both linear and branching temporal logics there is an exponential blow-up involved in going from formulas to automata. This suggests that any algorithm that uses these translations as one of its steps is going to be an exponential-time algorithm. Thus, the automata-theoretic approach did not seem to be applicable to branching-time model checking, which in many cases can be done in linear execution time [15, 17, 60].

In the mid 1990s, it was shown that if one uses *alternating* automata rather than *nondeterministic* automata, then these problems can be addressed [42, 74]. Alternating automata generalize the standard notion of nondeterministic automata by allowing several successor states to go down along the same word or the same branch of the tree. In

this chapter we argue that *alternating automata* offer the key to a comprehensive and satisfactory automata-theoretic framework for temporal logics. We demonstrate this claim by showing how alternating automata can be used to derive model-checking and satisfiability algorithms for both linear and branching temporal logics. The key observation is that while the translation from temporal logic formulas to nondeterministic automata is exponential [82, 83], the translation to alternating automata is linear [27, 42, 53, 74]. Thus, the advantage of alternating automata is that they enable one to decouple the logic from the combinatorics. The translations from formulas to automata handle the logic, and the algorithms that handle the automata handles the combinatorics.

Historical Note: The connection between logic and automata goes back to work in the early 1960s [6, 20, 73] on monadic second-order logic and automata over finite words. This was extended in [7] to infinite words, in [19, 72] to finite trees, and in [61] to infinite trees. As temporal logics can be expressed in first-order or monadic second-order logic [38, 35], the connection between monadic second-order logic and automata yields a connection between temporal logics and automata. Developing decision procedures that go via monadic second-order logic was a standard approach in the 1970s, see [33]. A direct translation to automata was proposed first in [70] in the context of propositional dynamic logic. A direct translation from temporal logic to automata was first given in [85] (see also [83] for linear time and in [80] for branching time). The translation to alternating automata was first proposed in [53] and pursued further in [42, 74, 75].

2 AUTOMATA THEORY

2.1 Words and Trees

We are given a finite nonempty alphabet Σ. A *finite word* is an element of Σ^*, i.e., a finite sequence $a_0, \ldots, a_n$ of symbols from Σ. An *infinite word* is an element of Σ^ω, i.e., an infinite sequence $a_0, a_1, \ldots$ of symbols from Σ.

A *tree* is a (finite or infinite) connected directed graph, with one node designated as the *root* and denoted by ε, and in which every non-root node has a unique parent (s is the *parent* of t and t is a *child* of s if there is an edge from s to t) and the root ε has no parent. The *arity* of a node x in a tree τ, denoted $arity(x)$, is the number of children of x in τ. The *level* of a node x, denoted $|x|$, is its distance from the root; in particular, $|\varepsilon| = 0$. Let N denote the set of positive integers. A *tree* τ *over* N is a subset of N^*, such that if $x \cdot i \in \tau$, where $x \in N^*$ and $i \in N$, then $x \in \tau$, there is an edge from x to $x \cdot i$, and if $i > 1$ then also $x \cdot (i-1) \in \tau$. By definition, the empty sequence ε is the root of such a tree. Let $\mathcal{D} \subseteq N$. We say that a tree τ is a $\mathcal{D}$*-tree* if τ is a tree over N and $arity(x) \in \mathcal{D}$ for all $x \in \tau$. A tree is called *leafless* if every node has at least one child.

A *branch* $\beta = x_0, x_1, \ldots$ of a tree is a maximal sequence of nodes such that x_0 is the root and x_i is the parent of x_{i+1} for all $i > 0$. Note that β can be finite or infinite; if it is finite, then the last node of the branch has no children. A Σ*-labeled tree*, for a finite alphabet Σ, is a pair $(\tau, \mathcal{T})$, where τ is a tree and $\mathcal{T}$ is a mapping $\mathcal{T} : nodes(\tau) \rightarrow \Sigma$ that assigns to every node a label. We often refer to $\mathcal{T}$ as the labeled tree, leaving its domain implicit. A branch $\beta = x_0, x_1, \ldots$ of $\mathcal{T}$ defines a word $\mathcal{T}(\beta) = \mathcal{T}(x_0), \mathcal{T}(x_1), \ldots$ consisting of the sequence of labels along the branch.

2.2 Nondeterministic Automata on Infinite Words

A *nondeterministic Büchi automaton* A on words is a tuple $(\Sigma, S, S^0, \rho, F)$, where Σ is a finite nonempty *alphabet*, S is a finite nonempty set of *states*, $S^0 \subseteq S$ is the set of *initial* states, $F \subseteq S$ is the set of *accepting* states, and $\rho : S \times \Sigma \to 2^S$ is a *transition function.* Intuitively, $\rho(s, a)$ is the set of states that A can move into when it is in state s and it reads the symbol a. Note that the automaton may be nondeterministic, since it may have many initial states and the transition function may specify many possible transitions for each state and symbol.

A run r of A on an infinite word $w = a_0, a_1, \ldots$ over Σ is a sequence $s_0, s_1, \ldots$, where $s_0 \in S^0$ and $s_{i+1} \in \rho(s_i, a_i)$, for all $i \geq 0$. We define $\lim(r)$ to be the set $\{s \,|\, s = s_i \text{ for infinitely many } i\text{'s}\}$, i.e., the set of states that occur in r infinitely often. Since S is finite, $\lim(r)$ is necessarily nonempty. The run r is *accepting* if there is some accepting state that repeats in r infinitely often, i.e., $\lim(r) \cap F \neq \emptyset$. The infinite word w is *accepted* by A if there is an accepting run of A on w. The set of infinite words accepted by A is denoted $L_\omega(A)$.

An important feature of nondeterministic Büchi automata is their closure under intersection.

PROPOSITION 1. [12] *Let A_1 and A_2 be nondeterministic Büchi automata with n_1 and n_2 states, respectively. Then there is a Büchi automaton A with $O(n_1 n_2)$ states such that $L_\omega(A) = L_\omega(A_1) \cap L_\omega(A_2)$.*

One of the most fundamental algorithmic issues in automata theory is testing whether a given automaton is "interesting", i.e., whether it accepts some input. A Büchi automaton A is *nonempty* if $L_\omega(A) \neq \emptyset$. The *nonemptiness problem* for automata is to decide, given an automaton A, whether A is nonempty. It turns out that testing nonemptiness for Büchi automata is easy A accepts some word iff in the graph $G_A = (S, E_A)$, where $E_A = \{(s,t) | t \in \rho(s,a) \text{ for some } a \in \Sigma\}$, there is a path from S_0 that reaches some state $f \in F$ and then cycles back to f. This can be checked using depth-first search [71] or space-efficient search [65].

PROPOSITION 2.

1. [29, 28] *The nonemptiness problem for nondeterministic Büchi automata is decidable in linear time.*

2. [83] *The nonemptiness problem for nondeterministic Büchi automata of size n is decidable in space $O(\log^2 n)$.*

2.3 Alternating Automata on Infinite Words

Nondeterminism gives a computing device the power of existential choice. Its dual gives a computing device the power of universal choice. It is therefore natural to consider computing devices that have the power of both existential choice and universal choice. Such devices are called *alternating.* Alternation was studied in [11] in the context of Turing machines and in [5, 11] for finite automata. The alternation formalisms in [5] and [11] are different, though equivalent. We follow here the formalism of [5], which was extended in [55] to automata on infinite structures.

For a given set X, let $\mathcal{B}^+(X)$ be the set of positive Boolean formulas over X (i.e., Boolean formulas built from elements in X using $\wedge$ and $\vee$), where we also allow the formulas **true** and **false**. Let $Y \subseteq X$. We say that Y *satisfies* a formula $\theta \in \mathcal{B}^+(X)$ if the truth assignment that assigns *true* to the members of Y and assigns *false* to the members of $X - Y$ satisfes θ. For example, the sets $\{s_1, s_3\}$ and $\{s_1, s_4\}$ both satisfy the formula $(s_1 \vee s_2) \wedge (s_3 \vee s_4)$, while the set $\{s_1, s_2\}$ does not satisfy this formula.

Consider a nondeterministic automaton $A = (\Sigma, S, s^0, \rho, F)$. The transition function ρ maps a state $s \in S$ and an input symbol $a \in \Sigma$ to a set of states. Each element in this set is a possible nondeterministic choice for the automaton's next state. We can represent ρ using $\mathcal{B}^+(S)$; for example, $\rho(s, a) = \{s_1, s_2, s_3\}$ can be written as $\rho(s, a) = s_1 \vee s_2 \vee s_3$. In alternating automata, $\rho(s, a)$ can be an arbitrary formula from $\mathcal{B}^+(S)$. We can have, for instance, a transition

$$\rho(s, a) = (s_1 \wedge s_2) \vee (s_3 \wedge s_4),$$

meaning that the automaton accepts the word aw, where a is a symbol and w is a word, when it is in the state s if it accepts the word w from both s_1 and s_2 or from both s_3 and s_4. Thus, such a transition combines the features of existential choice (the disjunction in the formula) and universal choice (the conjunctions in the formula).

Formally, an *alternating Büchi automaton* is a tuple $A = (\Sigma, S, s^0, \rho, F)$, where Σ is a finite nonempty alphabet, S is a finite nonempty set of states, $s^0 \in S$ is an initial state, F is a set of accepting states, and $\rho : S \times \Sigma \rightarrow \mathcal{B}^+(S)$ is a transition function. As a convention, if $\rho(s, a)$ is not specified, we assume that it is **false**.

Because of the universal choice in alternating transitions, a run of an alternating automaton is a tree rather than a sequence. A run of A on an infinite word $w = a_0 a_1 \ldots$ is an S-labeled tree r such that $r(\varepsilon) = s^0$ and the following holds:

> if $|x| = i$, $r(x) = s$, and $\rho(s, a_i) = \theta$, then x has k children $x_1, \ldots, x_k$, for some $k \leq |S|$, and $\{r(x_1), \ldots, r(x_k)\}$ satisfies θ.

For example, if $\rho(s_0, a_0)$ is $(s_1 \vee s_2) \wedge (s_3 \vee s_4)$, then the nodes of the run tree at level 1 include the label s_1 or the label s_2 and also include the label s_3 or the label s_4. Note that the run can also have finite branches; if $|x| = i$, $r(x) = s$, and $\rho(s, a_i) = \mathbf{true}$, then x does not need to have any children. On the other hand, we cannot have $\rho(s, a_i) = \mathbf{false}$, since **false** is not satisfiable. The run is *accepting* if $\lim(r(\beta)) \cap F \neq \emptyset$ for every branch $\beta = x_0, x_1, \ldots$ of the run. that is, for every infinite branch $\beta = x_0, x_1, \ldots$, we have that $r(x_i) \in F$ for infinitely many i's. A word w is accepted by A is A has an accepting run on w.

What is the relationship between alternating Büchi automata and nondeterministic Büchi automata? It is easy to see that alternating Büchi automata generalize nondeterministic Büchi automata; nondeterministic automata correspond to alternating automata where the transitions are pure disjunctions. It turns out that they have the same expressive power (although alternating Büchi automata are more succinct than nondeterministic Büchi automata).

PROPOSITION 3. [51] *Let A be an alternating Büchi automaton with n states. Then there is a nondeterministic Büchi automaton A_{nd} with 3^n states such that $L_\omega(A_{nd}) = L_\omega(A)$.*

By combining Propositions 2 and 3 (with its exponential blowup), we can obtain a nonemptiness test for alternating Büchi automata.

PROPOSITION 4.

1. *The nonemptiness problem for alternating Büchi automata is decidable in exponential time.*

2. *The nonemptiness problem for alternating Büchi automata is decidable in quadratic space.*

2.4 Nondeterministic Automata on Infinite Trees

We now consider automata on labeled leafless $\mathcal{D}$-trees. A *nondeterministic Büchi tree automaton* A is a tuple $(\Sigma, \mathcal{D}, S, S^0, \rho, F)$. Here Σ is a finite alphabet, $\mathcal{D} \subset N$ is a finite set of arities, S is a finite set of states, $S^0 \subseteq S$ is the set of initial states, $F \subseteq S$ is a set of accepting states, and $\rho : S \times \Sigma \times \mathcal{D} \to 2^{S^*}$ is a transition function, where $\rho(s, a, k) \subseteq S^k$ for each $s \in S$, $a \in \Sigma$, and $k \in \mathcal{D}$. Thus, $\rho(s, a, k)$ is a set of k-tuples of states. Intuitively, when the automaton is in state s and it is reading a k-ary node x of a tree $\mathcal{T}$, it nondeterministically chooses a k-tuple $\langle s_1, \ldots, s_k\rangle$ in $\rho(s, \mathcal{T}(x))$, makes k copies of itself, and then moves to the node $x \cdot i$ in the state s_i for $i = 1, \ldots, k$. A *run* $r : \tau \to S$ of A on a Σ-labeled $\mathcal{D}$-tree $\mathcal{T}$ is an S-labeled $\mathcal{D}$-tree such that the root is labeled by an initial state and the transitions obey the transition function ρ; that is, $r(\varepsilon) \in S^0$, and for each node x such that $arity(x) = k$, we have $\langle r(x \cdot 1), \ldots, r(x \cdot k)\rangle \in \rho(r(x), \mathcal{T}(x), k)$. The run is *accepting* if $\lim(r(\beta)) \cap F \neq \emptyset$ for every branch $\beta = x_0, x_1, \ldots$ of τ; that is, for every branch $\beta = x_0, x_1, \ldots$, we have that $r(x_i) \in F$ for infinitely many i's. The set of trees accepted by A is denoted $T_\omega(A)$. It is easy to see that nondeterministic Büchi automata on infinite words are essentially Büchi automata on $\{1\}$-trees.

Again, a key issue is testing emptiness.

PROPOSITION 5. [62, 82] *The nonemptiness problem for nondeterministic Büchi tree automata is decidable in quadratic time.*

2.5 Alternating Automata on Infinite Trees

An *alternating Büchi tree automaton* A is a tuple $(\Sigma, \mathcal{D}, S, s^0, \rho, F)$. Here Σ is a finite alphabet, $\mathcal{D} \subset N$ is a finite set of arities, S is a finite set of states, $s^0 \in S$ is an initial state, $F \subseteq S$ is a set of accepting states, and $\rho : S \times \Sigma \times \mathcal{D} \to \mathcal{B}^+(N \times S)$ is a partial transition function, where $\rho(s, a, k) \in \mathcal{B}^+(\{1, \ldots, k\} \times S)$ for each $s \in S$, $a \in \Sigma$, and $k \in \mathcal{D}$ such that $\rho(s, a, k)$ is defined. For example, $\rho(s, a, 2) = ((1, s_1) \vee (2, s_2)) \wedge ((1, s_3) \vee (2, s_1))$ means that the automaton can choose between four splitting possibilities. In the first possibility, one copy proceeds in direction 1 in the state s_1 and one copy proceeds in direction 1 in the state s_3. In the second possibility, one copy proceeds in direction 1 in the state s_1 and one copy proceeds in direction 2 in the state s_1. In the third possibility, one copy proceeds in direction 2 in the state s_2 and one copy proceeds in direction 1 in the state s_3. Finally, in the fourth possibility, one copy proceeds in direction 2 in the state s_2 and one copy proceeds in direction 2 in the state s_1. Note that it is possible for more than one copy to proceed in the same direction.

A run r of an alternating Büchi tree automaton A on a Σ-labeled leafless $\mathcal{D}$-tree $\langle \tau, \mathcal{T}\rangle$ is a $\tau \times S$-labeled tree. Each node of r corresponds to a node of τ. A node in r, labeled by (x, s), describes a copy of the automaton that reads the node x of τ in the state s.

Note that many nodes of r can correspond to the same node of τ; in contrast, in a run of a nondeterministic automaton on $\langle \tau, \mathcal{T} \rangle$ there is a one-to-one correspondence between the nodes of the run and the nodes of the tree. The labels of a node and its children have to satisfy the transition function. Formally, r is a Σ_r-labeled tree $\langle \tau_r, \mathcal{T}_r \rangle$ where $\Sigma_r = \tau \times S$ and $\langle \tau_r, \mathcal{T}_r \rangle$ satisfies the following:

1. $\mathcal{T}_r(\varepsilon) = (\varepsilon, s^0)$.

2. Let $y \in \tau_r$, $\mathcal{T}_r(y) = (x, s)$, $arity(x) = k$, and $\rho(s, \mathcal{T}(x), k) = \theta$. Then there is a set $Q = \{(c_1, s_1), (c_1, s_1), \ldots, (c_n, s_n)\} \subseteq \{1, \ldots, k\} \times S$ such that

   - Q satisfies θ, and
   - for all $1 \leq i \leq n$, we have $y \cdot i \in \tau_r$ and $\mathcal{T}_r(y \cdot i) = (x \cdot c_i, s_i)$.

For example, if $\langle \tau, \mathcal{T} \rangle$ is a tree with $arity(\varepsilon) = 2$, $\mathcal{T}(\varepsilon) = a$ and $\rho(s^0, a) = ((1, s_1) \vee (1, s_2)) \wedge ((1, s_3) \vee (1, s_1))$, then the nodes of $\langle \tau_r, \mathcal{T}_r \rangle$ at level 1 include the label $(1, s_1)$ or $(1, s_2)$, and include the label $(1, s_3)$ or $(1, s_1)$.

As with alternating Büchi automata on words, alternating Büchi tree automata are as expressive as nondeterministic Büchi tree automata.

PROPOSITION 6. [52, 56] *Let A be an alternating Büchi tree automaton with n states. Then there is a nondeterministic Büchi tree automaton A_n with 3^n states such that $T_\omega(A_n) = T_\omega(A)$.*

By combining Propositions 5 and 6 (with its exponential blowup), we can obtain a nonemptiness test for alternating Büchi tree automata.

PROPOSITION 7. *The nonemptiness problem for alternating Büchi tree automata is decidable in exponential time.*

Does the size of the alphabet affect the complexity of the nonemptiness problem? For nondeterministic tree automata, the nonemptiness problem is reducible to the 1-letter nonemptiness problem, that is, to the nonemptiness problem for nondeterministic tree automata over 1-letter alphabets (i.e., $|\Sigma| = 1$). Indeed, instead checking the nonemptiness of an automaton $A = (\Sigma, \mathcal{D}, S, S^0, \rho, F)$, one can check the nonemptiness of the automaton $A' = (\{a\}, \mathcal{D}, S, S^0, \rho', F)$ where for all $s \in S$, we have $\rho'(s, a, k) = \bigcup_{a \in \Sigma} \rho(s, a, k)$. It is easy to see that A accepts some tree iff A' accepts some a-labeled tree. This can be viewed as if A' first guesses a Σ-labeling for the input tree and then proceeds like A on this Σ-labeled tree.

This reduction is not valid for alternating tree automata. Suppose that we defined A' by taking $\rho'(s, a, k) = \bigvee_{a \in \Sigma} \rho(s, a, k)$. Then, if A' accepts some a-labeled tree, it still does not guarantee that A accepts some tree. A necessary condition for the validity of the reduction is that different copies of A' that run on the same subtree guess the same Σ-labeling for this subtree. Nothing, however, prevents one copy of A' to proceed according to one labeling and another copy to proceed according to a different labeling. This problem does not occur when A is defined over a singleton alphabet. There, it is guaranteed that all copies proceed according to the same (single) labeling.

As we see later, in our applications we sometimes do have 1-letter alphabets, which makes the 1-letter nonemptiness problem for alternating automata of interest. It turns out that this problem is easier than the general nonemptiness problem. Actually, it is

as easy as the nonemptiness problem for nondeterministic Büchi tree automata (Proposition 5). This result requires also *uniformity*, i.e., $|\mathcal{D}| = 1$.

PROPOSITION 8. [42] *The 1-letter nonemptiness problem for uniform alternating Büchi tree automata is decidable in quadratic time.*

As we shall see later, the alternating automata in our applications have a special structure, studied first in [54]. A *weak alternating tree automaton* (WAA) is an alternating Büchi tree automaton in which there exists a partition of the state set S into disjoint sets $S_1, \ldots, S_n$ such that for each set S_i, either $S_i \subseteq F$, in which case S_i is an *accepting set*, or $S_i \cap F = \emptyset$, in which case S_i is a *rejecting set*. In addition, there exists a partial order $\leq$ on the collection of the S_i's such that for every $s \in S_i$ and $s' \in S_j$ for which s' occurs in $\rho(s, a, k)$, for some $a \in \Sigma$ and $k \in \mathcal{D}$, we have $S_j \leq S_i$. Thus, transitions from a state in S_i lead to states in either the same S_i or a lower one. It follows that every infinite path of a run of a WAA ultimately gets "trapped" within some S_i. The path then satisfies the acceptance condition if and only if S_i is an accepting set. That is, a run visits infinitely many states in F if and only if it gets trapped in an accepting set. The number of sets in the partition of S is defined as the *depth* of the automaton.

It turns out that the nonemptiness problem for WAA on 1-letter alphabets is easier than nonemptiness problem for alternating Büchi automata on 1-letter alphabets.

PROPOSITION 9. [42] *The 1-letter nonemptiness problem for uniform weak alternating tree automata is decidable in linear time.*

As we shall see, the WAA that we use have an even more special structure. In these WAA, each set S_i can be classified as either *transient*, *existential*, or *universal*, such that for each set S_i and for all $s \in Q_i$, $a \in \Sigma$, and $k \in \mathcal{D}$, the following hold:

1. If S_i is transient, then $\rho(s, a, k)$ contains no elements of S_i.
2. If S_i is existential, then $\rho(s, a, k)$ only contains *disjunctively related* elements of S_i (i.e. if the transition is rewritten in disjunctive normal form, there is at most one element of S_i in each disjunct).
3. If Q_i is universal, then $\rho(s, a, k)$ only contains *conjunctively related* elements of S_i (i.e. if the transition is rewritten in conjunctive normal form, there is at most one element of Q_i in each conjunct).

This means that it is only when moving from one S_i to the next, that alternation actually occurs (alternation is moving from a state that is conjunctively related to states in its set to a state that is disjunctively related to states in its set, or vice-versa). In other words, when a copy of the automaton visits a state in some existential set S_i, then as long as it stays in this set, it proceeds in an "existential mode"; namely, it imposes only existential requirement on its successors in S_i. Similarly, when a copy of the automaton visits a state in some universal set S_i, then as long as it stays in this set, it proceeds in a "universal mode". Thus, whenever a copy alternates modes, it must be that it moves from one S_i to the next. We call a WAA that satisfies this property a *limited-alternation*[1] WAA.

PROPOSITION 10. [42] *The 1-letter nonemptiness problem for uniform limited-alternation WAA of size n and depth m can be solved in space $O(m \log^2 n)$.*

[1]The term used in [42] is *hesitant*.

3 TEMPORAL LOGICS AND ALTERNATING AUTOMATA

3.1 Linear Temporal Logic

Formulas of *linear temporal logic* (LTL) are built from a set *Prop* of atomic propositions and are closed under the application of Boolean connectives, the unary temporal connective X (*next*), and the binary temporal connectives U (*until*) and R (*release*) [22]. LTL is interpreted over *computations.* A computation is a function $\pi : \omega \to 2^{Prop}$, which assigns truth values to the elements of *Prop* at each time instant (natural number). (This corresponds to using the ordered natural numbers as the frame; see Chapter 11). A computation π and a point $i \in \omega$ satisfies an LTL formula φ, denoted $\pi, i \models \varphi$, under the following conditions:

- $\pi, i \models p$ for $p \in Prop$ iff $p \in \pi(i)$.
- $\pi, i \models \xi \wedge \psi$ iff $\pi, i \models \xi$ and $\pi, i \models \psi$.
- $\pi, i \models \neg\varphi$ iff not $\pi, i \models \varphi$
- $\pi, i \models X\varphi$ iff $\pi, i+1 \models \varphi$.
- $\pi, i \models \xi U \psi$ iff for some $j \geq i$, we have $\pi, j \models \psi$ and for all k, $i \leq k < j$, we have $\pi, k \models \xi$.[2]
- $\pi, i \models \xi R \psi$ iff for all $j \geq i$, if $\pi, j \not\models \psi$, then for some k, $i \leq k < j$, we have $\pi, k \models \xi$.

Note that $\neg(X\varphi)$ is equivalent to $X(\neg\varphi)$ and $\neg(\xi U \psi)$ is equivalent to $(\neg\xi) R \psi$. This implies that we can assume that formulas are in *positive normal form*, in which negations are applied only to atomic propositions. This normal form is obtained by pushing negations inward as far as possible, using De Morgan's laws and dualities as above. For example, the formula $G(\neg\mathsf{request} \vee (\mathsf{request} U \mathsf{grant}))$ says that whenever a request is made it holds continuously until it is eventually granted. We say that π *satisfies* a formula φ, denoted $\pi \models \varphi$, iff $\pi, 0 \models \varphi$.

Computations can also be viewed as infinite words over the alphabet 2^{Prop}. It turns out that the computations satisfying a given formula are exactly those accepted by some finite automaton on infinite words. The following theorem establishes a very simple translation between LTL and alternating Büchi automata on infinite words.

THEOREM 11. [53, 74] *Given an LTL formula φ, one can build an alternating Büchi automaton $A_\varphi = (\Sigma, S, s^0, \rho, F)$, where $\Sigma = 2^{Prop}$ and $|S|$ is in $O(|\varphi|)$, such that $L_\omega(A_\varphi)$ is exactly the set of computations satisfying the formula φ.*

Proof. The set S of states consists of all subformulas of φ. The initial state s^0 is φ itself. The set F of accepting states consists of all formulas in S of the form $(\xi R \psi)$. It remains to define the transition function ρ.

- $\rho(p, a) = \mathbf{true}$ if $p \in a$,
- $\rho(\neg p, a) = \mathbf{true}$ if $p \notin a$,

[2]Note that our U operator is not strict; cf. Chapter 11.

- $\rho(p, a) = \mathbf{false}$ if $p \notin a$,
- $\rho(\neg p, a) = \mathbf{false}$ if $p \in a$,
- $\rho(\xi \wedge \psi, a) = \rho(\xi, a) \wedge \rho(\psi, a)$,
- $\rho(\xi \vee \psi, a) = \rho(\xi, a) \vee \rho(\psi, a)$,
- $\rho(X\psi, a) = \psi$,
- $\rho(\xi U \psi, a) = \rho(\psi, a) \vee (\rho(\xi, a) \wedge \xi U \psi)$.
- $\rho(\xi R \psi, a) = \rho(\psi, a) \wedge (\rho(\xi, a) \vee \xi R \psi)$.

❑

By applying Proposition 3, we now get:

COROLLARY 12. [83] *Given an LTL formula φ, one can build a nondeterministic Büchi automaton $A_\varphi = (\Sigma, S, s^0, \rho, F)$, where $\Sigma = 2^{Prop}$ and $|S|$ is in $2^{O(|\varphi|)}$, such that $L_\omega(A_\varphi)$ is exactly the set of computations satisfying the formula φ.*

For a description of optimized translations from LTL to automata, seefor example, [32]. While our focus here is on LTL, the automata-theoretic approach applies also to more expressive, recent industrial specification languages such as ForSpec [2]; see [1, 10].

3.2 Branching Temporal Logic

The branching temporal logic CTL (Computation Tree Logic) provides temporal connectives that are composed of a path quantifier immediately followed by a single linear temporal connective [22]. The path quantifiers are A ("for all paths") and E ("for some path"). The linear-time connectives are X, U, and R. Thus, given a set $Prop$ of atomic propositions, a CTL formula in positive normal form is one of the following:

- p or $\neg p$, for all $p \in AP$,
- $\xi \wedge \psi$ or $\xi \vee \psi$, where ξ and ψ are CTL formulas.
- $EX\xi$, $AX\xi$, $E(\xi U \psi)$, $A(\xi U \psi)$, $E(\xi R \psi)$, or $A(\xi R \psi)$, where ξ and ψ are CTL formulas.

The semantics of CTL is defined with respect to *programs*. A program over a set $Prop$ of atomic propositions is a structure of the form $P = (W, w^0, R, V)$, where W is a set of states, $w^0 \in W$ is an initial state, $R \subseteq W^2$ is a total accessibility relation (i.e., every state can access at least one state), and $V : W \rightarrow 2^{Prop}$ assigns truth values to propositions in $Prop$ for each state in W. The intuition is that W describes all the states that the program could be in (where a state includes the content of the memory, registers, buffers, program counter, etc.), R describes all the possible transitions between states (allowing for nondeterminism), and V relates the states to the propositions (e.g., it tells us in what states the proposition `request` is true); see [47] for a discussion on modelling programs. The assumption that R is total (i.e., that every state has an R-successor) is for technical convenience. We can view a terminated execution as repeating forever its last state. We

say that P is a *finite-state* program if W is finite. A *path* in P is a sequence of states, $\mathbf{u} = u_0, u_1, \ldots$ such that for every $i \geq 0$, we have that $u_i R u_{i+1}$ holds. Such a path is called a u_0-path.

A program $P = (W, w^0, R, V)$ and a state $u \in W$ satisfies a CTL formula φ, denoted $P, u \models \varphi$, under the following conditions:

- $P, u \models p$ for $p \in Prop$ if $p \in V(u)$.
- $P, u \models \neg p$ for $p \in Prop$ if $p \notin V(u)$.
- $P, u \models \xi \wedge \psi$ iff $P, u \models \xi$ and $P, u \models \psi$.
- $P, u \models \xi \vee \psi$ iff $P, u \models \xi$ or $P, u \models \psi$.
- $P, u \models EX\varphi$ if $P, v \models \varphi$ for some v such that uRv holds.
- $P, u \models AX\varphi$ if $P, v \models \varphi$ for all v such that uRv holds.
- $P, u \models E(\xi U \psi)$ if there exist a u-path π such that $\pi, 0 \models \xi U \psi$.
- $P, u \models A(\xi U \psi)$ if for every u-path π we have $\pi, 0 \models \xi U \psi$.
- $P, u \models E(\xi R \psi)$ if there exist a u-path π such that $\pi, 0 \models \xi R \psi$.
- $P, u \models A(\xi R \psi)$ if for every u-path π we have $\pi, 0 \models \xi R \psi$.

For example, the formula $AG(\mathsf{request} \rightarrow EF\mathsf{grant})$ says that whenever a request is made it is eventually granted in some possible future. We say that p satisfies φ, denoted $P \models \varphi$, if $P, w^0 \models \varphi$.

A program $P = (W, w^0, R, V)$ is a *tree program* if (W, R) is a tree and w^0 is its root. Note that in this case P is a leafless 2^{Prop}-labeled tree (it is leafless, since R is total). P is a $\mathcal{D}$-tree program, for $\mathcal{D} \subset N$, if (W, R) is a $\mathcal{D}$-tree. It turns out that the tree programs satisfying a given formula are exactly those accepted by some finite tree automaton. The following theorem establishes a very simple translation between CTL and weak alternating Büchi tree automata.

THEOREM 13. [42, 53] *Given a CTL formula φ and a finite set $\mathcal{D} \subset N$, one can build a limited-alternation WAA $A_\varphi = (\Sigma, \mathcal{D}, S, s^0, \rho, F)$, where $\Sigma = 2^{Prop}$ and $|S|$ is in $O(|\varphi|)$, such that $T_\omega(A_\varphi)$ is exactly the set of $\mathcal{D}$-tree programs satisfying φ.*

Proof. The set S of states consists of all subformulas of φ. The initial state s^0 is φ itself. The set F of accepting states consists of all formulas in S of the form $E(\xi R \psi)$ and $A(\xi R \psi)$. It remains to define the transition function ρ. In the following definition we use the notion of dual, defined in the proof of Theorem 11.

- $\rho(p, a, k) = \mathbf{true}$ if $p \in a$.
- $\rho(\neg p, a, k) = \mathbf{true}$ if $p \notin a$.
- $\rho(p, a, k) = \mathbf{false}$ if $p \notin a$.
- $\rho(\neg p, a, k) = \mathbf{false}$ if $p \in a$.
- $\rho(\xi \wedge \psi, a, k) = \rho(\xi, a, k) \wedge \rho(\psi, a, k)$.

- $\rho(\xi \vee \psi, a, k) = \rho(\xi, a, k) \vee \rho(\psi, a, k)$.
- $\rho(EX\psi, a, k) = \bigvee_{c=0}^{k-1}(c, \psi)$.
- $\rho(AX\psi, a, k) = \bigwedge_{c=0}^{k-1}(c, \psi)$.
- $\rho(E(\xi U \psi), a, k) = \rho(\psi, a, k) \vee (\rho(\xi, a, k) \wedge \bigvee_{c=0}^{k-1}(c, E(\xi U \psi)))$.
- $\rho(A(\xi U \psi), a, k) = \rho(\psi, a, k) \vee (\rho(\xi, a, k) \wedge \bigwedge_{c=0}^{k-1}(c, A(\xi U \psi)))$.
- $\rho(E(\xi R \psi), a, k) = \rho(\psi, a, k) \wedge (\rho(\xi, a, k) \vee \bigvee_{c=0}^{k-1}(c, E(\xi R \psi)))$.
- $\rho(A(\xi U \psi), a, k) = \rho(\psi, a, k) \wedge (\rho(\xi, a, k) \vee \bigwedge_{c=0}^{k-1}(c, A(\xi U \psi)))$.

Finally, we define a partition of S into disjoint sets and a partial order over the sets. Each formula $\psi \in S$ constitutes a (singleton) set $\{\psi\}$ in the partition. The partial order is then defined by $\{\xi\} \leq \{\psi\}$ iff ξ a subformula of ψ. Here, all sets are transient, expect for sets of the form $\{E(\xi U \psi)\}$ and $\{\neg A(\xi U \psi)\}$, which are existential, and sets of the form $\{A(\xi U \psi)\}$ and $\{\neg E(\xi U \psi)\}$, which are universal. Thus, A_φ is a limited-alternation WAA. ❑

While temporal logic was introduced in both a branching-time setting and linear-time setting [59], its introduction to computer science was in a linear-time setting [57], to be followed soon by a branching-time setting [14]. The debate in the computer-science literature regarding the relative merits of the linear-time and branching-time goes back to the early 1980s [3, 13, 23, 25, 28, 43, 58, 76, 78]. For a description of earlier discussions of this distinction in the philosophical-logic literature, see [9]. For a more recent account, see [79].

4 MODEL CHECKING

In this section we focus on model checking finite-state programs. Our computational-complexity results are stated in terms of the size of the programs and the temporal properties being checked. The size $|\varphi|$ of a temporal formula φ is simply its length (as a character string). The size of a finite-state program $P = (W, w^0, R, V)$ is the size of its encoding, which is proportional to the number of states in W and the number of transitions in R. Of course, the size of P can be rather large. For example, if P is a computer circuit with n memory bits, then there are 2^n possible states. In general, the number of states of a program is at least exponential in the size of its description by means of a programing language or a hardware-description languages. This blow-up is referred to as the *state-explosion problem*. Much of the research on model checking is focused on dealing with the state-explosion problem, including on-the-fly search techniques, which search through the state space in a demand-driven fashion [36], and symbolic techniques, which represent large state spaces compactly [4]. See [16, 37] for extensive discussions.

4.1 Linear Temporal Logic

We assume that we are given a finite-state program and an LTL formula that specifies the legal computations of the program. The problem is to check whether all computations of the program are legal.

Let $\mathbf{u} = w_0, w_1 \ldots$ be a w_0-path of a finite-state program $P = (W, w^0, R, V)$. The sequence $V(w_0), V(w_1) \ldots$ is a *computation of* P (note that such a sequence can indeed be viewed as a function $\pi_{\mathbf{u}} : \omega \to 2^{Prop}$, which is how we described computations earlier). We say that P *satisfies* an LTL formula φ if *all* computations of P satisfy φ. The *LTL verification problem* is to check whether P satisfies φ.

We now describe the automata-theoretic approach to the LTL verification problem. A finite-state program $P = (W, w^0, R, V)$ can be viewed as a nondeterministic Büchi automaton $A_P = (\Sigma, W, \{w^0\}, \rho, W)$, where $\Sigma = 2^{Prop}$ and $v \in \rho(u, a)$ iff uRv holds and $a = V(u)$. As this automaton has a set of accepting states equal to the whole set of states, any infinite run of the automaton is accepting. Thus, $L_\omega(A_P)$ is the set of computations of P.

Hence, for a finite-state program P and an LTL formula φ, the verification problem is to verify that all infinite words accepted by the automaton A_P satisfy the formula φ. By Corollary 12, we know that we can build a nondeterministic Büchi automaton A_φ that accepts exactly the computations satisfying the formula φ. The verification problem thus reduces to the automata-theoretic problem of checking that all computations accepted by the automaton A_P are also accepted by the automaton A_φ, that is $L_\omega(A_P) \subseteq L_\omega(A_\varphi)$. Equivalently, we need to check that the automaton that accepts $L_\omega(A_P) \cap L_\omega(\overline{A_\varphi})$ is empty, where $L_\omega(\overline{A_\varphi}) = \overline{L_\omega(A_\varphi)} = \Sigma^\omega - L_\omega(A_\varphi)$.

First, note that, by Corollary 12, $L_\omega(\overline{A_\varphi}) = L_\omega(A_{\neg\varphi})$ and the automaton $A_{\neg\varphi}$ has $2^{O(|\varphi|)}$ states. (A straightforward approach, starting with the automaton A_φ and then complementing it, would result in a doubly exponential blow-up, since complementation of nondeterministic Büchi automata is exponential [41, 50]). To get the intersection of the two automata, we use Proposition 1. Consequently, we can build an automaton for $L_\omega(A_P) \cap L_\omega(A_{\neg\varphi})$ having $|W| \cdot 2^{O(|\varphi|)}$ states. We need to check this automaton for emptiness. Using Proposition 2, we get the following results.

THEOREM 14. [44, 67, 81] *Checking whether a finite-state program P satisfies an LTL formula φ can be done in time $O(|P| \cdot 2^{O(|\varphi|)})$ or in space $O((|\varphi| + \log |P|)^2)$.*

We note that a time upper bound that is polynomial in the size of the program and exponential in the size of the specification is considered here to be reasonable, since the specification is usually rather short [44]. For practical verification algorithms that are based on the automata-theoretic approach see [8, 18].

4.2 Branching Temporal Logic

For linear temporal logic, each program may correspond to infinitely many computations. Model checking is thus reduced to checking inclusion between the set of computations allowed by the program and the language of an automaton describing the formula. For branching temporal logic, each program corresponds to a single “computation tree”. On that account, model checking is reduced to checking acceptance of this computation tree by the automaton describing the formula.

A program $P = (W, w^0, R, V)$ can be viewed as a W-labeled tree $\langle \tau_P, \mathcal{T}_P \rangle$ that corresponds to the unwinding of P from w^0. For every node $w \in W$, let $arity(w)$ denote the number of R-successors of w and let $succ_R(w) = \langle w_1, \ldots, w_{arity(w)} \rangle$ be an ordered list of w's R-successors (we assume that the nodes of W are ordered). τ_P and $\mathcal{T}_P$ are defined inductively:

1. $\varepsilon \in \tau_P$ and $\mathcal{T}_P(\varepsilon) = w^0$.

2. For $y \in \tau_P$ with $succ_R(\mathcal{T}_P(y)) = \langle w_1, \ldots, w_k \rangle$ and for all $1 \leq i \leq k$, we have $y \cdot i \in \tau_P$ and $\mathcal{T}_P(y \cdot i) = w_i$.

Let $\mathcal{D}$ be the set of arities of states of P, i.e., $\mathcal{D} = \{arity(w) \ : \ w \in W\}$. Clearly, τ_P is a $\mathcal{D}$-tree. If P is finite, then $\mathcal{D}$ is finite.

Let $\langle \tau_P, V \cdot \mathcal{T}_P \rangle$ be the 2^{Prop}-labeled $\mathcal{D}$-tree defined by $V \cdot \mathcal{T}_P(y) = V(\mathcal{T}_P(y))$ for $y \in \tau_P$. Let φ be a CTL formula. Suppose that $A_{\mathcal{D},\varphi}$ is an alternating automaton that accepts exactly all $\mathcal{D}$-tree programs that satisfy φ. It can easily be shown that $\langle \tau_P, V \cdot \mathcal{T}_P \rangle$ is accepted by $A_{\mathcal{D},\varphi}$ iff $P \models \varphi$. We now show that by taking the product of P and $A_{\mathcal{D},\varphi}$ we get an alternating Büchi tree automaton on a 1-letter alphabet that is empty iff $\langle \tau_P, V \cdot \mathcal{T}_P \rangle$ is accepted by $A_{\mathcal{D},\varphi}$.

Let $A_{\mathcal{D},\varphi} = (2^{AP}, \mathcal{D}, S, \varphi, \rho, F)$ be a limited-alternation WAA that accepts exactly all $\mathcal{D}$-tree programs that satisfy φ, and let $S_1, \ldots, S_n$ be the partition of S. The *product automaton* of P and $A_{\mathcal{D},\varphi}$ is the limited-alternation WAA $A_{P,\varphi} = (\{a\}, \mathcal{D}, W \times S, \delta, \langle w^0, \varphi \rangle, G)$, where δ and G are defined as follows:

- Let $s \in S$, $w \in W$, $succ_R(w) = \langle w_1, \ldots, w_k \rangle$, and $\rho(s, V(w), k) = \theta$. Then $\delta(\langle w, s \rangle, a, k) = \theta'$, where θ' is obtained from θ by replacing each atom (c, s') in θ by the atom $(c, \langle w_c, s' \rangle)$.

- $G = W \times F$

- $W \times S$ is partitioned to $W \times S_1, W \times S_2, \ldots, W \times S_n$.

- $W \times S_i$ is transient (resp., existential, universal) if S_i is transient (resp., existential, universal), for $1 \leq i \leq n$.

Note that if P has m_1 states and $A_{\mathcal{D},\varphi}$ has m_2 states then $A_{P,\varphi}$ has $O(m_1 m_2)$ states.

PROPOSITION 15. *$A_{P,\varphi}$ is nonempty if and only if $P \models \varphi$.*

We can now put together Propositions 9, 10, and 15 to get a model-checking algorithm for CTL.

THEOREM 16. [15, 42] *Checking whether a finite-state program P satisfies a CTL formula φ can be done in time $O(|P| \cdot |\varphi|)$ or in space $O(|\varphi| \log^2 |P|)$.*

See also [8, 84] for description of practical algorithms. For an extension of automata-theoretic branching-time model checking to more expressive branching-time logics, such as the branching-time logic CTL*, which merges CTL and LTL and is more expressive than both [25], or the modal fixpoint logic, which is more expressive than CTL* [39], see [42].

5 VALIDITY CHECKING

5.1 Linear Temporal Logic

We are given an LTL formula φ. We say that φ is *valid* iff it is true in all computations. By Corollary 12, we know that we can build a nondeterministic Büchi automaton A_φ that accepts exactly the computations in which φ is true. In other words, φ is valid iff $L_\omega(A_\varphi) = \Sigma^\omega$, where $\Sigma = 2^{Prop}$, which holds iff $\Sigma^\omega - L_\omega(A_\varphi) = \emptyset$. Since $\Sigma^\omega - L_\omega(A_\varphi) = L_\omega(A_{\neg\varphi})$, we have that φ is valid iff $L_\omega(A_{\neg\varphi}) = \emptyset$. Thus, validity checking is been reduced to emptiness checking. We can now combine Proposition 2 with Corollary 12:

THEOREM 17. [67] *Checking whether an LTL formula φ is valid can be done in time $O(2^{O(|\varphi|)})$ or in space $O((|\varphi|)^2)$.*

We note that the upper space bound of Theorem 17 is essentially optimal, since the validity problem for LTL is PSPACE-hard [67].

5.2 Branching Temporal Logic

We are given a CTL formula φ. we say that φ is *valid* iff it is true in all programs. For LTL, Theorems 11 and 12 provided automata-theoretic characterizations of all models of the formula. This is not the case for CTL, as Theorem 13 provides only a characterization of tree models. Fortunately, this suffices for validity checking due to the following proposition.

PROPOSITION 18. [22] *Let φ be a CTL formula. Then φ is valid iff φ is true in all $|\varphi|$-tree programs.*

Let A_φ be the automaton $A_\varphi^{\{|\varphi|\}}$, i.e., it is the automaton $A_\varphi^{\mathcal{D}}$ of Theorem 13, with $\mathcal{D} = \{|\varphi|\}$. It follows from Proposition 18 that a CTL formula is valid iff $T_\omega(A_{\neg\varphi}) = \emptyset$. Combining this with Proposition 7, we get:

THEOREM 19. [24] *Checking whether a CTL formula φ is valid can be done in time $O(2^{O(|\varphi|)})$.*

We note that the upper time bound of Theorem 19 is essentially optimal, since the validity problem for CTL is EXPTIME-hard [31]. For a practical algorithm to decide CTL validity, see [49]. For extension of automata-theoretic validity checking to expressive modal logics, see [40, 64, 77].

1 INTRODUCTION

Modal logic plays an important role in the field of artificial intelligence (AI). This can be understood from the fact that AI tries to capture aspects of human intelligence by formalizing these in such a way that they can be implemented in an artificial system, particularly a computer-based system. This entails the need for formalization of mental attitudes such as beliefs and desires. In philosophical logic one has studied many of these attitudes using modal logic. Therefore it is only natural that AI researchers have resorted to modal logic for the formal description of the mental attitudes of their intended artifacts. (This is not to say that modal logic is the only way to represent these mental attitudes, since some choose to stick to classical predicate logic as closely as possible. Still, it is recognized widely within the AI community that modal logic presents a valuable tool!)

So, in this chapter we will be concerned with the use of modal logic techniques to formally describe mental attitudes of intelligent systems. We have chosen to split our

treatment into two parts. The first part deals with the use of modal logic for the description of so-called *intelligent agents*, an area of AI that emerged at the end of the 80s, dealing with the theory and practice of the construction of autonomous software or hardware entities that act intelligently (rationally). Typical issues are how to deal with motivational attitudes such as intentions and with informational attitudes such as beliefs. Special attention is paid to 'social' attitudes within a 'multi-agent system'. In such an 'agent society' it becomes important to analyze multi-agent informational and motivational attitudes such as common knowledge and collective intention.

The second part is related to this, but the topics discussed are older. An important problem in AI concerns the question as to how to formalize *commonsense reasoning*, the way humans reason 'in daily life', so to speak, as opposed to reasoning in formal sciences such as mathematics and logic. For example, here one is interested in reasoning patterns connected with defaults (rules of thumb) and counterfactuals ('if ... had been the case, then ... would have been the case'). The study of these reasoning mechanisms appeared to be much more difficult than originally anticipated, and has become a major subject of study within AI since the beginning of the 80s. It includes so-called *non-monotonic reasoning* (reasoning in which earlier conclusions can get lost when more premises become available) and *belief revision* (dealing with how the beliefs of a reasoner change when new information becomes available and is incorporated).

Of course, since also in commonsense reasoning notions such as knowledge and belief play an important role, there is a natural relation with the field of intelligent agents, but the emphasis is different. However, as artificial agents become more intelligent and will invade daily life (such as e.g. the application in so-called companion robots that are supposed to assist and entertain elderly people), undoubtedly there will be a moment where these agents should also employ some (possibly restricted) form of commonsense reasoning![1]

2 INTELLIGENT AGENTS

Intelligent agents have become a major field of research in AI. Although there is little consensus about the precise definition of an intelligent agent, it is generally held that agents are *autonomous* pieces of hardware/software, able to take initiative on behalf of a user or, more generally, to satisfy some goal. Agents are often held to possess *mental attitudes*; they are supposed to deal with information, and act upon this, based on motivation. This calls for a description in terms of the agent's beliefs/knowledge, desires, goals, intentions, commitments, obligations, etc. To describe these mental or cognitive attitudes one may fruitfully employ *modal logic*. Typically for the description of agents one needs an amalgam of modal operators/logics to cater for several of the mental attitudes as mentioned above. Moreover, since agents by definition act and display behavior, it is important to include the *dynamics* of these mental attitudes in the description. One might even maintain that the logics of some of these attitudes, such as goal directedness and *a fortiori* desire, have little interest *per se*: they are rather weak logics without exciting properties. What makes them interesting is their dynamics: their change over time in connection with each other! So, although (modal) logics for e.g. knowledge, belief,

[1]The first part (section 2–8) were written by John-Jules Meyer. Frank Veltman is responsible for part 2 (sections 9–11).

desires etc. certainly play a role, it is also imperative to be able to specify the agent's behavior / attitudes over time. Therefore, generally also a (modal) logic of time or action plays a role in agent specification logics. In this section we will first spend some time on modal logics for some of the mental attitudes in isolation, after which we will turn to agent logics proper that are proposed in the literature, which typically are mixtures of these 'single-attitude' logics and contain an element of time and/or action. Our emphasis in this part lies on the presentation of the logical languages and their semantics, and less on axiomatics and metatheory.

3 EPISTEMIC AND DOXASTIC LOGIC

Epistemic logic deals with the mental attitude of knowledge while doxastic logic treats belief. These logics have become quite popular in both computer and artificial intelligence to describe the knowledge/belief involved in (particularly distributed) computation processes and in agents. As to the former, the work of Halpern et al. [31] must be mentioned. In this chapter we concentrate on the role of epistemic/doxastic logic in AI, and on the description of intelligent agents in particular. The modal approach to knowledge/belief is built on the observation that if an agent is not sure about the truth of a certain proposition p (say that it rains outside), it must reckon both with the possibility that p holds and with the possibility that p does not hold. Formally this is captured by a Kripke model in which in the actual world, the agent considers several possible alternatives (captured by the accessibility relation), some of which satisfy p while other ones do not satisfy p. So we have a very intuitive use of modal semantics here: a formula φ is known / believed by the agent if all alternatives deemed possible by the agent (formally, all worlds accessible for the agent from the actual world) satisfy φ.

Thus, we have the following formal definitions. The language is obtained by taking classical (propositional) logic augmented by a clause for the knowledge or belief operator. We assume a set $\mathcal{P}$ of atomic formulas.

DEFINITION 1. (Language of epistemic/doxastic logic)

- Every atomic formula in $\mathcal{P}$ is an epistemic (doxastic) formula;
- if φ_1 and φ_2 are epistemic (doxastic) formulas, then $\neg\varphi_1, \varphi_1 \vee \varphi_2$ are epistemic (doxastic) formulas;
- if φ is an epistemic (doxastic) formula, then $\mathbf{K}\varphi$ ($\mathbf{B}\varphi$) is an epistemic (doxastic) formula.

Other propositional connectives (such as $\wedge, \rightarrow, \leftrightarrow$) are introduced as (the usual) abbreviations.

DEFINITION 2. (Kripke models for epistemic/doxstic languages)
A model for an epistemic/doxastic language is a triple

$$\mathfrak{M} = \langle W, V, R \rangle,$$

where:

- W is a non-empty set of states (or worlds);
- V is a truth assignment function per state;
- R is an accessibility relation on W for interpreting the modal operator $\mathbf{K}$ or $\mathbf{B}$. In the former case R is assumed to be an equivalence relation, while for the latter R is assumed to be euclidean, transitive and serial.

The set of worlds that are accessible from a certain world must be viewed as epistemic alternatives for this world: if the agent is in this world he is not able to distinguish between these accessible worlds due to his (lack of) knowledge/belief; as far he is concerned he could be in any of the alternatives.

The reason that for modelling knowledge the accessibility relation is taken to be an equivalence relation, can be understood as follows: the agent, being in a certain state, considers a set of alternatives which are all alternatives of each other and one of which is the actual state (so the agent considers his true state as an alternative).

For belief this would be too strong: in particular, for belief it is not reasonable to assume that the agent always considers his true state as an alternative, since he may be mistaken. So, for belief, weaker assumptions are assumed, which nevertheless result in a number of interesting validities.

DEFINITION 3. (Interpretation of epistemic / doxastic formulas.)
In order to determine whether an epistemic (doxastic) formula is true in a model/state pair $\mathfrak{M}, w$ (if so, we write $\mathfrak{M}, w \models \varphi$), we stipulate:

- $\mathfrak{M}, w \models p$ iff $V(w)(p) = \mathit{true}$, for $p \in \mathcal{P}$;
- the logical connectives are interpreted as usual;
- $\mathfrak{M}, w \models \mathbf{K}\varphi(\mathbf{B}\varphi)$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $R(w, w')$.

The last clause can be understood as follows: an agent knows (believes) a formula to be true if the formula is true in all the epistemic alternatives that the agent considers at the state he is in (represented by the accessibility relation).

DEFINITION 4. (Validity)

- A formula φ is verified by a model $\mathfrak{M} = \langle W, V, R \rangle$ iff it is true in all worlds of $\mathfrak{M}$: $\mathfrak{M} \models \varphi \Leftrightarrow \mathfrak{M}, w \models \varphi$ for all $w \in W$.
- A formula is valid iff it is verified by all models of a given form: $\models \varphi \Leftrightarrow \mathfrak{M} \models \varphi$ for all models $\mathfrak{M}$ of the form considered.

Validities in epistemic logic with respect to the given models (which we will refer to the 'axioms' of knowledge) are:

PROPOSITION 5.

- $\models \mathbf{K}(\varphi \to \psi) \to (\mathbf{K}\varphi \to \mathbf{K}\psi)$
- $\models \mathbf{K}\varphi \to \varphi$

- $\models \mathbf{K}\varphi \to \mathbf{KK}\varphi$
- $\models \neg\mathbf{K}\varphi \to \mathbf{K}\neg\mathbf{K}\varphi$

The first validity says that knowledge is closed under implication: if both the implication $\varphi \to \psi$ and the antecedent φ is known then also the conclusion ψ is known. This is of course a very 'idealized' property of knowledge, but its validity is at the very heart of using so-called normal modal logic as we do here.

The second validity expresses that knowledge is true. (One cannot honestly, truthfully and justifiably state to *know* something that is false.) The third and fourth validities express a form of introspection: the agent knows what it knows, in the sense that it knows that it knows something (the second axiom), and, moreover, it knows what it does *not* know (the third axiom). Of course, this may be very unrealistic to assume for some intelligent agents, such as humans, but often it makes sense to assume it in the case of artificial agents, either by virtue of their finitary nature or by way of some idealization. In any case it makes life easier, since the resulting logic, called **S5**, is very elegant (has relatively simple models) and enjoys several pleasant properties ([56]).The logic can be axiomized by taking the four above validities as axioms, together with an axiomatization of classical propositional logic and the rules of Modus Ponens and Necessitation ($\varphi/\mathbf{K}\varphi$).

With respect to doxastic logic we obtain the following validities:

PROPOSITION 6.

- $\models \mathbf{B}(\varphi \to \psi) \to (\mathbf{B}\varphi \to \mathbf{B}\psi)$
- $\models \neg\mathbf{B}\bot$
- $\models \mathbf{B}\varphi \to \mathbf{BB}\varphi$
- $\models \neg\mathbf{B}\varphi \to \mathbf{B}\neg\mathbf{B}\varphi$

Again we observe the introspection properties, but the second validity now states that an agent's belief is not inconsistent, which is weaker than the property that belief should be true. If one takes these properties as axioms completed by modus ponens, necessitation for **B** and (sufficient) classical propositional validities, one obtains the system known as **KD45**.

A natural question is whether the knowledge and belief modalities are interrelated in some meaningful way. The answer is more involved than one might suspect. In the literature (for example [50, 75, 89, 90]), several interesting possibilities for such an interaction have been investigated. In these studies it became clear that one has to be careful in putting several plausible properties together, as one might otherwise end up with undesirable properties such as the collapse of knowledge and belief! As usual with applications of modal logic, one may wonder whether the properties one obtains are all desirable and not 'over-idealizations'. In the realm of epistemic/doxastic logic one may dispute the so-called paradoxes of *logical omniscience*. Most of these are inherent in the use of (normal) modal logic using standard Kripke semantics. For example, the basic modal property $\models \mathbf{K}(\varphi \to \psi) \to (\mathbf{K}\varphi \to \mathbf{K}\psi)$ gives rise to a Sorites-like paradox: the agent knows *all* consequences of its knowledge, and likewise for belief. For 'finitary', resource-bounded agents this is unrealistic. One can now either take this for granted and

view the modal operators for knowledge/belief as idealizations of the real thing, or one has to resort to non-standard ('non-normal') semantics (such as neighborhood semantics) to be able to avoid validities such as the above one. For a fuller treatment of this issue we refer to [56, 54].

4 DEONTIC LOGIC

4.1 Standard deontic logic

One of the first systems for deontic logic that really was a serious attempt to capture deontic reasoning was the now so-called "Old System" of Von Wright ([87]), of which a modal logic (Kripke-style) version has become known as Standard Deontic Logic (**SDL**). The syntax of SDL is that of a propositional modal logic with a modal operator O for obligation. $O\varphi$ is read as 'φ is obligatory / obligated' or 'it ought to be the case that φ'. The modalities F and P for 'it is forbidden' and 'it is permitted', respectively, are introduced as abbreviations: $F\varphi = O\neg\varphi$ and $P\varphi = \neg F\varphi$: something is forbidden iff its negation is obligatory, and something is permitted iff it is not forbidden. **SDL** has a Kripke-style modal semantics based on a set of possible worlds (, a truth assignment function of primitive propositions per possible world) and an accessibility relation associated with the O-modality. This accessibility relation points to "ideal" or "perfect deontic alternatives" of the world under consideration. The crux behind this is that in some possible world something (say φ) is obligated, if φ holds in all the perfect alternatives of this world, as indicated by the accessibility relation.

So, formally these models have the following form: $\mathfrak{M} = (W, V, R_O)$, where W is the set of states/ worlds, V is a truth assignment function, and R_O is the deontic accessibility relation, which is assumed to be serial, i.e. for all $w \in W$ there is a $w' \in W$ such that $R_O(w, w')$.

The operator O is interpreted by means of the relation R_O: $\mathfrak{M}, w \models O\varphi$ iff $M, w' \models \varphi$ for all w' with $R_O(w, w')$. Validity is defined as usual for modal logic. We obtain the following validities:

PROPOSITION 7.

- $O(\varphi \to \psi) \to (O\varphi \to O\psi)$
- $O(\varphi \wedge \psi) \leftrightarrow (O\varphi \wedge O\psi)$
- $P(\varphi \wedge \psi) \to (P\varphi \wedge P\psi)$
- $(F\varphi \vee F\psi) \to F(\varphi \wedge \psi)$
- $(O\varphi \vee O\psi) \to O(\varphi \vee \psi)$
- $P(\varphi \vee \psi) \leftrightarrow (P\varphi \vee P\psi)$
- $F(\varphi \vee \psi) \leftrightarrow (F\varphi \wedge F\psi)$
- $\neg(O\varphi \wedge O\neg\varphi)$

The first and the last of these properties together with modus ponens, necessitation ($\varphi/O\varphi$) and a sufficient number of axioms of propositional logic can be used to axiomatize **SDL**. (This system coincides with the system **KD** in the classification of Chellas ([17]).)

Again the question arises whether the above properties are adequate for deontic reasoning. **SDL** suffers from a number of paradoxes, again mostly inherent in the (normal) modal semantics of the operators. For example, Ross's paradox: $O\varphi \rightarrow O(\varphi \vee \psi)$: if one ought to mail the letter then one ought to mail it or burn it. This sounds peculiar, but if one interprets O as holding in ideal alternative worlds it is evidently true. What is problematic here, is that in natural language an obligation of a disjunction is normally held to be an obligation of one of the disjuncts that may be chosen arbitrarily by the agent, and this intuition is simply not captured by SDL semantics. There are also more serious paradoxes, notably those having to do with contrary-to-duty (CTD) imperatives, in which certain obligations are specified in case one is already violating another obligation. For example, one ought to refrain from killing animals. But if one kills an animal, one ought to do it gently. This kind of CTD obligations cannot be expressed adequately in **SDL**. To reason about CTDs, or more generally about *conditional* obligations of the form $O(\varphi/\psi)$, read as the obligation to φ under circumstance ψ, so-called *dyadic deontic logic* was introduced, already in the 60s by von Wright [88]. However, in the 90s it became apparent that a truly adequate treatment of CTDs seems to force one to enter the realm of *nonmonotonic / defeasible / preferential* reasoning, which is beyond the scope of this chapter. More about this can be found in [58] and particularly [60, 15].

4.2 Dynamic deontic logic

Another issue that plays a role in deontic logic is the confusion about the argument of the modal operators. In **SDL** these are propositions (and we may refer to the O-operator as being of an 'ought-to be' nature). But many examples in the literature (and indeed also the example we gave illustrating Ross's paradox) actually seem to concern actions rather than propositions. (This is already noted by e.g. Castañeda [16].) One may also try and capture this notion of 'ought-to-do' in a different logic, and this is what we do next. **DDL**, introduced in [59], is a version of dynamic logic especially tuned to use as ought-to-do style deontic logic. It is based on the idea of Anderson's reduction of ought-to-be style deontic logic to alethic modal logic ([3]), but instead it reduces ought-to-do deontic logic to dynamic logic ([42]). The basic idea is very simple: some action is forbidden if doing the action leads to a state of violation. In a formula: $\hat{F}\alpha \leftrightarrow_{def} [\alpha]V$, where the dynamic logic formula $[\alpha]\varphi$ denotes that execution / performance of the action α leads (necessarily) to a state (or states) where φ holds, and V is a special atomic formula denoting violation. (We write $\hat{F}$ instead of F to indicate that this operator is of a different (viz. 'to-do') kind than the SDL operator; likewise for the other operators in this section.) Formally, we say that the meaning of action α is captured by an accessibility relation $R_\alpha \subseteq W \times W$ associated with α, where W is the set of possible worlds. This relation R_α describes exactly what possible moves (state transitions) are induced by performance of the action α: $R_\alpha(u, w)$ says that from world u one can get into world w by performing α. (In concurrency semantics and process algebra this is often specified by a so-called (labeled) transition system which enables one to derive (all) transitions of the kind $u \rightarrow_\alpha w$, which in fact defines the relation R_α for all possible actions α.) Now the formal meaning of the formula $[\alpha]\varphi$ is given by: $[\alpha]\varphi$ is true in a possible world w iff all states w' with

$R_\alpha(w, w')$ satisfy φ. This then provides the formal definition of the $\hat{F}$-operator, as given above. In the sequel we will also employ the dual $\langle\alpha\rangle$ of $[\alpha]$: $\langle\alpha\rangle\varphi$ is true in w iff there is some state w' satisfying φ such that $R_\alpha(w, w')$.

The other deontic modalities are derivatives of $\hat{F}$: permission is not-forbidden ($\hat{P}\alpha \leftrightarrow \neg\hat{F}\alpha$), and obligation is forbidden-not-to ($\hat{O}\alpha \leftrightarrow \hat{F}\bar{\alpha}$), where $\bar{\alpha}$ has the meaning of "not-α". The formal semantics of this negated action is non-trivial, especially in case one considers composite actions (cf. [59, 91, 26, 92]). In the cited papers we considered connectives for composing non-atomic actions, such as '$\cup$' (choice, the dynamic analogue of disjunction in a static setting), '&' (parallel, the analogue of conjunction), '$-$' (non-performance, the analogue of negation), and ';' (sequential composition, which has no analogue in a static setting). Without giving a formal semantics here (see the papers mentioned above for that), the meaning of these are as follows: $\alpha_1 \cup \alpha_2$ expresses a choice between α_1 and α_2 (this—roughly—corresponds to taking $R_{\alpha_1 \cup \alpha_2}$ as the set-theoretic union of R_{α_1} and R_{α_2}), $\alpha_1 \& \alpha_2$ a parallel performance of α_1 and α_2 (this amounts to more or less taking $R_{\alpha_1 \& \alpha_2}$ to be the intersection of R_{α_1} and R_{α_2}), $\bar{\alpha}$ (we will also write $-\alpha$) the non-performance of α, as stated above (it more or less amounts to taking $R_{\bar{\alpha}}$ to be some complement of R_α, but see also the discussion below), and $\alpha_1; \alpha_2$ the performance of α_1 followed by that of α_2. For a full account of the semantics of particularly negated actions we refer to [59, 26, 23, 25].

With this semantics the following formulas are valid:

PROPOSITION 8.

- $[\alpha](\varphi \to \psi) \to ([\alpha]\varphi \to [\alpha]\psi)$
- $[\alpha; \beta]\varphi \leftrightarrow [\alpha][\beta]\varphi$
- $[\alpha \cup \beta]\varphi \leftrightarrow ([\alpha]\varphi \wedge [\beta]\varphi)$
- $[\alpha]\varphi \to [\alpha\&\beta]\varphi$
- $[-(\alpha; \beta)]\varphi \leftrightarrow ([-\alpha]\varphi \wedge [\alpha][-\beta]\varphi)$
- $[-\alpha]\varphi \to [-(\alpha \cup \beta)]\varphi$
- $[-(\alpha\&\beta)]\varphi \leftrightarrow ([-\alpha]\varphi \wedge [-\beta]\varphi)$
- $\hat{F}\alpha \leftrightarrow [\alpha]V$
- $\hat{P}\alpha \leftrightarrow \neg\hat{F}\alpha (\leftrightarrow \langle\alpha\rangle\neg V)$
- $\hat{O}\alpha \leftrightarrow \hat{F}(-\alpha)(\leftrightarrow [-\alpha]V)$
- $\hat{O}(\alpha; \beta) \leftrightarrow (\hat{O}\alpha \wedge [\alpha]\hat{O}\beta)$
- $\hat{P}(\alpha; \beta) \leftrightarrow \langle\alpha\rangle\hat{P}\beta$
- $\hat{F}(\alpha; \beta) \leftrightarrow [\alpha]\hat{F}\beta$
- $\hat{O}(\alpha\&\beta) \leftrightarrow (\hat{O}\alpha \wedge \hat{O}\beta)$
- $\hat{P}(\alpha\&\beta) \to (\hat{P}\alpha \wedge \hat{P}\beta)$

- $(\hat{F}\alpha \vee \hat{F}\beta) \rightarrow \hat{F}(\alpha \& \beta)$
- $(\hat{O}\alpha \vee \hat{O}\beta) \rightarrow \hat{O}(\alpha \cup \beta)$
- $\hat{P}(\alpha \cup \beta) \leftrightarrow (\hat{P}\alpha \vee \hat{P}\beta)$
- $\hat{F}(\alpha \cup \beta) \leftrightarrow (\hat{F}\alpha \wedge \hat{F}\beta)$

Modal action logics that contain action negation (complement) operators have been studied by several authors, for instance [20, 37, 9]. From these studies, in particular [9], it has become clear that there are several ways to define action negation, particularly in the context of the operators ';' and intersection. The choices made in **DDL** above were motivated mainly by the desirability of the validities concerning the deontic operators above. There have been proposed several dynamic deontic logics that could be viewed as some kind of refinement of the original logic as presented here. These concern -amongst other ones- issues of context (pertaining to the kind of complement / negation again) [23], the exact way action bring about violations [24], and of a more refined view of action than just input-output relations [78, 13].

5 BDI LOGIC

BDI logic as proposed by Rao & Georgeff [62] came about after the ground-breaking work of Bratman [8] on the philosophy of intelligent (human) agents. In this work Bratman made a case for the notion of *intention* besides belief and desire, to describe the behavior of rational agents. Intentions force the agent to commit to certain desires and to really 'go for them'. So focus of attention is an important aspect here, which also enables the agent to monitor how s/he is doing and take measures if things go wrong. Rao & Georgeff stress that in the case of resource-bounded agents it is imperative to focus on desires / goals and make choices. This was also observed by Cohen & Levesque [18], who tried to formalize the notion of intention in a linear-time temporal logic in terms of the notion of a (persistent) goal. Here we follow Rao & Georgeff who use a branching-time temporal logic framework to give a formal-logical account of BDI theory. BDI logic has influenced many researchers (including Rao & Georgeff themselves) to think about architectures of agent-based systems in order to realize these systems. Rao & Georgeff's BDI logic is more liberal than that of Cohen & Levesque in the sense that they *a priori* regard each of the three attitudes of belief, desire and intention as primitive: they introduce separate modal operators for belief, desire and intention, and then study possible relations between them.

The language of BDI logic is defined as follows. Two types of formulas are distinguished: state formulas and path formulas. We assume some given first-order signature. Furthermore, we assume a set E of event types with typical element e. The operators $BEL, GOAL, INTEND$ have as obvious intended reading the belief, goal and intention of an agent, respectively, while $\mathsf{U}, \Diamond, \mathsf{O}$ are the usual temporal operators, viz. 'until', 'eventually' and 'next', respectively.

DEFINITION 9. (State and path formulas.)

1. The set of *state formulas* is the smallest closed under the following conditions:
    - any first-order formula with respect to the given signature is a state formula;

- if φ_1 and φ_2 are state formulas then also $\neg\varphi_1, \varphi_1 \vee \varphi_2, \exists x \varphi_1$ are state formulas;
- if e is an event type, then $succeeded(e), failed(e)$ are state formulas;
- if φ is a state formula, then $BEL(\varphi), GOAL(\varphi), INTEND(\varphi)$ are state formulas;
- if ψ is a *path formula*, then $optional(\psi)$ is a state formula.

2. The set of *path formulas* is the smallest set closed under:
   - any state formula is a path formula;
   - if ψ_1, ψ_2 are path formulas, then $\neg\psi_1, \psi_1 \vee \psi_2, \psi_1 \mathsf{U} \psi_2, \Diamond\psi_1, \mathsf{O}\psi_1$ are path formulas.

State formulas are interpreted over a state, that is a (state of the) world at a particular point in time, while path formulas are interpreted over a path of a time tree (representing the evolution of a world). In the sequel we will see how this will be done formally. Here we just give the informal readings of the operators. The operators *succeeded* and *failed* are used to express that events have (just) succeeded and failed, respectively. As in the framework of Cohen & Levesque action-like entities should be given a place in the theory by means of additional operators. Here we see that Rao & Georgeff's approach also account for the distinction of trying an action / event and succeeding versus failing. With the latter one may think of several things: either the agent tried to do some action which failed due to circumstances in the environment. For example, for an action 'grip' to be successful there should be an object to be gripped; for a motor to be started there should be fuel, etc.; perhaps there is also some internal capacity missing needed for successful performance of an action: again for an action 'grip' to be successful the robot should have a gripper. This is related to the well-known *qualification problem in AI*, [67].

Next there are the modal operators for belief, goal and intend. (In the original version of BDI theory [62], desires are represented by goals, or rather a GOAL operator. In a later paper [64] the *GOAL* operator was replaced by *DES* for desire.) The optional operator states that there is a future (represented by a path) where the argument of the operator holds. Finally, there are the familiar (linear-time) temporal operators, such as the 'until', 'eventually' and 'next time', which are to be interpreted along a linear time path.

Furthermore, the following abbreviations are defined:

DEFINITION 10.

1. $\Box\psi = \neg\Diamond\neg\psi$ (always);
2. $inevitable(\psi) = \neg optional(\neg\psi)$;
3. $done(e) = succeeded(e) \vee failed(e)$;
4. $succeeds(e) = inevitable\mathsf{O}(succeeded(e))$;
5. $fails(e) = inevitable\mathsf{O}(failed(e))$;
6. $does(e) = inevitable\mathsf{O}(done(e))$.

The 'always' operator is the familiar one from (linear-time) temporal logic. The 'inevitability' operator expresses that its argument holds along all possible futures (paths from the current time). The 'done' operator states that an event occurs (action is done) no matter whether it is succeeding or not. The final three operators state that an event succeeds, fails, or is done iff it is inevitable (i.e. in any possible future) it is the case that at the next instance the event has succeeded, failed, or has been done, respectively. (So, this means that an event, succeeding or failing, is supposed to take one unit of time!)

DEFINITION 11. (Semantics)
The semantics is given with respect to models of the form $\mathfrak{M} = \langle W, E, T, \prec, \mathcal{U}, B, G, I, \Phi\rangle$, where

- W is a set of possible worlds;
- E is a set of primitive event types;
- T is a set of time points;
- $\prec$ is a binary relation on time points, which is serial, transitive and back-wards linear;
- $\mathcal{U}$ is the universe of discourse;
- Φ is a mapping of first-order entities to $\mathcal{U}$, for any world and time point;
- $B, G, I \subseteq W \times T \times W$ are accessibility relations for $BEL, GOAL, INTEND$, respectively.

The semantics of BDI logic, Rao & Georgeff-style, is rather complicated. Of course, we have possible worlds again, but as we will see below, these are not just unstructured elements, but they are each time trees, describing possible flows of time. So, we also need time points and an ordering on them. As BDI logic is based on branching time, the ordering need not be linear in the sense that all time points are related in this ordering. However, it is stipulated that the time ordering is serial (every time point has a successor in the time ordering), the ordering is transitive and backwards-linear, which means that every time point has only one direct predecessor. The accessibility relations for the 'BDI'-modalities are standard apart from the fact that they are also time-related, that is to say that worlds are (belief/goal/intend-)accessible with respect to a time point. Another way of viewing this is that – for all three modalities – for every time point there is a distinct accessibility relation between worlds.

Next we elaborate on the structure of the possible worlds.

DEFINITION 12. (Possible worlds)
Possible worlds in W are assumed to be *time trees*: an element $w \in W$ has the form $w = \langle T_w, A_w, S_w, F_w\rangle$, where

- $T_w \subseteq T$ is the set of time points in world w;
- A_w is the restriction of the relation $\prec$ to T_w;
- $S_w : T_w \times T_w \to E$ maps adjacent time points to (successful) events;

- $F_w : T_w \times T_w \to E$ maps adjacent time points to (failing) events;
- the domains of the functions S_w and F_w are disjoint.

As announced before, a possible world itself is a time tree, a temporal structure representing possible flows of time. The definition above is just a technical one stating that the time relation within a possible world derives naturally from the *a priori* given relation on time points. Furthermore it is indicated by means of the functions S_w and F_w how events are associated with adjacent time points.

Now we come to the formal interpretation of formulas on the above models. Naturally we distinguish state formulas and path formulas, since the former should be interpreted on states whereas the latter are interpreted on paths. In the sequel we use the notion of a *fullpath*: a fullpath in a world w is an *infinite* sequence of time points such that, for all i, $(t_i, t_{i+1}) \in A_w$. We denote a fullpath in w by $(w_{t0}, w_{t1}, \ldots)$, and define $fullpaths(w)$ as the set of all fullpaths occurring in world w (i.e. all fullpaths that start somewhere in the time tree w).

DEFINITION 13. (Interpretation of formulas)
The interpretation of formulas with respect to a model

$$\mathfrak{M} = \langle W, E, T, \prec, \mathcal{U}, B, G, I, \Phi \rangle$$

is given by:

1. (state formulas)

   - $\mathfrak{M}, v, w_t \models q(y_1, \ldots, y_n) \leftrightarrow (v(y_1), \ldots, v(y_n)) \in \Phi(q, w, t)$;
   - $\mathfrak{M}, v, w_t \models \neg\varphi \leftrightarrow \mathfrak{M}, v, w_t \not\models \varphi$;
   - $\mathfrak{M}, v, w_t \models \varphi_1 \vee \varphi_2 \leftrightarrow \mathfrak{M}, v, w_t \models \varphi_1$ or $\mathfrak{M}, v, w_t \models \varphi_2$;
   - $\mathfrak{M}, v, w_t \models \exists x \varphi \leftrightarrow \mathfrak{M}, v\{d/x\}, w_t \models \varphi$ for some $d \in \mathcal{U}$;
   - $\mathfrak{M}, v, w_{t0} \models optional(\psi) \leftrightarrow$ there exists some fullpath $(w_{t0}, w_{t1}, \ldots)$ such that $\mathfrak{M}, v, (w_{t0}, w_{t1}, \ldots) \models \psi$;
   - $\mathfrak{M}, v, w_t \models BEL(\varphi) \leftrightarrow$ for all $w' \in B(w,t) : \mathfrak{M}, v, w'_t \models \varphi$;
   - $\mathfrak{M}, v, w_t \models GOAL(\varphi) \leftrightarrow$ for all $w' \in G(w,t) : \mathfrak{M}, v, w'_t \models \varphi$;
   - $\mathfrak{M}, v, w_t \models INTEND(\varphi) \leftrightarrow$ for all $w' \in I(w,t) : \mathfrak{M}, v, w'_t \models \varphi$;
   - $\mathfrak{M}, v, w_t \models succeeded(e) \leftrightarrow$ exists $t0$ such that $S_w(t0, t) = e$;
   - $\mathfrak{M}, v, w_t \models failed(e) \leftrightarrow$ exists $t0$ such that $F_w(t0, t) = e$.

   In the above and elsewhere $v\{d/x\}$ denotes the function v modified such that $v(x) = d$, and $R(w,t) = \{w' \mid R(w,t,w')\}$ for $R = B, G, I$

2. (path formulas)

   - $\mathfrak{M}, v, (w_{t0}, w_{t1}, \ldots) \models \varphi \leftrightarrow \mathfrak{M}, v, w_{t0} \models \varphi$, for φ state formula;
   - $\mathfrak{M}, v, (w_{t0}, w_{t1}, \ldots) \models \mathsf{O}\varphi \leftrightarrow \mathfrak{M}, v, (w_{t1}, w_{t2}, \ldots) \models \varphi$;
   - $\mathfrak{M}, v, (w_{t0}, w_{t1}, \ldots) \models \Diamond\varphi \leftrightarrow \mathfrak{M}, v, (w_{tk}, \ldots) \models \varphi$ for some $k \geq 0$;

- $\mathfrak{M}, v, (w_{t0}, w_{t1}, \ldots) \models \psi_1 \mathsf{U} \psi_2 \leftrightarrow$ either (i) there exists $k \geq 0$ such that $\mathfrak{M}, v, (w_{tk}, \ldots) \models \psi_2$ and for all $0 \leq j < k$: $\mathfrak{M}, v, (w_{tj}, \ldots) \models \psi_1$, or (ii) for all $j \geq 0$: $\mathfrak{M}, v, (w_{tj}, \ldots) \models \psi_1$.

Most of the above clauses should be clear, including those concerning the modal operators for belief, goal and intention. The clause for the 'optional' operator expresses exactly that optionally ψ is true if ψ is true in one of the possible futures represented by fullpaths starting at the present time point. The interpretation of the temporal operators is as usual.

Rao & Georgeff now discuss a number of properties that may be desirable to have as axioms. In the following we use α to denote so-called *O-formulas*, which are formulas that contain no positive occurrences of the '*inevitable*' operator (or negative occurrences of '*optional*") outside the scope of the modal operators $BEL, GOAL$ and $INTEND$.

1. $GOAL(\alpha) \rightarrow BEL(\alpha)$
2. $INTEND(\alpha) \rightarrow GOAL(\alpha)$
3. $INTEND(does(e)) \rightarrow does(e)$
4. $INTEND(\varphi) \rightarrow BEL(INTEND(\varphi))$
5. $GOAL(\varphi) \rightarrow BEL(GOAL(\varphi))$
6. $INTEND(\varphi) \rightarrow GOAL(INTEND(\varphi))$
7. $done(e) \rightarrow BEL(done(e))$;
8. $INTEND(\varphi) \rightarrow inevitable\Diamond(\neg INTEND(\varphi))$

In order to render these formulas validities further constraints should be imposed on the models, since in the general setting above these are not yet valid. For reasons of space we only consider the first two. (More can be found in [62, 64, 93].) In order to define constraints on the models such that these two become valid, we introduce the relation $\lhd$ on worlds, as follows: $w'' \lhd w' \Leftrightarrow fullpaths(w'') \subseteq fullpaths(w')$. So, $w'' \lhd w'$ means that there the world (time tree) w'' represents less choices than w'. Now we define the *B-G condition* as the property that the following holds:

$$\forall w' \in B(w, t)\ \exists w'' \in G(w, t) : w'' \lhd w'$$

Informally, this condition says that for any belief accessible world there is a goal accessible world that contains less choices. It is now easy to prove the following proposition.

PROPOSITION 14.
Let $\mathcal{BG}$ be the class of models of the above form that satisfy the B-G condition. Then

$$\mathcal{BG} \models GOAL(\alpha) \rightarrow BEL(\alpha)$$

for O-formulas α.

Similarly one can define the *G-I condition* as

$$\forall w' \in G(w, t)\ \exists w'' \in I(w, t) : w'' \lhd w'$$

and obtain:

PROPOSITION 15.
Let $\mathcal{GI}$ be the class of models of the above form that satisfy the G-I condition. Then

$$\mathcal{GI} \models INTEND(\alpha) \rightarrow GOAL(\alpha)$$

for O-formulas α.

Let us now consider the properties deemed desirable by Rao & Georgeff again. Actually, the first one is rather controversial. (Cohen & Levesque had the inverse implication in their framework, although admittedly that framework is quite different from Rao & Georgeff's because of the different temporal model – linear time instead of branching time, so that it is not completely fair to compare formulas...!) Rao & Georgeff try to render the formula concerned (which they call 'belief-goal compatibility') plausible by considering a typical O-formula α of the form $optional(\psi)$, and then note that if it is a goal that something is optional (true in some future) then it should also be believed that it is optional (true in some future). This, indeed, sounds plausible in the sense that a rational and realistic agent would adhere to it. But also objective (nonmodal) formulas are O-formulas, and whether this property is also plausible for these formulas is debatable.

The second formula is similar to the first. This one is called goal-intention compatibility, and is defended by Rao & Georgeff by stating that if an optionality is intended it should also be wished (a goal in their terms). So, Rao & Georgeff have a kind of selection filter in mind: intentions (or rather intended options) are filtered / selected goals (or rather goal (wished) options), and goal options are selected believed options.

The third one says that the agent really does the primitive actions that s/he intends to do. This means that if one adopts this as an axiom the agent is not allowed to do something else (first).

The fourth, fifth and seventh express that the agent is conscious of its intentions, goals and what primitive action he has done in the sense that he believes what he intends, has as a goal and what primitive action he has just done. The sixth one says something like that intentions are really wished for: if something is an intention then it is a goal that it is an intention.

The eighth formula states that intentions will inevitably (in every possible future) be dropped eventually, so there is no infinite deferral of its intentions. This leaves open, whether the intention will be fulfilled eventually, or will be given up for other reasons. Below we will discuss several possibilities of giving up intentions according to different types of commitment an agent may have.

BDI-logical expressions can be used to characterize different types of agents. Rao & Georgeff mention the following possibilities:

1. (blindly committed agent) $INTEND(inevitable\Diamond\varphi) \rightarrow$
   $inevitable(INTEND(inevitable\Diamond\varphi)\mathsf{U}BEL(\varphi))$

2. (single-minded committed agent) $INTEND(inevitable\Diamond\varphi) \rightarrow$
   $inevitable(INTEND(inevitable\Diamond\varphi)\mathsf{U}(BEL(\varphi) \vee \neg BEL(optional\Diamond\varphi)))$

3. (open minded committed agent) $INTEND(inevitable\Diamond\varphi) \rightarrow$
   $inevitable(INTEND(inevitable\Diamond\varphi)\mathsf{U}(BEL(\varphi) \vee \neg GOAL(optional\Diamond\varphi)))$

A blindly committed agent maintains his intentions to inevitably obtaining eventually something until he actually believes that that something has been fulfilled. A single-minded committed agent is somewhat more flexible: he maintains his intention until he believes he has achieved it *or he does not believe that it can be reached (it is still an option in some future) anymore*. Finally, the open minded committed agent is even more flexible: he can also drop his intention if it is not a goal (desire) anymore.

Rao & Georgeff obtain results under which conditions the various types of committed agents will reach their intentions. For example, under the assumption of the axioms we have discussed earlier it holds for a blindly committed agent that:

$$INTEND(inevitable\Diamond\varphi) \to inevitable\Diamond BEL(\varphi)$$

expressing that if the agent intends to eventually obtain φ (s)he will inevitably eventually believe that it has succeeded in achieving φ.

6 KARO LOGIC

In this section we turn to the KARO formalism, in which *action* rather than time, together with knowledge / belief, is the primary concept, on which other agent notions are built. The KARO framework has been developed in a number of papers (e.g. [80, 81, 77, 57]) as well as in the thesis of Van Linder ([79]).

The KARO formalism is an amalgam of dynamic logic and epistemic / doxastic logic, augmented with several additional (modal) operators in order to deal with the motivational aspects of agents. So, besides operators for knowledge (**K**), belief (**B**) and action ($[\alpha]$, "after performance of α it holds that"), there are additional operators for ability (**A**) and desire (**D**).

Assume a set $\mathcal{A}$ of atomic actions and a set $\mathcal{P}$ of atomic propositions.

DEFINITION 16. (Language)
The language $\mathcal{L}_{KARO}$ of KARO-formulas is given by the BNF grammar:

$$\begin{array}{rcl} \varphi & ::= & p(\in \mathcal{P}) \mid \neg\varphi \mid \varphi_1 \wedge \varphi_2 \mid \ldots \\ & & \mathbf{K}\varphi \mid \mathbf{B}\varphi \mid \mathbf{D}\varphi \mid [\alpha]\varphi \mid \mathbf{A}\alpha \end{array}$$

$$\begin{array}{rcl} \alpha & ::= & a(\in \mathcal{A}) \mid \alpha_1;\alpha_2 \mid \varphi? \mid \\ & & \texttt{if}\ \varphi\ \texttt{then}\ \alpha_1\ \texttt{else}\ \alpha_2\ \texttt{fi} \mid \\ & & \texttt{while}\ \varphi\ \texttt{do}\ \alpha\ \texttt{od} \end{array}$$

Thus formulas are built by means of the familiar propositional connectives and the modal operators for knowledge, belief, desire, action and ability. The action expressions defined in the second (α)-clause are familiar from imperative programming: atomic actions, tests and sequential composition, conditional and repetition.

DEFINITION 17. (KARO models)

1. The semantics of the knowledge, belief and desires operators is given by means of Kripke structures of the following form: $\mathfrak{M} = \langle W, V, R_K, R_B, R_D \rangle$, where
   - W is a non-empty set of states (or worlds);
   - V is a truth assignment function per state;
   - R_K, R_B, R_D are accessibility relations for interpreting the modal operators $\mathbf{K}, \mathbf{B}, \mathbf{D}$.

     The relation R_K is assumed to be an equivalence relation, while the relation R_B is assumed to be euclidean, transitive and serial. Furthermore we assume that $R_B \subseteq R_K$. (No special constraints are assumed for the relations R_D.)
2. The semantics of actions is given by means of structures of type $\langle \Sigma, \{R_a \mid a \in \mathcal{A}\}, \mathcal{C}, Ag \rangle$, where
   - Σ is the set of possible model/state pairs (i.e. models of the above form, together with a state appearing in that model);
   - R_a ($a \in \mathcal{A}$) are relations on Σ encoding the behavior of atomic actions;
   - $\mathcal{C}$ is a function that gives the set of actions that the agent is able to do per model/state pair;
   - Ag is a function that yields the set of actions that the agent is committed to (the agent's 'agenda') per model/state pair.

Knowledge, belief, and desire are modeled by accessibility relationson worlds, as usual. Actions are modelled as model/state pair transformers to emphasize their influence on the mental state (that is, the complex of knowledge, belief and desires) of the agent rather than just the state of the world. Both (cap)abilities and commitments are given by functions that yield the relevant information per model / state pair.

DEFINITION 18. (Interpretation of formulas)
In order to determine whether a formula $\varphi \in \mathcal{L}$ is true in a model/state pair $(\mathfrak{M}, w)$, we stipulate:

- $\mathfrak{M}, w \models p$ iff $V(w)(p) = \mathit{true}$, for $p \in \mathcal{P}$;
- the logical connectives are interpreted as usual;
- $\mathfrak{M}, w \models \mathbf{K}\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $R_K(w, w')$;
- $\mathfrak{M}, w \models \mathbf{B}\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $R_B(w, w')$;
- $\mathfrak{M}, w \models \mathbf{D}\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $R_D(w, w')$;
- $\mathfrak{M}, w \models [\alpha]\varphi$ iff $\mathfrak{M}', w' \models \varphi$ for all $\mathfrak{M}', w'$ with $R_\alpha((\mathfrak{M}, w), (\mathfrak{M}', w'))$;
- $\mathfrak{M}, w \models \mathbf{A}\alpha$ iff $\alpha \in \mathcal{C}(\mathfrak{M}, w)$;[2]

[2] In [76] we have shown that the ability operator can alternatively defined by means of a second accessibility relation for actions, in a way analogous to the opportunity operator below.

- $\mathfrak{M}, w \models \mathbf{Com}(\alpha)$ iff $\alpha \in Ag(\mathfrak{M}, w)$.[3]

Here R_α is defined as usual in dynamic logic by induction from the basic case R_a (cf. e.g. [43, 79, 77], but now on model/state pairs rather than just states). Likewise the function $\mathcal{C}$ is lifted to sets of complex actions ([79, 77]).

Knowledge, belief and desire are interpreted as modal operators, as usual. The action modality gets a similar interpretation: something (necessarily) holds after the performance / execution of action α if it holds in all the situations that are accessible from the current one by doing the action α. The only thing which is slightly nonstandard is that a situation is characterized here as a model / state pair. The interpretations of the ability and commitment operators are rather trivial in this setting (but see the footnotes): an action is enabled (or rather: the agent is able to do the action) if it is indicated so by the function C, and, likewise, an agent is committed to an action α if it is recorded so in the agent's agenda.

Furthermore, we will make use of the following syntactic abbreviations serving as auxiliary operators:

DEFINITION 19.

- (dual) $\langle\alpha\rangle\varphi = \neg[\alpha]\neg\varphi$, expressing that the agent has the opportunity to perform α resulting in a state where φ holds.
- (opportunity) $\mathbf{O}\alpha = \langle\alpha\rangle\top$, i.e., an agent has the opportunity to do an action iff there is a successor state with respect to the R_α-relation;
- (practical possibility) $\mathbf{P}(\alpha, \varphi) = \mathbf{A}\alpha \wedge \mathbf{O}\alpha \wedge \langle\alpha\rangle\varphi$, i.e., an agent has the practical possibility to do an action with result φ iff it is both able and has the opportunity to do that action and the result of actually doing that action leads to a state where φ holds;
- (can) $\mathbf{Can}(\alpha, \varphi) = \mathbf{KP}(\alpha, \varphi)$, i.e., an agent can do an action with a certain result iff it knows it has the practical possibility to do so;
- (realizability) $\Diamond\varphi = \exists a_1, \ldots, a_n \mathbf{P}(a_1; \ldots; a_n, \varphi)$[4], i.e., a state property φ is realizable iff there is a finite sequence of atomic actions of which the agent has the practical possibility to perform it with the result φ;
- (goal) $\mathbf{G}\varphi = \neg\varphi \wedge \mathbf{D}\varphi \wedge \Diamond\varphi$, i.e., a goal is a formula that is not (yet) satisfied, but desired and realizable.[5]
- (possible intend) $\mathbf{I}(\alpha, \varphi) = \mathbf{Can}(\alpha, \varphi) \wedge \mathbf{KG}\varphi$, i.e., an agent (possibly) intends an action with a certain result iff the agent can do the action with that result and it moreover knows that this result is one of its goals.

[3] The agenda is assumed to be closed under certain conditions such as taking 'prefixes' of actions (representing initial computations). Details are omitted here, but can be found in [57].

[4] We abuse our language here slightly, since strictly speaking we do not have quantification in our object language. See [57] for a proper definition.

[5] In fact, here we simplify matters slightly. In [57] we also stipulate that a goal should be explicitly selected somehow from the desires it has, which is modelled in that paper by means of an additional modal operator. Here we leave this out for simplicity's sake.

REMARK

- The dual of the (box-type) action modality expresses that there is at least a resulting state where a formula φ holds. It is important to note that in the context of *deterministic* actions, i.e. actions that have at most one successor state, this means that the *only* state satisfies φ, and is thus in this particular case a stronger assertion than its dual formula $[\alpha]\varphi$, which merely states that if there are any successor states they will (all) satisfy φ. Note also that if atomic actions are assumed to be deterministic all actions including the complex ones will be deterministic.

- Opportunity to do an action is modelled by having at least one successor state according to the accessibility relation associated with the action.

- Practical possibility to to an action with a certain result is modelled as having both ability and opportunity to do the action with the appropriate result. Note that $\mathbf{O}\alpha$ in the formula $\mathbf{A}\alpha \wedge \mathbf{O}\alpha \wedge \langle\alpha\rangle\varphi$ is actually redundant since it already follows from $\langle\alpha\rangle\varphi$. However, to stress the opportunity aspect it is added.

- The Can predicate applied to an action and formula expresses that the agent is 'conscious' of its practical possibility to do the action resulting in a state where the formula holds.

- A formula φ is realizable if there is a 'plan' consisting of (a sequence of) atomic actions of which the agent has the practical possibility to do them with φ as a result.

- A formula φ is a goal in the KARO framework if it is not true yet, but desired and realizable in the above meaning, that is, there is a plan of which the agent has the practical possibility to realize it with φ as a result.

- An agent is said to (possibly) intend an action α with result φ if he Can do this (knows that he has the practical possibility to do so), and, moreover, knows that φ is a goal.

In order to manipulate both knowledge / belief and motivational matters special actions `revise`, `commit` and `uncommit` are added to the language. These operators cannot be nested. So, e.g., $\texttt{commit}(\texttt{uncommit}\alpha)$ is not a well-formed action expression. (For a proper definition of the language the reader is referred to [57].) The semantics of these actions are again given as model/state transformers (We only do this here in a very abstract manner, viewing the accessibility relations associated with these actions as functions. For further details we refer to e.g. [79, 77, 57]):

DEFINITION 20. (Accessibility of revise, commit and uncommit actions)

1. $R_{\texttt{revise}\varphi}(\mathfrak{M}, w) = \mathit{update\_belief}(\varphi, (\mathfrak{M}, w))$.

2. $R_{\texttt{commit}\alpha}(\mathfrak{M}, w) = \mathit{update\_agenda}^{+}(\alpha, (\mathfrak{M}, w))$, if $\mathfrak{M}, w \models \mathbf{I}(\alpha, \varphi)$ for some φ, otherwise $R_{\texttt{commit}\alpha}(\mathfrak{M}, w) = \emptyset$ (indicating failure of the commit action).

3. $R_{\texttt{uncommit}\alpha}(\mathfrak{M}, w) = \mathit{update\_agenda}^{-}(\alpha, (\mathfrak{M}, w))$, if $\mathfrak{M}, w \models \mathbf{Com}(\alpha)$, otherwise $R_{\texttt{uncommit}\alpha}(\mathfrak{M}, w) = \emptyset$ (indicating failure of the uncommit action).

4. $\texttt{uncommit}\alpha \in \mathcal{C}(\mathfrak{M}, w)$ iff $\mathfrak{M}, w \models \neg\mathbf{I}(\alpha, \varphi)$ for all formulas φ, that is, an agent is able to uncommit to an action if it is not intended to do it (any longer) for any purpose.

Here *update_belief*, *update_agenda*$^+$ and *update_agenda*$^-$ are functions that update the agent's belief and agenda (by adding or removing an action), respectively. Details are omitted here, but essentially these actions are model/state transformers again, representing a change of the mental state of the agent (regarding beliefs and commitments, respectively). The *update_belief*$(\varphi, (\mathfrak{M}, w))$ function changes the model $\mathfrak{M}$ in such a way that the agent's belief is updated with the formula φ, while *update_agenda*$^+(\alpha, (\mathfrak{M}, w))$ changes the model $\mathfrak{M}$ such that α is added to the agenda. The same holds for the *update_agenda*$^-$ function, but now with respect to removing an action from the agenda. The formal definitions can be found in [80, 81] and [57]. The `revise` operator can be used to cater for revisions due to observations and communication with other agents, which we will not go into further here (see [81]).

The interpretation of formulas containing revise and (un)commit actions is now done using the accessibility relations above. One can now define validity as usual with respect to the KARO-models. One then obtains the following validities (of course, in order to be able to verify these one should use the proper model and not the abstraction we have presented here.) Besides the familiar properties from epistemic / doxastic logic, typical properties of this framework, called the KARO logic, include (cf. [80, 57]):

PROPOSITION 21.

1. $\models \mathbf{O}(\alpha;\beta) \leftrightarrow \langle\alpha\rangle\mathbf{O}\beta$
2. $\models \mathbf{Can}(\alpha;\beta,\varphi) \leftrightarrow \mathbf{Can}(\alpha, \mathbf{P}(\beta,\varphi))$
3. $\models [\texttt{revise}\varphi]\mathbf{B}\varphi$
4. $\models \mathbf{K}\neg\varphi \leftrightarrow [\texttt{revise}\varphi]\mathbf{B}\bot$
5. $\models \mathbf{K}(\varphi \leftrightarrow \psi) \rightarrow ([\texttt{revise}\varphi]\mathbf{B}\chi \leftrightarrow [\texttt{revise}\psi]\mathbf{B}\chi)$
6. $\models \mathbf{I}(\alpha,\varphi) \rightarrow \langle\texttt{commit}\alpha\rangle\mathbf{Com}(\alpha)$
7. $\models \mathbf{I}(\alpha,\varphi) \rightarrow \neg\mathbf{A}\texttt{uncommit}(\alpha)$
8. $\models \mathbf{Com}(\alpha) \rightarrow \langle\texttt{uncommit}(\alpha)\rangle\neg\mathbf{Com}(\alpha)$
9. $\models \mathbf{Com}(\alpha) \wedge \neg\mathbf{Can}(\alpha,\top) \rightarrow \mathbf{Can}(\texttt{uncommit}(\alpha), \neg\mathbf{Com}(\alpha))$
10. $\models \mathbf{Com}(\alpha) \rightarrow \mathbf{KCom}(\alpha)$
11. $\models \mathbf{Com}(\alpha_1;\alpha_2) \rightarrow \mathbf{Com}(\alpha_1) \wedge \mathbf{K}[\alpha_1]\mathbf{Com}(\alpha_2)$
12. $\models \mathbf{Com}(\texttt{if } \varphi \texttt{ then } \alpha_1 \texttt{ else } \alpha_2 \texttt{ fi}) \wedge \mathbf{K}\varphi \rightarrow \mathbf{Com}(\varphi?;\alpha_1)$
13. $\models \mathbf{Com}(\texttt{if } \varphi \texttt{ then } \alpha_1 \texttt{ else } \alpha_2 \texttt{ fi}) \wedge \mathbf{K}\neg\varphi \rightarrow \mathbf{Com}(\neg\varphi?;\alpha_2)$
14. $\models \mathbf{Com}(\texttt{while } \varphi \texttt{ do } \alpha \texttt{ od}) \wedge \mathbf{K}\varphi \rightarrow \mathbf{Com}((\varphi?;\alpha);\texttt{while } \varphi \texttt{ do } \alpha \texttt{ od})$

The first of these properties says that having the opportunity to do a sequential composition of two actions amounts to having the opportunity of doing the first action first and then having the opportunity to do the second. The second states that an agent that *can* do a sequential composition of two actions with result φ iff the agent can do the first actions resulting in a state where it has the practical possibility to do the second with φ as result. The third expresses that a revision with φ results in a belief of φ. The fourth states that the revision with φ results in inconsistent belief iff the agent knows $\neg\varphi$ for certain. The fifth expresses that revisions with formulas that are known to be equivalent have identical results. The sixth asserts that if an agent possibly intends to do α with some result φ, it has the opportunity to commit to α with result that it is committed to α (i.e. α is put into its agenda). The seventh says that if an agent intends to do α with a certain purpose, then it is unable to uncommit to it (so, if it is committed to α it has to persevere in it). The eighth property says that if an agent is committed to an action and it has the opportunity to uncommit to it with as result that indeed the commitment is removed. The ninth says that whenever an agent is committed to an action that is no longer known to be practically possible, it knows that it can undo this impossible commitment. The tenth property states that commitments are known to the agent. The last four properties have to do with commitments to complex actions. For instance, the eleventh says that if an agent is committed to a sequential composition of two actions then it is committed to the first one, and it knows that after doing the first action it will be committed to the second action.

The KARO framework has been extended in various ways. In [76] we have given an account of abilities based on dynamic logic (like we did already for results and opportunities). In [46] we considered *automated reasoning* (viz. resolution) methods for (a fragment of) KARO. Furthermore, Dignum and Van Linder [28] have extended it to deal with *speech acts*. Aldewereld *et al.* [2] have extended KARO with multi-agent notions such as *joint* beliefs, actions, goals and commitments. (We will return to this briefly in the next section.) Finally we mention that KARO can also be employed beyond the realm of rational agents: in [55] it is indicated how the framework may be used to describe *emotional* aspects of agency.

7 MULTI-AGENT LOGICS

In the previous sections we have concentrated mainly on single agents and how to describe them. Of course, if multiple agents are around, things become both more complicated as well as more interesting. In this section we will look at two generalizations of single-agent logics to multi-agent logics, viz. multi-agent epistemic logic and multi-agent BDI logic.

7.1 Multi-agent epistemic logic

In a multi-agent setting one can extend a single-agent framework in several ways. To start with, with respect to the epistemic (doxastic) aspect, one can introduce epistemic (doxastic) operators for every agent, resulting in a multi-modal logic, called $\mathbf{S5}_n$. Models for this logic are inherently less simple and elegant as those for the single agent case (cf. [56]). One has indexed operators $\mathbf{K}_i$ and $\mathbf{B}_i$ for agent i's knowledge and belief, respectively. But one can go on and define knowledge operators that involve a group of

agents in some way. This gives rise to the notions of common and (distributed) group knowledge.

The simplest notion is that of 'everybody knows', often denoted by the operator $\mathbf{E_K}$. But one can also add an operator $\mathbf{C_K}$ for 'common knowledge, which is much more powerful. The language is the same as epistemic logic, only now extended with the clause:

DEFINITION 22. (multi-agent epistemic logic.)

- if φ is a multi-agent epistemic formula, then $\mathbf{E_K}\varphi$ and $\mathbf{C_K}\varphi$ are multi-agent epistemic formulas.

For the interpretation we use the following models:

DEFINITION 23.
Models for n-agent epistemic logic are Kripke structures of the form

$$\mathfrak{M} = \langle W, V, R_1, \ldots, R_n, R_E, R_C \rangle$$

where:

- W is a non-empty set of states (or worlds);
- V is a truth assignment function per state;
- The R_i are accessibility relations on W for interpreting the modal operators $\mathbf{K}_i$, assumed to be equivalence relations;
- $R_E = \bigcup_i R_i$;
- $R_C = R_E^*$, the reflexive transitive closure of R_E.

DEFINITION 24. (Interpretation of multi-agent epistemic formulas)
In order to determine whether an multi-agent epistemic formula is true in a model/state pair $\mathfrak{M}, w$ ($\mathfrak{M}, w \models \varphi$), we stipulate:

- $\mathfrak{M}, w \models p$ iff $V(w)(p) = true$, for $p \in \mathcal{P}$;
- the logical connectives are interpreted as usual;
- $\mathfrak{M}, w \models \mathbf{K}_i\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $R_i(w, w')$;
- $\mathfrak{M}, w \models \mathbf{E_K}\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $R_E(w, w')$;
- $\mathfrak{M}, w \models \mathbf{C_K}\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $R_C(w, w')$.

Using the analogous notion of validity as for single-agent epistemic logic, we obtain:

PROPOSITION 25.

- $\models \mathbf{E_K}\varphi \leftrightarrow \mathbf{K}_1\varphi \wedge \ldots \wedge \mathbf{K}_n\varphi$
- $\models \mathbf{C_K}(\varphi \to \psi) \to (\mathbf{C_K}\varphi \to \mathbf{C_K}\psi)$

- $\models \mathbf{C_K}\varphi \to \varphi$
- $\models \mathbf{C_K}\varphi \to \mathbf{C_K}\mathbf{C_K}\varphi$
- $\models \neg\mathbf{C_K}\varphi \to \mathbf{C_K}\neg\mathbf{C_K}\varphi$
- $\models \mathbf{C_K}\varphi \to \mathbf{E_K}\mathbf{C_K}\varphi$
- $\models \mathbf{C_K}(\varphi \to \mathbf{E_K}\varphi) \to (\varphi \to \mathbf{C_K}\varphi)$

The first statement of this proposition shows that the ‘everybody knows’ modality is indeed what its name suggests. The next four says that common knowledge has at least the properties of knowledge: closed under implication, it is true, and enjoys the introspective properties. The sixth property says that common knowledge is known by everybody. The last is a kind of induction principle: the premise gives the condition under which one can ‘upgrade the truth of φ to common knowledge of φ; this premise expresses that it is common knowledge that the truth of φ is known by everybody.

As to multi-agent doxastic logic one can look at similar notions of ‘everybody believes’ and common belief . One can introduce operators $\mathbf{E_B}$ and $\mathbf{C_B}$ for these notions:

DEFINITION 26. (multi-agent doxastic logic)

- if φ is a multi-agent doxastic formula, then $\mathbf{E_B}\varphi$ and $\mathbf{C_B}\varphi$ are multi-agent doxastic formulas

For the interpretation we use the following models:

DEFINITION 27. Models for n-agent doxastic logic are Kripke structures of the form

$$\mathfrak{M} = \langle W, V, R_1, \ldots, R_n, R_F, R_D \rangle$$

where:

- W is a non-empty set of states (or worlds);
- V is a truth assignment function per state;
- The R_i are accessibility relations on W for interpreting the modal operators $\mathbf{B}_i$, assumed to be serial, transitive and euclidean relations;
- $R_F = \bigcup_i R_i$;
- $R_D = R_F^+$, the (nonreflexive) transitive closure of R_F.

Note that the accessibility relation for common belief is the *non*reflexive closure of R_F, contrary to that for common knowledge. This has to do with the fact that common belief needs not to be true!

DEFINITION 28. (Interpretation of multi-agent doxastic formulas.)
In order to determine whether an multi-agent epistemic formula is true in a model/state pair $\mathfrak{M}, w$ ($\mathfrak{M}, w \models \varphi$), we stipulate:

- ... (as usual)
- $\mathfrak{M}, w \models \mathbf{B}_i\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $R_i(w, w')$;
- $\mathfrak{M}, w \models \mathbf{E_B}\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $R_F(w, w')$;
- $\mathfrak{M}, w \models \mathbf{C_B}\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $R_D(w, w')$.

Now we obtain a similar set of properties for common belief (cf. [50]):

PROPOSITION 29.

- $\models \mathbf{E_B}\varphi \leftrightarrow \mathbf{B}_1\varphi \wedge \ldots \wedge \mathbf{B}_n\varphi$
- $\models \mathbf{C_B}(\varphi \to \psi) \to (\mathbf{C_B}\varphi \to \mathbf{C_B}\psi)$
- $\models \mathbf{C_B}\varphi \to \mathbf{E_B}\varphi$
- $\models \mathbf{C_B}\varphi \to \mathbf{C_B}\mathbf{C_B}\varphi$
- $\models \neg\mathbf{C_B}\varphi \to \mathbf{C_B}\neg\mathbf{C_B}\varphi$
- $\models \mathbf{C_B}\varphi \to \mathbf{E_B}\mathbf{C_B}\varphi$
- $\models \mathbf{C_B}(\varphi \to \mathbf{E_B}\varphi) \to (\mathbf{E_B}\varphi \to \mathbf{C_B}\varphi)$

Note the differences due to the fact that common belief is not based on a reflexive accessibility relation.

7.2 Multi-agent BDI logic

Also with respect to the other modalities one may consider multi-agent aspects. In this subsection we focus on the notion of collective or joint intentions. We follow ideas from [29] (but we give a slightly different but equivalent presentation of definitions). We now assume that we have belief and intention operators $\mathbf{B}_i, \mathbf{I}_i$ for every agent $1 \leq i \leq n$. First we enrich the language of multi-agent doxastic logic with operators $\mathbf{E_I}$ (everybody intends) and $\mathbf{M_I}$ (mutual intention). (We call this a multi-agent BDI logic, although multi-agent BI logic would be a more adequate name, since we leave out the modality of desire / goal.)

DEFINITION 30. (multi-agent BDI logic.)
Multi-agent BDI logic is obtained by taking the (analogous clauses of) multi-agent doxastic logic of the previous subsection extended with the clauses:

- if φ is a multi-agent BDI formula, then so is $\mathbf{I}_i\varphi$ for every $1 \leq i \leq n$).
- if φ is a multi-agent BDI formula, then $\mathbf{E_I}\varphi$ and $\mathbf{M_I}\varphi$ are multi-agent BDI formulas.

The language thus obtained is interpreted on slightly enhanced models.

DEFINITION 31.
Models for n-agent BDI logic are Kripke structures of the form

$$\mathfrak{M} = \langle W, V, R_1, \ldots, R_n, R_F, R_D, S_1, \ldots, S_n, S_F, S_D \rangle$$

where:

- W is a non-empty set of states (or worlds);
- V is a truth assignment function per state;
- The R_i are accessibility relations on W for interpreting the modal operators $\mathbf{B}_i$, assumed to be serial, transitive and euclidean relations, while the S_i are accessibility relations on W for interpreting the modal operators $\mathbf{I}_i$, assumed to be serial relations.
- $R_F = \bigcup_i R_i$ and $S_F = \bigcup_i S_i$;
- $R_D = R_F^+$ and $S_D = S_F^+$, the (nonreflexive) transitive closure of R_F and S_F, respectively.

DEFINITION 32. (Interpretation of multi-agent BDI formulas.) In order to determine whether an multi-agent epistemic formula is true in a model/state pair $\mathfrak{M}, w$ ($\mathfrak{M}, w \models \varphi$), we stipulate:

- $\mathfrak{M}, w \models \mathbf{I}_i\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $S_i(w, w')$;
- $\mathfrak{M}, w \models \mathbf{E_I}\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $S_F(w, w')$;
- $\mathfrak{M}, w \models \mathbf{M_I}\varphi$ iff $\mathfrak{M}, w' \models \varphi$ for all w' with $S_D(w, w')$;

Hence we get similar properties for mutual intention as we had for common belief (but of course no introspective properties):

PROPOSITION 33.

- $\models \mathbf{E_I}\varphi \leftrightarrow \mathbf{I}_1\varphi \wedge \ldots \wedge \mathbf{I}_n\varphi$;
- $\models \mathbf{M_I}(\varphi \to \psi) \to (\mathbf{M_I}\varphi \to \mathbf{M_I}\psi)$;
- $\models \mathbf{M_I}\varphi \to \mathbf{E_I}\varphi$;
- $\models \mathbf{M_I}\varphi \to \mathbf{E_I}\mathbf{M_I}\varphi$;
- $\models \mathbf{M_I}(\varphi \to \mathbf{E_I}\varphi) \to (\mathbf{E_I}\varphi \to \mathbf{M_I}\varphi)$.

We see that E-intentions ('everybody intends') and mutual intentions are defined in a way completely analogous with E-beliefs ('everybody believes') and common beliefs, respectively.

Next we define the notion of *collective intention* ($\mathbf{C_I}$) as follows:

DEFINITION 34.

- $\mathbf{C_I}\varphi \;=\; \mathbf{M_I}\varphi \wedge \mathbf{C_B}\mathbf{M_I}\varphi$

This definition states that collective intentions are those formulas that are mutually intended and of which this mutual intention is a common belief amongst all agents in the system.

Furthermore, we mention here that in the literature there is also other work on BDI-like logics for multi-agent systems where we encounter such notions as joint intentions, joint goals and joint commitments, mostly coined in the setting of how to specify teamwork. Seminal work was done by Cohen & Levesque [19]. This work was a major influence on our own multi-agent version of KARO [2]. An important complication in a notion of joint goal involves that of persistence of the goal: where in the single agent case the agent pursues its goal until it believes it has achieved it or believes it can never be achieved, in the context of multiple agents, the agent that realizes this, has to inform the others of the team about it so that the group / team as a whole will believe that this is the case and may drop the goal. Also the work of Singh [71] must be mentioned here, where an interesting distinction is made between *exodeictic* and *endodeictic* intentions of groups, where the former is 'pointing outward' (intention of the group as viewed by others) while the latter is 'pointing inward' (intention as viewed by the group itself).

8 FURTHER DEVELOPMENTS

One may wonder where the development of agent logics is heading. Moreover, aren't these logics which are ever increasing in expressive power, becoming much too complex in terms of computational complexity to be used in practice? To begin with the latter: yes, one may indeed expect higher complexity when stacking modalities (cf. [44]), but whether this is considered a bad thing, depends on the application. It is my impression that logics for (particularly single) agents have been employed to try and coin philosophical concepts more concretely and give them a precise meaning within the logical formalisms that have been proposed. They were not meant for practical reasoning about agents in the first instance. After having done this work, agent researchers such as Rao & Georgeff turned to devising practical implementations of agent systems, employing the concepts they studied in the logics in a much more practical way (e.g. databases of beliefs and goals instead of modal operators), which begs the very important and not yet completely resolved question how the formal and practical notions of e.g. BDI relate to each other. Other people tried to render their logical specifications directly executable by considering fragments of modal/temporal logics (e.g. the researchers working on the METATEM language [33]). On the other hand there is also some positive (or at least not too negative) news even for those who are interested in the computational complexity of the theoretical BDI-like logics. In [64] it is reported that the complexity of tableau-based decision procedures for propositional logic is not higher than the complexity of the underlying temporal logic (which is, admittedly, quite hard, viz. exponential in the size of the input formula). Furthermore, one may also consider restricting the languages of combined modal formalisms to reduce complexity, but, of course, this will generally come with a reduction of expressive power as well, and it depends on the applications whether this is sensible. We refer to [5] for a discussion of both (positive and negative) results on the complexity of combined modal logics and possible ways to respond to these results. As said before, concerning logics for specifying the behavior and attitudes of single agents one can observe that recent work has turned away from purely logical theories towards more implementation-oriented approaches. For example, research on agent-oriented programming languages such as Agent0 [70], AgentSpeak(L) [63], and 3APL [45], and agent-oriented software engineering (AOSE, [94]), more generally. Of course, as in software engineering in general, there is a need to verify that the software

one has developed is correct in the sense that it behaves as specified *a priori*. In the field of agent-oriented programming this has sparked off research on correctness logics that are adequate in this context. Naturally, these logics are very close to the logics we have seen in this chapter: if one programs in terms of cognitive notions such as beliefs, desires, goals, plans, etc., it is obvious that one also needs to reason about these notions when one tries to verify such a program! For example, Bordini *et al.* [7] work on the use of model-checking techniques for a linear-time temporal logic in which properties of programs written in AgentSpeak can be specified. We ourselves have initiated work on the correctness of (fragments of) 3APL [82]. Time will tell how successful these approaches will be. As for logics for multi-agent systems: if one considers 'societies of agents' obviously also other notions become important besides mere multi-agent extensions of -notions. For instance, one can investigate how communication takes place in such a system, and how this affects the mental states of the agents in the system. This, in turn, is important for synchronization, coordination, and cooperation in the system. There has also been done some work on this. As mentioned before, Dignum and Van Linder [28] have extended the KARO framework to deal with speech acts. Moreover, in societies it may be important to consider norms, obligations and permissions as a way to control societal behavior.

In a series of papers [12, 11, 10] Van der Torre *et al.* have extended the BDI framework to what they call the BOID framework dealing with the Beliefs, Obligations, Intentions and Desires of agents. Although the language of BOID contains operators for belief (B), obligation (O), intention (I) and desire (D), and thus looks like an amalgam of BDI and deontic logic, BOID logic is not really a modal logic in the proper sense. The operators are not interpreted by means of accessibility relations in Kripke models. Instead, a default logic [65] is employed and a BOID agent is specified by a number of default rules involving the BOID notions/operators, together with a priority relation on these rules. The form of these rules is $X_1 \hookrightarrow X_2$, where X_1, X_2 typically are expressions of the form $\mathrm{B}\varphi$, $\mathrm{O}\varphi$, $\mathrm{I}\varphi$, or $\mathrm{D}\varphi$. The main concern is which (consistent) extensions are yielded representing how the beliefs, obligations, intentions and desires can be combined (consistently) taking the priority on rules into account. Another extension with a similar philosophy in mind of incorporating social notions into the BDI framework was proposed by Dignum *et al.* [27, 22]. This framework is called B-DOING, and treats Beliefs, Desires, Obligations, Intentions, Norms and Goals. This approach is more like a normal modal logic, although a number of extra elements is added. As to the deontic aspect, this framework is built on dyadic (conditional) obligations. Logically, the most important addition is the incorporation of two operators: $N^z(p|q)$ and $O^x_{ab}(p|q)$, with as intended meanings 'it is a norm of the society / organization z that p should be true when q is true' and 'when q is true, individual a is obliged to b that p should be true, where z is the organization/society that is responsible for enforcing the penalty', respectively. Formally, to give an interpretation to these operators a possible world semantics is employed that is rather involved. The upshot of this semantics is that $N^z(p|q)$ ($O^z(p|q)$) holds if $p \wedge q$ worlds are preferred to $\neg p \wedge q$ ones and the (maximally) preferred q worlds satisfy p, where the preference relation on worlds is induced by (associated with) the norms and obligations in organization z, respectively. Related to this is a development in the implementation of multi agent systems where one tries to restrain/constrain individual agents by means of an (electronic) institution [30]). The idea here is that agents in a MAS or agent society must obey certain norms and to assist them in doing this certain protocols are devised that the agents in the system are advised or even enforced to follow

in order to abide by the norms. This calls for questions as to the relation between the typically abstract norms and the typically very concrete protocols, and how following the protocols guarantees non-violation of the norms. These questions are partly of a logical nature. For instance, how may a particular step of the protocol *count as* an implementation of an abstract norm [47]? This is of vital importance if one wants to verify whether the protocol guarantees norm compliance. Interestingly, also the logic of 'counts-as' can be put into a modal logic setting [39], opening up a new area of modal logic applications. In conclusion we can state that the application area of modal logic to reason about multi-agent systems is still flourishing, and many interesting problems remain to be investigated and solved...!

9 COUNTERFACTUAL CONDITIONALS

A chapter on modal logics in Artificial Intelligence should contain a section in which conditional logics are discussed, because conditionals logics, in particular the logics developed for counterfactual conditionals, pop up everywhere in AI where non-monotonicity plays a role.

Counterfactual conditionals are sentences of the form

(1) $\ulcorner$*If it had been the case that* φ*, it would have been the case that* $\psi\urcorner$

They are typically uttered in contexts where the antecedent is false and known to be false. Therefore, they cannot be analyzed as material implications, because material implications with a false antecedent are true no matter what the consequent says.

Counterfactuals cannot be analyzed as strict implications either. One cannot equate a sentence of the form given in 1 with a formula of the form

(2) $\Box(\varphi \to \psi)$

where $\Box$ is the necessity operator of any normal system of modal logic, because any such system validates logical principles that do not hold for counterfactuals. One such principle is *Strengthening the Antecedent.* In any extension of **K**, we have

$$\Box(\varphi \to \chi) \models \Box((\varphi \wedge \psi) \to \chi)$$

However, from

(3) *If I had put sugar in my coffee, it would have tasted better,*

it does not follow that

(4) *If I had put sugar and diesel oil in my coffee, it would have tasted better.*

The starting point for the discussion in the following sections is the analysis of counterfactuals developed by Robert Stalnaker [72] and David Lewis [52]. Roughly put, they proposed the following truth condition for counterfactual conditionals.

- A sentence of the form $\ulcorner$*If it had been the case that* φ*, it would have been the case that* $\psi\urcorner$ is true in the actual world w iff the consequent ψ is true in all accessible worlds in which (a) the antecedent φ is true, and which (b) in other respects differ minimally from w.

In other words, the consequent ψ need not be true in *all* accessible worlds in which the antecedent φ is true, which it would have to be if counterfactuals were strict implications. What matters is ψ's truth value in a particular subset of this set, the φ-worlds that are most similar to the actual world. It is easy to see how this semantics blocks the inference from 3 to 4. Consider the set S of worlds in which (i) *I put sugar in my coffee* is true and which (ii) in other respects differ minimally from the actual world. Presumably, *I put diesel oil in my coffee* is false in all these worlds. Given this, the set T of worlds in which (i) *I put sugar and diesel oil in my coffee* is true, but which (ii) in other respects differ minimally from the actual world will not be a subset of S. Now, *the coffee tastes fine* could very well be true in every world in S, but false in some of the worlds in T.

Let us get more precise. In the sequel we are interested in languages, frames and models that are built up as follows.

- Extend the languages of propositional logic with a new binary operator $\rightsquigarrow$. Until further notice we will read '$\varphi \rightsquigarrow \psi$' as '*If it had been the case that φ, it would have been the case that ψ*'.

- Interpret the resulting languages in frames $\mathfrak{F} = \langle W, \prec \rangle$, where (i) $W \neq \emptyset$ and (ii) $\prec$ is a function which assigns to every $w \in W$ a strict partial ordering $\prec_w$ on some subset W_w of W. The elements of W will play the role of possible worlds. Until further notice the strict partial ordering $\prec_w$ is meant to play the role of a comparative similarity relation; read '$u \prec_w v$' as ' u is more similar to w than v'. The field W_w of this relation $\prec_w$ is the set of worlds that are accessible from w. Inaccessible worlds, i.e. the worlds outside W_w are supposed to be so unlike w that in w it is absurd to assume that the real world might have been be one of those.

- Supply a frame with a valuation V which assigns a truth value to every atomic sentence in every world to get a model $\mathfrak{M} = \langle W, \prec, V \rangle$. As elsewhere in this book, '$\mathfrak{M}, w \models \varphi$' is used to indicate that the formula φ is true in the world w (of the model $\mathfrak{M}$). I will write '$[\![\varphi]\!]_{\mathfrak{M}}$' to refer to $\{w \in W \mid \mathfrak{M}, w \models \varphi\}$, and call this set the proposition expressed by φ (in $\mathfrak{M}$). When it is clear which model $\mathfrak{M}$ is at stake the subscript '$\mathfrak{M}$' in $[\![\varphi]\!]_{\mathfrak{M}}$ will be omitted. Worlds in $[\![\varphi]\!]_{\mathfrak{M}}$ will be called $[\![\varphi]\!]$-worlds.

- Add the following clause to the list of truth conditions for the standard connectives.

  $\mathfrak{M}, w \models \varphi \rightsquigarrow \psi$ iff for every $u \in W_w \cap [\![\varphi]\!]$ the following holds:
  there is some $u' \in [\![\varphi]\!]$ such that $u' \preceq_w u$ and $\mathfrak{M}, u'' \models \psi$ for every $u'' \in [\![\varphi]\!]$ such that $u'' \preceq_w u'$.

Part of the complexity of this truth condition is due to the fact that the partial orders introduced above do not have to satisfy the so-called

Limit Assumption : For every $w \in W$, the relation $\prec_w$ is well-founded.

Call any $u \in U$ a *closest* U-world to w iff $u \in W_w \cap U$ and there is no $v \in U$ such that $v \prec_w u$. Given the Limit Assumption we can be sure that in every non empty subset U of W_w we can find some worlds that are closest to w. This enables us to reformulate the truth condition in a more perspicuous way.

- Suppose the frame $\mathfrak{F} = \langle W, \prec \rangle$ satisfies the Limit Assumption, and consider the model $\mathfrak{M} = \langle W, \prec, V \rangle$. The following holds:

  $\mathfrak{M}, w \models (\varphi \rightsquigarrow \psi)$ iff $\mathfrak{M}, u \models \psi$ for every closest $[\![\varphi]\!]$-world u to w.

Is it reasonable to assume that the comparative similarity relation is well-founded? Are there propositions $[\![\varphi]\!]$ such that for every $[\![\varphi]\!]$-world u some $[\![\varphi]\!]$world v exists that is more similar to w than u is — so that one can get closer and closer to w without ever getting in a $[\![\varphi]\!]$-world that is closest to w? It is not difficult to think of examples. How tall would you be in the closest world in which you are taller than you actually are?

The logic generated by the semantics sketched above is given by the following axioms and rules:

$$\begin{array}{rl}
\text{(CI)}: & \vdash \varphi \rightsquigarrow \varphi \\
\text{(CC)}: & \vdash ((\varphi \rightsquigarrow \psi) \wedge (\varphi \rightsquigarrow \chi)) \rightarrow (\varphi \rightsquigarrow (\psi \wedge \chi)) \\
\text{(CW)}: & \vdash (\varphi \rightsquigarrow \psi) \rightarrow (\varphi \rightsquigarrow (\psi \vee \chi)) \\
\text{(ASC)}: & \vdash ((\varphi \rightsquigarrow \psi) \wedge (\varphi \rightsquigarrow \chi)) \rightarrow ((\varphi \wedge \psi) \rightsquigarrow \chi) \\
\text{(AD)}: & \vdash ((\varphi \rightsquigarrow \chi) \wedge (\psi \rightsquigarrow \chi)) \rightarrow ((\varphi \vee \psi) \rightsquigarrow \chi) \\
\text{(MP}\rightarrow\text{)}: & \varphi \rightarrow \psi, \varphi \vdash \psi \\
\text{(REA)}: & \text{If } \vdash \varphi \leftrightarrow \psi, \text{ then } \varphi \rightsquigarrow \chi \vdash \psi \rightsquigarrow \chi
\end{array}$$

Here, (CI) is short for *Conditional Identity* , (CC) for *Conjunction of Consequents*, (CW) for *Weakening the Consequent*, (SAC) for *Strengthening the Antecedent with a Consequent*, (AD) for *Disjunction of Antecedents*, (MP$\rightarrow$)for *Modus Ponens for* $\rightarrow$, and (REA) for *Replacement of Equivalent Antecedents.*[6]

This system, called **P**, is for conditional logic what **K** is for modal logic: it is the minimal system, which you get if you assume that the relations $\prec_w$ are just partial orderings[7] and have no additional properties. That **P** is (weakly) complete with respect to the class of partial orders was first proved by Burgess in [14]. This proof has been simplified by Friedman and Halpern in [41]. An altogether different proof of (strong) completeness is given in Veltman[84].

If in **P** the scheme (ASC) is strengthened to

$$\textit{Strengthening the Antecedent (AS)}: \quad (\varphi \rightsquigarrow \chi) \rightarrow ((\varphi \wedge \psi) \rightsquigarrow \chi)$$

one gets the system $\mathbf{K}^{\rightsquigarrow}$, which is just **K** in disguise.

PROPOSITION 35.

1. *In the language of modal logic, define* $\varphi \rightsquigarrow \psi$ *by* $\Box(\varphi \rightarrow \psi)$. *Suppose* $\Delta \cup \{\varphi\}$ *consists of formulas of the language of conditional logic. Then* $\Delta \vdash_{\mathbf{K}^{\rightsquigarrow}} \varphi$ *iff* $\Delta \vdash_{\mathbf{K}} \varphi$.

2. *In the language of conditional logic, define* $\Box\varphi$ *as* $\neg\varphi \rightsquigarrow \bot$. *Suppose* $\Delta \cup \{\varphi\}$ *consist of formulas of the language of modal logic.* $\Delta \vdash_{\mathbf{K}} \varphi$ *iff* $\Delta \vdash_{\mathbf{K}^{\rightsquigarrow}} \varphi$.

It is straightforward to prove (i) and (ii) from left to right. To prove (i) from right to left use (ii) from left to right, and similarly for (ii) from right to left use (i) from left to right.

[6] Given CC and WW, one does not need a separate Replacement rule for Equivalent Consequents to prove the full Replacement Rule: If $\vdash \varphi \leftrightarrow \psi$, then $\chi \vdash \chi'$ where χ' is the result of substituting φ for ψ at one or more places where ψ occurs in χ.

[7] Actually, the only property that matters is transitivity. Irreflexivity is not expressible.

Does the Limit Assumption make a difference to the logical properties of $\rightsquigarrow$? It does, but only for arguments with infinitely many premises. Under the Limit Assumption compactness fails:

PROPOSITION 36.
Let $p_1, \ldots, p_n, \ldots$ be countably many distinct atomic sentences, and let φ_k, and ψ_k, for any k be defined as follows:

$$\varphi_k = ((p_1 \vee \ldots, p_{k+1}) \rightsquigarrow \neg(p_1 \vee \ldots, p_k))$$

$$\psi_k = \neg((p_1 \vee \ldots, p_{k+1}) \rightsquigarrow (p_1 \vee \ldots, p_k))$$

Consider the set Δ consisting of all φ_k's and ψ_k's. The Limit Assumption holds iff Δ is not satisfiable.

So far no constraints have been imposed on the comparative similarity relation $\prec$ that distinguish it from any other other relation that holds between three objects u, v and w when 'u is more ... to w than v. What extras does the fact one has to fill the dots with the word 'similar' bring?

Weak Centering: $w \in W_w$ for every $w \in W$, and for no $v \in W_w$ it holds that $v \prec_w w$.

Imposing this constraint means the next rule gets valid.

$$\textit{Modus Ponens for} \rightsquigarrow (\mathrm{MP}^{\rightsquigarrow}): \quad \varphi \rightsquigarrow \psi, \varphi \vdash \psi$$

Weak centering says that no world can be closer to a world w than w itself. If in addition you think that no world different from w can be equally close to w as w itself, you get this.

Strong Centering: $w \in W_w$ for every $w \in W$, and for every $v \in W_w$ such that $v \neq w$, $w \prec_w v$.

The logical pay off is this:

$$\textit{Conjunctive Sufficiency}: \quad (\varphi \wedge \psi) \rightarrow (\varphi \rightsquigarrow \psi)$$

If in establishing similarities and dissimilarities *all* characteristics of the worlds are taken into consideration, one of the consequences will be that only the world w itself will resemble the world w as much as the world w does. But in cases in which only *some* characteristics matter, there will often be more than one world that is just like w in all relevant respects. In these cases the structures will satisfy *Weak Centering*, but not *Strong Centering*

If you believe that two different worlds cannot be equally close to the actual one, you will support the following constraint:

$$\textit{Connectedness:} \quad \text{for any } u, v \in W_w, \text{ either, } u = w, \text{ or } u \prec_w v, \text{ or } v \prec_w u.$$

In the presence of the Limit Assumption Connectedness implies that there will always be for any antecedent φ at most one $[\![\varphi]\!]$-world most resembling the actual world. This uniqueness assumption brings the following principle in its train:

$$\textit{Conditional Excluded Middle } (\mathrm{CEM}): \quad (\varphi \rightsquigarrow \psi) \vee (\varphi \rightsquigarrow \neg\psi)$$

Couldn't there be cases where we have several $[\![\varphi]\!]$-worlds, all equally close to the actual world and all closer to the actual world than any other world? In [52] Lewis brings in the following example, due to W.V.O. Quine, to show that such cases do exist:

(5) *If Bizet and Verdi had been compatriots, Bizet would have been Italian.*

(6) *If Bizet and Verdi had been compatriots, Verdi would have been French.*

Now, if there is only one world closest to the actual world in which Bizet and Verdi are compatriots, it is impossible that both (5) and (6) are false while (7) is true:

(7) *If Bizet and Verdi had been compatriots, either Verdi would have been French or Bizet would have been Italian.*

According to Lewis one can accept (7) without having to accept (5) or (6), and so he rejects the uniqueness assumption.

Lewis does accept the following constraint:

Almost-Connectedness: for any $u, v, w \in W_z$, if $u \prec_z w$, then either $u \prec_z v$ or $v \prec_z w$.

Define $u \simeq_w v$ iff neither $u \prec_w v$ nor $u \prec_w v$. The relation $\simeq_w$ is reflexive, and symmetric, but not necessarily transitive. Requiring that the relation $\prec_w$ is almost connected amounts to requiring that $\simeq_w$ is transitive. In that case we can read '$u \simeq_w v$' as 'u and v are equally similar to w', and we can picture the relation $\prec_w$ as a linear order of equivalence classes of worlds. The corresponding axiom scheme is this:

Strengthening with a Possibility (ASP): $(\neg(\varphi \rightsquigarrow \neg\psi) \wedge (\varphi \rightsquigarrow \chi)) \rightarrow ((\varphi \wedge \psi) \rightsquigarrow \chi)$

The axiom ASP says that an antecedent of a counterfactual $\varphi \rightsquigarrow \chi$ may be strengthened with a formula ψ provided that the counterfactual assumption φ does not exclude the possibility that ψ. So, given the validity of ASC, this leaves only one case in which it is not allowed to strengthen the antecedent of a counterfactual $\varphi \rightsquigarrow \chi$ with the formula ψ. That's when $\varphi \rightsquigarrow \neg\psi$ is true and $\varphi \rightsquigarrow \psi$ is false. In the other three cases:

1. $\varphi \rightsquigarrow \psi$ is true, $\varphi \rightsquigarrow \neg\psi$ is true
2. $\varphi \rightsquigarrow \psi$ is true, $\varphi \rightsquigarrow \neg\psi$ is false
3. $\varphi \rightsquigarrow \psi$ is false, $\varphi \rightsquigarrow \neg\psi$ is false

strengthening the antecedent φ with ψ is valid.

Is it reasonable to assume that the comparative similarity relation is almost connected? Everybody who has tried to analyze the notion of comparative similarity and to explain how it comes about, concluded that it is not.[8] Still, it is not easy to find a convincing counterexample to ASP. Ginsberg [38] suggests:

It's not the case that if Verdi and Satie had been compatriots, Satie and Bizet would not have been compatriots.
If Verdi and Satie had been compatriots, Bizet would have been French

---

If both Verdi and Satie, and Satie and Bizet had been compatriots, Bizet would have been French.

Despite this counterexample and the theoretical arguments underlying it, presently the most popular system for counterfactuals is given by $\mathbf{P}$ + ASP + $\mathrm{MP}^{\rightsquigarrow}$.

---

[8]For a critical analysis of the notion comparative similarity see Fine[32], Veltman[83], [86], Tichy[73], Pollock[61], Lewis[53], Kratzer[48], Kratzer[49].

10 NON-MONOTONIC CONSEQUENCE RELATIONS

The standard model theoretic notion of logical validity is monotonic: if ψ follows from $\varphi_1, \ldots, \varphi_n$, then ψ follows from $\varphi_1, \ldots, \varphi_n, \varphi_{n+1}$. This is so, because the standard notion requires that the conclusion be true in *any* model in which the premises are true, and, clearly, if ψ is true in *any* model in which $\varphi_1, \ldots, \varphi_n$ are true, then certainly so in *any* model in which $\varphi_1, \ldots, \varphi_n$ plus φ_{n+1} are true.

Non-monotonic logic started when in the late seventies logicians working in Artificial Intelligence noticed that in many practical situations when people draw a conclusion, they do not reckon with all conceivable possibilities left open by the premises, but only with some of these, the *most normal* ones or the ones *most likely* to occur. Something similar happened in the field of epistemic logic when at some point one got interested in arguments in which the premises represent 'all that is known'. In such cases the question is not so much whether the conclusion holds in all situations in which the premises hold, but whether it holds in the *'most ignorant'* situations among these.

There are more examples in which the phrase *'any model'* occurring in the definition of the standard notion of validity is restricted to 'the most ... models', where the dots are to be filled by some adjective. All these alternative notions of validity can be formally captured by assuming that the models of the language are ordered by a well-founded partial ordering $\prec$ and to stipulate that ψ is a (non-monotonic) consequence of $\varphi_1, \ldots, \varphi_n$ iff ψ is true in all models that are $\prec$-minimal in the class of models in which the premises $\varphi_1, \ldots, \varphi_n$ are true.

This must remind the reader of the frames and the truth-condition for counterfactuals introduced in the preceding section. Indeed, we are dealing here with a special case of the framework introduced there. In addition to the Limit Assumption, the following constraints are at stake.

Universality:	for every $w \in W, W_w = W$.
Absoluteness:	for every $u, w \in W, \prec_u = \prec_w$.

Absoluteness says that the relation $\prec_w$ is in fact independent of w, so that one can omit the subscript. *Universality* adds that $\prec$ is an ordering of the set of all possible worlds. So, the relations $\prec_w$ are all equal to one and the same well-founded partial ordering $\prec$ of the set of all possible worlds.

Secondly, given *Universality* and *Absoluteness*, if a sentence of the form $\varphi \rightsquigarrow \psi$ is true in one world of a model $\mathfrak{M}$, it will in fact be true in every world of $\mathfrak{M}$. This means that the following holds:

$$\mathfrak{M} \models \varphi \rightsquigarrow \psi \text{ iff } \mathfrak{M}, w \models \psi \text{ for every } \prec\text{-minimal world } w \text{ in } [\![\varphi]\!].$$

Finally, let's write '$\varphi_1, \ldots, \varphi_n \mid\!\sim \psi$' instead of '$(\varphi_1 \wedge \ldots \wedge \varphi_n) \rightsquigarrow \psi$', and '$\varphi_1, \ldots, \varphi_n \mid\!\sim_{\mathfrak{M}} \psi$' instead of '$\mathfrak{M} \models (\varphi_1 \wedge \ldots \wedge \varphi_n) \rightsquigarrow \chi$'. In doing so, we arrive at what in Kraus et al.[51] appears as the definition of 'the entailment relation $\mid\!\sim_{\mathfrak{M}}$ defined by the model $\mathfrak{M}$'.

(*) $\qquad \varphi_1, \ldots, \varphi_n \mid\!\sim_{\mathcal{M}} \psi$ iff $\mathfrak{M}, w \models \psi$ for every $\prec$-minimal world w in $[\![\varphi_1]\!] \cap \ldots \cap [\![\varphi_n]\!]$.

The authors of [51] refer to the relation $\prec$ as a preference relation, and to the models $\mathfrak{M} = \langle W, \prec, V \rangle$ as preferential models. They are interested in the properties of the *preferential* consequence relation $\mid\!\sim$, formally modeled by (*).

It will come as no surprise that $\mid\!\sim$ behaves like a counterfactual implication $\rightsquigarrow$. However, there is an important syntactic difference between between $\mid\!\sim$ and $\rightsquigarrow$. Conditionals sometimes occur nested in other conditionals — as in $\varphi \rightsquigarrow (\psi \rightsquigarrow \chi)$ — but nesting sentences expressing an entailment relation is quite incomprehensible. The entailment relation belongs to the metalanguage rather than the object language. What could $\varphi \mid\!\sim (\psi \mid\!\sim \chi)$ possibly mean?

This, however, does not give rise to important semantic differences between $\mid\!\sim$ and $\rightsquigarrow$.

PROPOSITION 37.
Let Δ be a set of formulas containing only non-nested conditionals. If Δ is satisfiable on any frame, then it is satisfiable on a frame with a universal and absolute $\prec$ relation.[9]

Given this, one might expect the system **P** to give a complete characterization of the properties of $\mid\!\sim$. Kraus et al.[51], using the methods of [84], prove that this is indeed the case. One easily recognizes the axiom schemes introduced in the previous section in the next principles of entailment.

$$\begin{array}{rl}
\text{(CI) becomes } \textit{Reflexivity}: & \varphi \mid\!\sim \varphi \\
\text{(CC) becomes } \textit{And}: & \text{If } \varphi \mid\!\sim \psi \text{ and } \varphi \mid\!\sim \chi, \text{ then } \varphi \mid\!\sim (\psi \wedge \chi) \\
\text{(CW) becomes } \textit{Right Weakening}^{10}: & \text{If } \varphi \mid\!\sim \psi \text{ and } \psi \models \chi, \text{ then } \varphi \mid\!\sim \chi \\
\text{(ASC) becomes } \textit{Cautious Monotony}: & \text{If } \varphi \mid\!\sim \psi \text{ and } \varphi \mid\!\sim \chi, \text{ then } \varphi, \psi \mid\!\sim \chi \\
\text{(AD) becomes } \textit{Or}: & \text{If } \varphi \mid\!\sim \chi \text{ and } \psi \mid\!\sim \chi, \text{ then } (\varphi \vee \psi) \mid\!\sim \chi \\
\text{(REA) becomes } \textit{Left Logical Equivalence}: & \text{If } \varphi \models \psi \text{ and } \psi \models \varphi, \text{ then} \\
& \quad \text{if } \varphi \mid\!\sim \chi, \text{ also } \psi \mid\!\sim \chi
\end{array}$$

The literal translation of (CW) would be ' If $\varphi \mid\!\sim \psi$, then $\varphi \mid\!\sim \psi \vee \chi$'. *Right Weakening* is equivalent to this. ($\models$ stands for the classical entailment relation.)

As a characterization of an entailment relation the system **P** is a bit odd. One would expect only purely structural principles. The principles *Or*, and *And*, however, presuppose that the object language has connectives with the properties of conjunction and disjunction. Kraus et al.[51] also discuss a weaker system consisting of only structural rules. It is called **C**, where '**C**' stands for 'cumulative', and it was originally proposed by Dov Gabbay[34] as a system describing the weakest reasonable consequence relation. It is given by: *Reflexivity, Right Weakening, Cautious Monotony, Left Logical Equivalence*, and

$$\textit{Cut}: \quad \text{If } \varphi, \psi \mid\!\sim \chi \text{ and } \varphi \mid\!\sim \psi, \text{ then } \varphi \mid\!\sim \chi$$

It is left to the reader to show that *Cut* is a derived rule of **P**.

An important field in which a non-monotonic consequence relation is employed is the field of default reasoning. Actually, in the modal approach to default reasoning not only the consequence relation but also the defaults rules themselves are modeled after conditionals. Read '$\varphi \rightsquigarrow \psi$' as '*If φ, then normally ψ*', and take the underlying well-founded ordering $\prec$ of the set of possible worlds to be the relation '*... is more normal than...*'. Then a rule $\varphi \rightsquigarrow \psi$ will hold in a model if ψ is true at the most normal $[\![\varphi]\!]$-worlds. An agent

[9]This proposition does not hold for arbitrary sets of formulas. If nesting is allowed one has to add the **S5** axioms $\Box\varphi \to \varphi$, $\Box\varphi \to \Box\Box\varphi$, and $\Diamond\varphi \to \Box\Diamond\varphi$ to **P** in order to get a system that is complete with respect to the universal and absolute frames. (Here $\Box\varphi =_{df} \neg\varphi \rightsquigarrow \bot$.)

who has learnt that φ is the case and who accepts the rule $\varphi \rightsquigarrow \psi$ will expect that ψ is the case provided there is no evidence that the case at hand is exceptional.

More generally, default rules are of crucial importance when some decision must be made in circumstances where the facts of the matter are only partly known. In such a case one must reckon with several possibilities. Default rules serve to narrow down this range of possibilities: some of these possibilities are more normal than other. An agent will expect that the actual world conforms to as many standards of normality as possible given the information at hand.

Several theories have been developed that formalize this phenomenon. They differ in the way they formally capture the idea that an agent will expect the actual world to be as normal as possible given the circumstances described by the premises. James Delgrande [21] was the first who proposed a definition for the set of worlds that best meet the agent's expectations. Alternative definitions are proposed in Asher & Morreau[4] and Veltman [85]. See [6] for a detailed comparison of these theories and Halpern et.al.[41] for technical insights.

11 BELIEF REVISION

There is still another way to read $\varphi \rightsquigarrow \psi$: 'After a revision by φ, it is believed that ψ'. Here the topic is belief revision, and the question at stake is how an agent should change his or her beliefs in the face of new information. The formula φ is supposed to bring new information — possibly contradicting the information available — and if $\varphi \rightsquigarrow \psi$ is true, this means that ψ is accepted after the incorporation φ in ones stock of beliefs.

Checking the axioms for $\rightsquigarrow$ with this reading in mind, we find that many of them sound quite plausible. For example: *Conditional Identity*, $\varphi \rightsquigarrow \varphi$, becomes *'After a revision by φ, it is believed that φ'*, and *Disjunction of Antecedents*, $(\varphi \rightsquigarrow \chi) \wedge (\psi \rightsquigarrow \chi)) \rightarrow ((\varphi \vee \psi) \rightsquigarrow \chi)$, can be read as '*If both a revision with φ and a revision by ψ lead to the belief χ, then so does a revision by $\varphi \vee \psi$*'. Are we here once more dealing with **P** or one of its extensions?

Let's start at the beginning. In 1985 Carlos Alchourron, Peter Gärdenfors and David Makinson published a by now classic paper [1] in which they discuss three forms of belief change: expansion, contraction and revision. Modeling an agents beliefs by a deductively closed theory K, called a belief set, a number of rationality postulates are laid down for the expansion K^+_φ of K by φ, the contraction K^-_φ of K by φ, and the revision K^*_φ of K by φ.

The constraints for expansion uniquely determine K^+_φ as the set $\{\psi \mid K, \varphi \vdash \psi\}$. The constraints for contraction and revision do not uniquely determine K^-_φ and K^*_φ because the outcomes of these operations do not depend on logical factors only. Epistemic factors may also play a role. For example, in revising their beliefs agents may be prepared to give up one sentence rather than the other because the empirical support for the one is much better than for the other.

Here are the so-called AGM postulates for revision as formulated in Gärdenfors[35]:

$\mathbf{K}^*1$ For any sentence φ and any belief set K, K^*_φ is a belief set

$\mathbf{K}^*2$ $\varphi \in K^*_\varphi$

$\mathbf{K}^*3$ $K^*_\varphi \subseteq K^+_\varphi$

K*4 If $\neg\varphi \notin K$, then $K^+_\varphi \subseteq K^*_\varphi$

K*5 $K^*_\varphi = \{\psi \mid \bot \vdash \psi\}$ iff $\vdash \neg\varphi$;

K*6 If $\vdash \varphi \leftrightarrow \psi$, then $K^*_\varphi = K^*_\psi$

K*7 $K^*_{\varphi\wedge\psi} \subseteq (K^*_\varphi)^+_\psi$

K*8 If $\neg\varphi \notin K$, then $(K^*_\psi)^+_\varphi \subseteq K^*_{\varphi\wedge\psi}$

Adam Grove[40] was the first to notice that the semantics for counterfactuals as defined in section 9, supplies an interpretation for these postulates. For every belief set K, we consider the set of *models for* K, where a model $\mathfrak{M}_K$ for K is given by $\mathfrak{M}_K = \langle W, \prec, V\rangle$, where

- W is the set of all maximal consistent theories of the language in which K is formulated;
- $\prec$ is a well-founded and almost connected strict partial ordering of W such that the $\prec$-minimal elements of W are given by the set of maximal consistent extensions of K;
- $V(p)(w) = 1$ iff $p \in w$.

PROPOSITION 38.
Let $\mathfrak{M}_K = \langle W, \prec, V\rangle$ be a model for K. Define K^*_φ for every φ as follows:

$$\psi \in K^*_\varphi \textit{ iff } \psi \in w \textit{ for every } w \textit{ such that } w \textit{ is } \prec\textit{-minimal in } [\![\varphi]\!].$$

Then the postulates **K*****1** *to* **K*****8** *are satisfied.*

Conversely, we have

PROPOSITION 39.
Let K^* be a revision function for some belief set K satisfying **K*****1** *to* **K*****8**.
Define $\mathfrak{M}_K = \langle W, \prec, V\rangle$ as follows:

- *W is the set of all maximal consistent theories of the language in which K is formulated;*
- *$u \prec w$ iff $\tau(w) \subseteq \tau(u)$ and $u \notin \tau(w)$.*

  Here, τ is given by: $v \in \tau(w)$ iff $v \in W$ and there is some φ such that $K^*_\varphi \subseteq w$ and $\varphi \in v$.
- *$V(p, w) = 1$ iff $p \in w$.*

Then $\mathfrak{M}_K = \langle W, \prec, V\rangle$ is a model for K for which the following holds:

$$\psi \in K^*_\varphi \textit{ iff } \psi \in w \textit{ for every } w \textit{ such that } w \textit{ is } \prec\textit{-minimal in } [\![\varphi]\!].$$

This means that whenever $\psi \in K^*_\varphi$, the model $\mathfrak{M}_K$ verifies $\varphi \rightsquigarrow \psi$. This model is almost connected. Therefore, in view the observations we made in section 1 and 10, it follows that the AGM revision constraints endow $\rightsquigarrow$ with the logic $\mathbf{P}$ + ASP.[11]

One may be tempted to conclude from the above that revising ones beliefs by φ and making the counterfactual assumption *if it had been the case that* φ amount to the same thing. However, even though these cognitive operations have much in common formally, there are huge differences between them. When you believe that φ is true and you try to imagine what would have been the case if φ had been false, you have to change your cognitive state, but it is it not the kind of change you would have to make if you were to discover that φ is *in fact* false. It is not a *correction.* Consider for example $\varphi =$ *Oswald killed Kennedy.* Supposing that Oswald had not killed Kennedy might make you think 'If Oswald had not killed Kennedy, Kennedy might still be alive'. If, however, at some point you were to find out that your belief that Oswald killed Kennedy is in fact wrong, and you had to revise your beliefs accordingly, it is very likely that after this revision you would still believe that Kennedy is dead.[12]

The rise of 'dynamic' versions of epistemic and doxastic logic have given new impetus to the study of of belief revision in the setting of modal logic. See van Benthem[74], Segerberg[68, 69] and Chapter 20 for further details.

1 INTRODUCTION

That logic and language are closely related is almost true by definition. Logic is concerned with the study of valid inferences in arguments, and these are most commonly defined in terms of truth in models. Symbolic logic studies formal languages (logics) as models of certain aspects of natural languages, such as quantification, while abstracting away from certain other aspects of natural languages, such as ambiguity, as models typically do. Linguistics studies the structure of natural languages as well as the relation of language to other areas of cognitive science. The roles that logic in general, and modal logic in particular, play in linguistics are quite varied, as we shall see.

In linguistic semantics, logic is used to formalize, or interpret, an *object language*. We take as given that we want to study the semantics of some natural language, and in this

chapter the language that we shall deal with is English. Above all else, we would like to directly interpret English sentences in some formally specified model. So even at this point we can see some connection to the Kripke semantics of modal operators: just as all of the other phenomena in this "applied" section of the handbook have been modeled with mathematical structures involving possible worlds, so too have these been used in semantic applications. For example, all manner of linguistic phenomena involving time have led to proposals for using the models from temporal logic. More generally, the main models of all types of *intensional* phenomena are closely related to the models in modal logic.

But so far we have only considered the matter of interpreting natural language directly. Usually, this is difficult or even impossible. (For example, consider the famous quantifier scope ambiguities in sentences like *every handbook has a famous editor*. The ambiguity is neatly expressed in logical notation as $\exists\forall$ vs $\forall\exists$: is there one person, let's call him Dov, who edits all the handbooks, or is it merely that every handbook has some editor or other? One lesson to take from such ambiguities is that it is impossible to associate a function from (English $\times$ models) to truth values in a way that respects our intuitions.) So one way or another, we translate natural language to some artificial language and then interpret that other language, in such a way that ambiguous sentences will be translated into multiple logical formulas. And here is a second place modal logic comes in: the language of higher-order modal logic has been used extensively to drive this translation process, as we shall see when we discuss Montague semantics.

We next turn to syntax, a field in which one finds several different uses of logic. There are syntactic frameworks which are heavily proof-theoretic, so the question of whether a given string is a sentence or not boils down to whether a related (formal) sentence is a theorem in some logical system. This proof-theoretic move is especially prominent in categorial grammar. Another quite different use of logic is as a *meta language* in which one formalizes a linguistic formalism declaratively. This is the move of *model theoretic syntax*, a research program we consider in depth in the second half our chapter. This application relates logic to linguistics in the same way that logic can be applied to formalize theories of other sciences, like set theory. However, the aims of this formalization are somewhat different from those of other areas, since model theoretic syntax is particularly interested in using *decidable* logics for this formalization so that matters can be implemented. This is of course one of the reasons why modal logics are attractive in this context, although much of the focus has been on monadic second-order logic of trees, which is decidable as well.

Applications of logic in linguistics have traditionally not been too concerned with meta-results. The main uses of modal logic in semantics are independent from the main concerns of modal logicians: completeness and correspondence. We are not aware of any serious application of the basic theory of modal logic in semantics, let alone the advanced theory that is showcased in various chapters of this handbook. The only exception is definability theory, interest in which is motivated by trying to find a logic for linguistic applications that has the right kind of "expressiveness." For example, the fact that *most A are B* is not first-order definable is of some importance for semantics. On the other side, the application of logic in syntax has led to more applications of sophisticated meta-results, for example proof theoretical results like cut-elimination or normalization in categorial grammar. It is interesting to note that definability is also of importance in model theoretic syntax, due to its relation to descriptive complexity theory. A re-

lated point: because so many current syntactic frameworks are designed with a hope of implementation, sharper theoretical results about them are called for.

In this chapter, we only survey applications of modal logic to the syntax and semantics of natural languages. We concentrate on these two applications because of the historical importance of modal logic in the development of natural language semantics and because of the significance of model theoretic syntax in current research in mathematical linguistics. There are many areas of applications of logic in linguistics that we do not mention, some of which are surveyed in the *Handbook of Logic & Language* [4].

2 SEMANTICS

Linguistic semantics studies meaning in natural languages. The central assumption of current semantic theory is that meaning should be studied model theoretically, in the same way that semantics of logics are studied. Thus, the study of *meaning* is tied to the concept of *truth*. Of course, there are other ways to pursue the project of understanding meaning, most notably to tie it to *action* in some way. As it happens, for some purposes possible worlds semantics is even better for this second purpose than for the first; see, for example, [69].

The interpretation of logical formulas usually involves the interpretation of subformulas in some systematic fashion. For instance, in propositional logic we have interpretational clauses like

$$[\![\varphi \wedge \psi]\!] = [\![\wedge]\!]([\![\varphi]\!], [\![\psi]\!])$$

where $[\![\wedge]\!]$ is the boolean *and* function. The methodological principle that stipulates that all interpretations of complex expressions should involve the interpretations of its parts is called the "principle of compositionality," and it plays a central role in linguistic semantics. Whether that principle is in fact a meaningful restriction on semantic theory or whether it is vacuous is a point of ongoing debate. For one source that discusses the matter at length, see Janssen [41].

Since natural language semantics applies model theoretic methods, the role of modal logic in this context involves the application of possible worlds semantics to natural languages, mainly to model *intensional* phenomena. However, in order to follow the principle of compositionality uniformly, the meanings of some expressions are modeled using higher-order logic. Thus, the most influential, systematic application of modal logic to linguistic semantics, usually referred to as *Montague semantics* after its founder, involved *higher-order intensional logic.* Although Montague's application of higher-order intensional logic to natural language semantics yielded many important results, almost all of the contemporary research is concerned with finding suitable alternatives to this framework. Many of these are surveyed in the *Handbook of Logic and Language* [4]. Another handbook in this area, with a more empirical and linguistic, as opposed to theoretical and logical, slant is the *Handbook of Contemporary Semantic Theory* [57]. There are many introductory textbooks in linguistic semantics, including [15, 22, 36].

2.1 Possible worlds in semantics

The major use of modal logic in semantics stems from possible worlds semantics. Indeed, this is the only kind of application we are considering in this chapter.

This is a good point to make a comment which relates to the place of this chapter in the overall handbook, and also one relating to current practice in the field of modal logic. One of the main subtexts in this volume is that research on modal logic has much to contribute to other areas. So the volume downplays the problematic points of possible worlds semantics by emphasizing topics in modal logic which are interest in areas far removed from those problems. In other words, one can put aside ontological worries (as one would like to do in any mathematical study) because in the kind of transition-system models emphasized in the study, these worries are not relevant. This kind of move is not appropriate for semantics: on the one side, problems about the status of possible worlds come up quicker and they persist; we shall shortly see an example. On the other side, there are few, if any, technical matters of interest in semantics. It is essentially all a matter of studying data from language, proposing treatments that use possible worlds, describing informal models related to the phenomena or the treatments, and occasionally working out the semantics of one or another formal logical language. In this section, we are mainly trying to provide a reader who is conversant with modal logic a feeling for what goes on in semantics.

Here is an example that motivates the use of possible worlds in semantics, taken from McCawley [64]. In a normative English sentence, two uses of a first person pronoun (*I/me/myself*) must be coreferential. And if the sentence has both a first person subject and object, the object must be the reflexive pronoun *myself*. So one cannot say *I kissed me* but instead must have *I kissed myself*. The only exception to this, and this is heart of the matter, is that "Multiple references for first-person pronouns arise when the sentence alludes to an alternative world in which the speaker ... is presented as experiencing something from someone else's vantage point" (McCawley [64]). For example,

(1) I dreamed that I was Brigitte Bardot and that I kissed me.

This would not mean the same thing as *I dreamed that I was Brigitte Bardot and that I kissed myself*. Getting back to (1), it shows what appears to be a hard-and-fast syntactic rule has to be understood in essentially semantic terms. (This is not as surprising as it might at first be: try formulating a principle of reflexive pronouns without using the semantic concepts of *subject* and *object*.)

(1) also shows that in some implicit sense speakers refer to "dream worlds" and more generally to alternative worlds of other kinds, or alternative ways this world could be. Note that the status of who *I* and *me* are in the dream world is problematic, but we shall not delve into this. The point is that if one wants to construct a formal semantics for (1) using Kripke models, then *prima facie* one would want to use worlds: a world where the speaker has a dream, and a world that represents what is happening in that dream. Note as well that what happens in dreams might be logically inconsistent, so Kripke models as one standardly finds them in modal logic are not going to be sufficient for representations of this kind. But they are a useful first step. Indeed, practicing semanticists have found the informal talk about possible worlds to be convenient and motivating. Like contemporary modal logicians, they are usually not interested in, or bothered by, worries about whether possible worlds are real. But again, the difference is that for modal logicians, the worries go away precisely because they tend to avoid modeling anything like an imaginary world, something which is evidently of linguistic interest.

For another example of why semanticists want to think in terms of possible worlds,

consider the following contrasting sentences:

(2) i. It's certain that you'll find a job, and it's conceivable that it will be a good-paying one.

ii. ??It's conceivable that you'll find a job, and it's certain that it will be a good-paying one.

This example is from McCawley [64] in a section entitled "'World-Creating' Predicates." (Incidentally, the quotes here are his, betraying already a certain discomfort with either the notion or the terminology. In any case, we shall expand on just this point below. But the terminology again shows an embrace of possible worlds as well.) The question marks in (2ii) indicates a semantic anomaly. That is, what appears strange in (2ii) is not due to syntactic ill-formedness: from (2i) and the fact that *certain* and *conceivable* both take sentence complements, one would expect (2ii) to be grammatical. So one of the goals of any analysis would be a principled explanation of the different acceptability judgments between (2i) and (2ii).

We encourage readers who are not familiar with semantics to attempt a translation into any logical language of (2i), and also to draw pictures of Kripke models to explain their intuitions. Incidentally, in both (2i) and (2ii), we are concerned with the "non-referential" interpretations: there is no specific job that Gladys is looking for.

Since the sentences in (2) are in the future, a representation should have at least two worlds: the present world, in which (presumably) you do not have a job but are seeking one, and at least one future world. Thus we are inclined to model (2i), say, by having one actual world, w and *many* alternative worlds for the relatively-near future, each with the property that you find some job or other in it. This is quite typical for semantic analysis: if one is going to use worlds to represent alternatives which are only partially specified, then very quickly one must consider many alternatives. Frequently there will be infinitely many. It is the second half of the sentence which gives more trouble; it seems to require that in some (or perhaps some significant proportion of) the successors of w, your job is a good-paying one. And even with this sketch of a representation, we have not learned the lesson that (2) teaches. The point is that a use of *it* in the second part of (2i) is dependent on the existence of a job. If the existence of a job is in doubt, as it is in the first part of (2ii), then it is infelicitous to use *it* to refer to one later. This kind of reasoning could be fleshed out in a fuller analysis in several ways. One would be to use a theory of presupposition. Another would be to ground the whole discussion in Discourse Representation Theory (DRT) [43] or some "dynamic" theory which has enough theoretical apparatus around to talk about different occurrences of pronouns like *it*. In any case, a DRT analysis of the sentences in (2) would most likely use possible worlds at the very least.

One last comment: from more sophisticated examples, such as ... *it is more likely than not that it will be a good-paying one*, we see that complex relations between worlds are going to be the norm rather than the exception. These relations can involve additional structure, as in this probabilistic setting, or various notions of nearness (as we find in treatments of conditionals).

2.2 Specific contributions: an overview

In an assessment of the importance of possible worlds semantics for linguistics, Partee [74] highlights the following six areas:

1. The identification of propositions with sets of possible worlds.
2. The analysis of intensional phenomena with functions from possible worlds to their extensions.
3. The semantics of propositional attitudes.
4. The semantics of conditionals.
5. The semantics of questions and the pragmatics of the question-answer relations.
6. Pragmatics in general, and presuppositions in particular.

Beginning with this subsection, we shall explore several of these contribution areas in detail. Some of these topics are not treated in our chapter: we won't have much to say about questions and answers or pragmatics. The prevalent view of the role of pragmatics in linguistics is that it is the part of semantics that is concerned with the *context-dependent* meaning of linguistic expressions. In the narrowest sense, pragmatics is concerned with the interpretation of indexical or deictic expressions, like personal pronouns, and that is the sense in which the term was used by Montague [99]. Since then, the subject matter of pragmatics has been extended to include many of the topics discussed by ordinary language philosophers like Austin, Grice, Strawson, and Searle. Thus, pragmatics now includes topics such as implicature, presupposition, and speech acts. There is also some overlap between pragmatics and sociolinguistics, though that overlap has little to do with modal logic.

Of the subjects of pragmatics mentioned above, primarily indexicals and presuppositions have been analyzed using possible worlds semantics, although Posner [78] reconstructs communicative actions and ultimately speech act theory in terms of suitable iterations of modal operators for believing, causing, and intending.

Concerning work related to questions and answers, we only mention one quite recent reference, the dissertation Murakami [68]. This proposes an analysis of notions like *complete and just complete answer to a question* based on the modal logic of *partitions*.

With respect to the first two items listed by Partee, one set of notions worth keeping in mind goes back at least to Carnap [14]. He emphasized the distinction between extension and intension, and linked these to particular syntactic items as follows:

Expression	Intension	Extension
sentence	proposition	truth-value
predicate	property	set
individual term	individual concept	individual.

Note that the identification of propositions with sets of possible worlds is a special case of this analysis, since sets of possible worlds are essentially the same as functions from possible worlds to the set of truth values. In essence, this identification of propositions with sets amounts to the imposition of a boolean algebra structure on the set of propositions. This kind of structure needs to be supplemented with accessibility relations or other more typically modal structures to be relevant to our discussion.

2.3 Intensionality

We have yet to discuss intensionality in a general way, and now is the time to do just that. It is relatively uncontroversial that some linguistic expressions refer to objects. For instance, names refer to the object that they name. Frege [29] postulated that there is another dimension to "meaning" other than reference in order to explain the apparent difference between statements of the form $a = b$ and $a = a$. While the latter is true *a priori*, the former, when true, typically requires some kind of observation. The difference between these two statements, according to Frege, is that, if $a = b$ is true, a and b have the same *reference* (*Bedeutung*), but different *sense* (*Sinn*). However, Frege did not give a formal definition of "sense." Carnap [14] used the concepts of *extension* and *intension* as a model of reference and sense, which is one of the first and most influential applications of modal logic to natural language semantics. Carnap, however, used *state descriptions*, maximally consistent sets of literals, instead of Kripke models for the semantics of modal logic. Montague is credited with bringing together Carnap's analysis of sense and reference with Kripke's possible world semantics. (Incidentally, a different analysis of *sense* along algorithmic lines has been suggested in recent years by Moschovakis; see [67].)

David Lewis [59] expressed the motivation for this approach to natural language semantics particularly well:

> In order to say what meaning *is*, we may first ask what a meaning *does* and then find something that does that. [...] It is the meaning which determines how the extension depends on the combination of relevant factors. What sort of things determine how something depends on something else? *Functions*, of course [...]

Thus, *intensions* are defined by Lewis to be functions from possible worlds (and possibly other indices, which are the *relevant factors*, above) to extensions. This is the central idea behind the possible world analysis of intensionality. So far, we have only mentioned the extensions of names: individuals. What about the extensions of other kinds of expressions? It has been part of the Fregean orthodoxy to consider the extension of a sentence to be its truth value. Since intensions are functions from possible worlds to extensions, the intensions of sentences are functions from possible worlds to truth values, or simply sets of possible worlds; i.e., those possible worlds in which the sentence is true. The intensions of sentences are also called "propositions." As Partee [74] points out, this analysis of the meaning of sentences gives a good approximation to the notion of "synonymity," since two sentences that have the same intensions are true in exactly the same possible worlds.

Other, classical, examples of intensional phenomena include intensional transitive verbs, like *seek*, and propositional attitude verbs, like *believe*. Interacting with both of these are the *de re* and *de dicto* distinctions. To illustrate this distinction, consider the following sentence, and note the intensional transitive verb: *Barney wants to drive the fastest car in town.* One reading of this sentence is where there is a specific car, say c, and Barney wants to drive c. (But the fact that c is the fastest car in town is not germane to Barney's wish: he just wants to drive c.) This is the *de re* reading. The *de dicto* reading is where Barney wishes to drive whatever car is the fastest in town; so if that description were to change referents over time, then Barney's desire would also change.

Before moving on, we should mention that the entire treatment of intensionality via possible worlds semantics is not universally accepted in semantics by any means. A good source for some criticisms is John Perry's side [76] of a discussion with Barbara Partee. In other areas as well, one has the feeling that the whole application of possible worlds in semantics is, as one prominent semanticist privately told one of us, a "counterfactual exercise": even though possible worlds semantics are the community's standard and the best thing known, many researchers believe that in the long run they cannot succeed at everything they are being applied to.

2.4 Propositional attitudes

The phenomena of interest in the context of propositional attitudes are belief and knowledge, and also the *root modals* like *can*, *may*, and *should*. The main lines of the standard treatments are probably closest to the heart of a semantically-oriented modal logician: one takes a space of worlds which is equipped with a relation corresponding to each attitude or modality of interest. Then one defines semantics for the attitudes themselves as modal operators in the expected way, by quantifying using the accessibility relations. Modal logicians will also recognize the parallel to the algebraic semantics of modal logic; see Chapter 6. The point is that by moving to the power set algebra of the set of worlds of a model is like moving to the space of *intensions*. So the propositional attitudes turn into operators on the intensional rather than extensional level. This is a two-edged sword: on the one hand, it allows us to explain why statements of identity are not preserved in modal contexts. But the down side is the problem of logical omniscience: logically necessary propositions wind up as being known by everyone at every point. So exactly the same advantages and disadvantages come up as in the theory of knowledge.

Here is one textbook treatment of the basics of propositional attitudes, following the final chapter of Heim and Kratzer [36]. This chapter is called a "first step" on the way to an intensional semantics, and the authors emphasize, and close with, the limitations of their work. The point for us concerns the treatment of the attitude verbs such as *know* and *believe*. The way things work syntactically, attitude verbs take sentences as their arguments; a verb phrase then results. So their categorial type (see Section 2.11 below) would be VP/S, and so their semantics is a function from propositions (i.e., functions from worlds to truth values) to VP meanings (here functions from individuals x to truth values). The semantics is then given by

(3) $[\![believes]\!] =$
$\lambda w.\lambda p.[\lambda x.(\forall w')(\text{if } w' \text{ is belief-consistent with } w \text{ for } x, \text{ then } p(w') = 1)].$

"Belief consistent" here a relation on worlds defined as follows: we say that w' is belief consistent with w for (person) x if all of x's beliefs in w are true in w'. (So in effect this treatment does not work on a set Kripke model whose accessibility relation is up to the semanticist to specify, but rather that the accessibility relation is *given* in terms of what we are calling belief consistency here.)

To illustrate this, we consider a sentence of the form *Mary believes S*, where S is another sentence. Overall principles of compositionality insure that for all worlds w,

$$[\![\textit{Mary believes S}]\!]_w = [\![\textit{believes S}]\!]_w(\textit{Mary}).$$

The definitions in the semantics are set up so that the following holds:

(4) $[\![believes\ S]\!]_w(Mary) = [\![believes]\!]_w(\lambda w'.[\![S]\!]_w(Mary))$.

At this point we apply the general definition of $[\![believes]\!]$ from (3). We see that *Mary believes S* is true in a world w just in case for all worlds w' which are belief consistent with w for Mary, S is true in w'. So in this way we reconstruct the semantics of the attitudes which would be expected from the Kripke semantics of modal logic. We shall discuss how the calculation in (4) works when we turn to Montague grammar in Section 2.11.

Before returning to a discussion of the modalities in language, here is another point on the treatment of belief in linguistics. McCawley [64] suggests a departure from what modal logicians might expect concerning belief when he writes, "Belief worlds may even conform to a different version of logic than the real world is taken to be subjected to; such worlds would be appropriate devices for analyzing such sentences as those in which an adherent of standard logic attributes beliefs to an intuitionist." But he also holds also that "one has a single set of beliefs at a time (possibly inconsistent beliefs, but a single set nonetheless)." So this seems to suggest that belief worlds might be *paraconsistent* in some sense. But later, in connection with wishes, he is of the opinion that "It will probably be clearest if one simply avoids terms such as 'wish world,' which misleadingly suggest that there is a single system of wishes whose simultaneous fulfillment is at issue, and instead use circumlocutions to say that a particular world corresponds to a particular wish. ... These worlds may serve as reference worlds for other worlds that correspond to, say, the fulfillment of wishes, hopes, and so forth, that are contingent on the fulfillment of a given wish."

In any case, much of the linguistic discussion is not about these kinds of points, but rather questions of reference and presupposition. For example, here are sentences from McCawley [64], page 426:

(5)
i. Arthur thinks that <u>a unicorn</u> has been eating his roses. He hopes he can catch <u>it</u>.
ii. Arthur denies that <u>a unicorn</u> has been eating his roses. ??He hopes he can catch <u>it</u>.

The underlined *it* in the first sentence refers to the unicorn in the preceding sentence. Actually, *a unicorn* is best understood non-referentially here; there is no particular unicorn which Arthur is thinking about, just some-unicorn-or-other. The point is that it is a property of *think* that it allows nonreferential NP's in its complement to be the antecedents of later pronouns (the subsequent *it*). In contrast, *deny* does not have this property. This is why the second sentence in (2 ii) is anomalous. This last example is intended to be more typical of the linguist's concerns than the previous paragraph on ontological points.

2.5 Conditionals

Modal-type notions are of central interest in work on conditionals, following Lewis [60] and Stalnaker [90]. The idea here is to analyze counterfactual conditionals (those whose antecedents are known or taken to be false) using a semantics that comes with some extra apparatus or other. One should see Chapter 18 for an extensive treatment of the logical systems that come from the natural semantics of counterfactual conditionals. But counterfactuals are only one type of conditionals, and another important type are

indicative conditionals (where the antecedent is true). See von Kutschera [106] for a proposal on indicative conditionals related to, but different from, the standard treatment of counterfactuals.

As it happens, most contemporary work in semantics does not use the Lewis-Stalnaker semantics but instead works with elaborations based on it. Probably the main proposal in the area is due to Kratzer [55]. Her work allows one to work with the combination of conditionals and modals, as in *If this is an article on linguistics, there must be examples from many languages.* Kratzer's semantics makes use of a "modal base"; this is basically a spelled out version of an accessibility relation. It also uses a three-placed similarity relation on worlds. It was later observed by Frank [28] and independently Zvolensky [107] that sentences of the form *If X, then it must be the case that X* came out automatically true in Kratzer's semantics. Modal logicians might find it interesting to note that a similar debate about the adequacy of modal semantics crops up in areas like deontic logic. Indeed, one of the lessons we learned in writing this chapter is exactly that similar questions about the adequacy of various semantic proposals coming from modal logic come up independently in different forms. From the point of view of *applied modal logic* it would clearly be of value for people to pay close attention to points like this, in order to make theoretical contributions that could be appreciated by people in different fields.

2.6 Time and tense

Another semantic area where ideas of possible worlds semantics are put to use concerns time and tense in natural language. Our discussion of these issues is once again intended only as an invitation to this fascinating field. It is based largely on the survey of the area in Mark Steedman's draft textbook [91] and also on Dick Crouch's ESSLLI notes [21]. We have also again found McCawley's book [64] full of insightful examples and proposals; see Section 12.2 on Tense Logic.[1] An essential resource for researchers in this area is Robert I. Binnick's web site [5] entitled "The Project on Annotated Bibliography of Contemporary Research in Tense, Grammatical Aspect, Aktionsart, and Related Areas":

`http://www.scar.utoronto.ca/~binnick/TENSE/`.

In particular, the logic part of the site lists a large collection of papers relevant to the subject of this handbook chapter.

For readers of this handbook, perhaps the primary observation concerning the analysis of time in natural language is that the whole matter of *temporal ontology* is highly complicated and problematic. First of all, there are words, endings, and expressions which are *usually* used to indicate past, present, and future time references. But even these have exceptions. For example, *ing* usually indicates a present tense, but in examples like *the editors are calling Larry tomorrow to complain that his paper contained a lot of misleading remarks*, the word *tomorrow* changes this to a future time reference. Yet

[1]Indeed, at various places in this chapter we have marveled at McCawley's use of the best logical tools available to him. He wrote "I teach courses on logic from a linguists point of view, taking a broad view of the subject matter of logic (logic has suffered 23 centuries of myopia, which I try to make up for) and giving full weight to linguistic considerations in revising (or replacing) existing systems of logic to maximize their contact with natural language syntax and linguistic semantics." [65] We therefore wonder what he as a linguist would have found useful in the exploding logical literature. Although we never met him personally, we would like to think that some of our comments about various connections and possible applications would have inspired him (and those who follow in his footsteps).

another point concerns *embedded tenses*; as our last example shows, it is not always straightforward even to interpret these constructions, let alone represent and analyze them. For another example along the same lines, *Sonia said that Rajiv liked to dance* should have the same meaning as *Sonia said "Rajiv likes to dance"*; the problem then is to account for this sameness. Finally, important temporal information is often absent from the surface forms. Consider

(6) John went to kindergarten with a bank president.

The intended meaning is that at some past time John went to kindergarten with some individual who would later become a president of a bank.

The first, and most basic, proposal for the representation of temporal phenomena is to add an explicit time parameter to propositional functions. So instead of a predicate like $alive(x)$ which indicates whether an object is alive or not, we might have $alive(x, t)$. Then one might want to translate various tense constructions into, say, a two-sorted first-order logic; the point is that one then has quantification over times and also a symbol $<$ for the relation of *preceding* on times. Then one can translate a future sentence like *Sonia will go* as

$$(\exists t > t_0)(go(Sonia, t)).$$

Note that there is a "now" time t_0; this can be taken to be either a constant or a variable.

However, this is usually not what is done. There are logical and also linguistic reasons for making other moves. In a comment directly related to this, Thomason [100] writes:

> Physics should have helped us realize that a temporal theory of a phenomenon X is, in general, more than a simple combination of two components: the statics of X and the ordered set of temporal instants. The case in which all functions from times to world-states are allowed is uninteresting; there are too many such functions, and the theory has not begun until we have begun to restrict them. And often the principles that emerge from the interaction of time with the phenomena seem new and surprising.

The new and surprising principles here are the interactions of tense and modality that Thomason discusses in his handbook article [100]. But mention of physics also raises the question of the structure of time. In the linguistic literature, the emphasis nearly always is on what might be called *linguistic time*, the common-sense notion that we want to tease out and model from "people on the street". It is not the notion that we would get from physics.

An alternative way to go is to take the basic sentences of language to be tenseless and then to add temporal modal operators P (for the past) and F (for the future). This is the basic move of Tense Logic, usually mentioned in connection with its main developer, Arthur Prior.

These are interpreted on linear orders $(L, <)$. The semantics is the standard one from temporal logic

$$(7)\quad \begin{array}{lll} l \models P\phi & \text{iff} & m \models \phi \text{ for some } m < l \\ l \models F\phi & \text{iff} & m \models \phi \text{ for some } m > l \end{array}$$

So P and F are *past* and *future* modalities.

Let us see how this idea fares with some examples. We should think of an atomic proposition as representing an untensed assertion. After a moment's thought, one can

The oracle speaks	p	The oracle spoke/has spoken	Pp
The oracle will speak	Fp	The oracle had spoken	PPp
The oracle will have spoken	FPp	The oracle never spoke	$\neg Pp$
There will be a time after which the oracle will not speak			$F\neg Fp$
There was a first time the oracle spoke			$P(p \wedge \neg Pp)$

Figure 1. Sentences and Priorean Translations

see that the very question of whether "untensed assertions" are possible will be a source of debate in this area. But let us ignore this and think of stative present tense assertions like *the oracle speaks* as an untensed assertion. Suppose that we take its semantics to be an atomic proposition p of the logic above. Then we can translate some English sentences as in Figure 1.

It is important to make a few comments about the contents of the figure. As with all translations from natural language into a formal language, one has to be clear on what has been achieved and what some of the problems are.

We also mention some ways that the system can be fruitfully extended. For example, it is straightforward to add binary modalities S and U for *since* and *until*. With a little more work, we can also add *now*. The simplest way to do this is to work on models $(L, <)$ with a distinguished l^* for the "present moment". Then we add to the clauses in (7) the following

$$l \models N\phi \quad \text{iff} \quad l^* \models \phi.$$

This proposal is due to Kamp [42], and it is discussed further in Burgess [11], Section 4B. Among the facts shown in these references is the fact that N is actually eliminable in this language. However, if one moves from a purely propositional setting one with more linguistically interesting phenomena, this reduction is rightfully lost. For example, consider

(8) i. The oracle predicted that there will be an earthquake.

ii. The oracle predicted that there would be an earthquake.

A natural representation of (1) is $Pr(o, NFe)$; the important point is that the future operator F is evaluated from the vantage point of "now". This contrasts with (2). Here a representation might be $Pr(o, Fe)$. The difference is that the prediction in (2) is that there will be an earthquake at some point later than the prediction, not the moment of utterance of the sentence.

There are some linguistic problems with any treatment of time as an extra parameter. One problem again concerns embedded tenses; these are especially interesting for modal logic since all of the important problems in modal logic arise precisely because modalities in formal systems may be iterated, and because accessibility relations in models can be deep. The natural symbolization of (6) in a modal approach comes out as something like

$$\begin{aligned} P \quad & ((\exists x)(\exists y)(\text{kindergarten}(x) \wedge \text{go}(J, x) \wedge \text{go}(y, x) \wedge \\ & F((\exists z)(\text{bank}(z) \wedge \text{president}(y, z))))). \end{aligned}$$

But then consider *John went to kindergarten with someone who has become a bank president.* Here the intended reading is that the person became a bank president before the utterance time. So having F in the scope of P in the representation would be a mistake. Another problem is that many temporal phenomena pertain more to events that distributed in time and hence do not admit a nice formulation: *Boris took piano lessons for six months.*

Sentences like Pp may be rendered either in the *simple past* as *The oracle spoke* or in the *present perfect* as *The oracle has spoken.* This means that whatever differences we ascribe to the two English forms will not be representable in the Priorean formalism.

Further, the logic contains forms like $PFPPFp$ which cannot be rendered into English except by transcribing the formal semantics into mathematical English. This is a problem not just for this work, but also for practically all accounts of any phenomenon which use recursion: the formalism will quickly contain forms not naturally renderable without heavy uses of devices like numbered or named pronouns.

For other natural English sentences that cannot be translated adequately in the Priorean formalism, consider *The oracle did not speak.* What we have here is an implicit reference to a particular time or set of times. So our sentence is not captured by $\neg Pp$, since that sentence amounts to a universal quantification over past times.

Furthermore, one would suspect that since we can add operators corresponding to *Since* and *Until*, we might also add an operator Y for *Yesterday.* Suppose our semantics makes use of a function $l \mapsto l-1$ and works by $l \models Y\phi$ iff $l-1 \models \phi$. However, here the a sentence like *Yesterday the oracle spoke* would correspond to Yp rather than YPp. So we are left with a puzzle about why the natural language sentence uses the past tense marker in the first place.

Hinrichs [37] noted that the sentence *Vincent left yesterday* has two natural renderings:

$$Y(P(leave(Vincent))) \qquad \text{and} \qquad P(Y(leave(Vincent))).$$

However, these both fail to have the intended meaning: the Y operator shifts the evaluation point to the previous day, but then the P operator takes the past from this point. A similar problem, noted by Partee [73] and reiterated in Hinrichs' paper is that tense and negation do not work well in Prior's approach. Translating "Vincent did not leave" by either $P(\neg leave(V))$ or the other alternative do not work.

Even though the rest of our discussion has dwelled the shortcomings of the Priorean approach, some aspects of the temporal system of language clearly are captured in it. Further discussion of tense logic and standard logic may be found in van Benthem [103, 104] and also Chapter 11 of this handbook. We also discuss an extension of Prior's approach due to Patrick Blackburn in Section 2.8 below.

2.7 The reference time

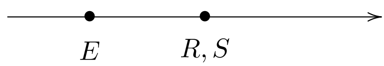
One of the key contributions to this area comes in Reichenbach's textbook (on logic (!)) [82]. He points out that linguistic tense does not involve only "now" and "then" but also a third time, the *reference time.* So he described the tense system in terms of three times, S (the speech point), E (the event point), and R (the reference point). R is the time in a sentence "that we are really talking about".

For example, consider the difference between the *simple past* and *past perfect* in English. The simple past is exemplified by *I saw John*; the past perfect by *I had seen John.*

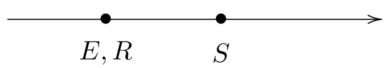
The difference between these is that in the past perfect, E is prior to R (and both come before S): the speaker is describing an event from a vantage point (R) which is later than the time (E) of the event itself. In contrast, in the simple past, the event time and reference time are the same.

Incidentally, although Reichenbach seems to have preferred to think in terms of R, E, and S as *points*, there is good reason to prefer to take them to be *intervals*. The use of intervals in tense logic is a natural move, and many semantics papers do in fact make it. Here are some examples of the way various tense and aspect combinations in Reichenbach's system come out when we take R, E, and S to be intervals, writing $<$ for the subinterval relation:

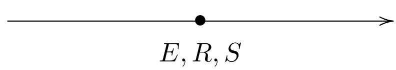
the past perfect: I had seen John.



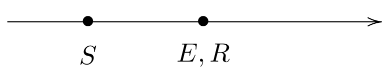
the present perfect: John has been to Boston.



the simple past: I gave a lecture.



the present: I name this ship *Chips*.



the simple future: I lecture (next week).

We have completed a quick tour of some of the central proposals concerning temporal ontology. It goes without saying that we have barely scratched the surface, that further work is in large measure concerned with corrections and criticisms of the classical ideas, etc. But we would be remiss in ending without mentioning that much of the current work is concerned not with points of time but rather with *events*; see for example, the book *The Proper Treatment of Events* [105]. Figure 2 contains a chart of some of the Reichenbach examples, worked in terms of events for S, E and R. The relation $<$ is that of *subevent*.

2.8 Temporal reference and hybrid logic

Reference to specific times can be incorporated into a Prior-style formalism by using ideas from hybrid logic (see Chapter 14 of this handbook). The basic idea of hybrid logic is to add a new sort of propositional symbol to the underlying modal language; these symbols are called *nominals*, and they are typically written i, j, and k. When working with nominals, one adds a semantic constraint that they be true at exactly one point. In this way, nominals 'name' the unique point they are true at.

This gives us a way of coping with some of the difficulties noted earlier. For example, we saw that *The oracle could not speak* could not be translated into the standard Priorean formalism; the simple representation $\neg Pp$ amounts to universal quantification over past times. But with the aid of nominals we have a better representation:

$$P(i \wedge \textit{the oracle not speak}).$$

This anchors the silence of the oracle at a particular time in the past, namely the time named by the nominal i.

Moreover, we now have a way handling reference times. Consider the sentence *The oracle had not spoken.* This picks out some past time (the reference time) and locates the silence of the oracle before that. This cannot be handled in the standard Priorean formalism, but once again with the aid of nominals, we can capture its meaning:

$$P(i \wedge P(\textit{the oracle not speak})).$$

This formula says that there is some time in the past (namely the one named by i) and that *before that* the oracle did not speak. In fact, as Blackburn [6] observes, all of Reichenbach's analyses can be handled in this way; the required hybrid representations are given in Figure 3.

It's also worth remarking that the ideas of hybrid logic combine naturally with multi-dimensional modal semantics of the type mentioned above. For example, Blackburn [6] uses this style of semantics to interpret propositional symbols like *yesterday*. The use of such symbols avoids the problems associated with the yesterday operator Y. For example, the hybrid representation of *Vincent left yesterday* would be

$$P(\textit{yesterday} \wedge \textit{Vincent leave}),$$

and this has the required interpretation. Moreover, the hybrid approach also correctly classifies sentences such as *Vincent will leave yesterday* as semantically anomalous. This sentence would be represented by the hybrid formula

$$F(\textit{yesterday} \wedge \textit{Vincent leave}).$$

This formula is false at all points in all models, hence the anomaly.

	Past	Present	Future
Simple	$E = R$, $R < S$ Mary saw John	$E = R = S$ Mary sees John	$E = R$, $S < R$ Mary will see John
Perfect	$E < R < S$ Mary had seen John	$E < R = S$ Mary has seen John	$E < R$, $S < R$ Mary will have seen John
Progressive	$E = R$, $R < S$ Mary was seing John	$E = R = S$ Mary is seeing John	$E = R$, $S < R$ Mary will be seeing John

Figure 2. Tense and Aspect in Terms of E, R, and S

Structure	**Name**	**English example**	**Representation**
E–R–S	Pluperfect	I had seen	$P(i \wedge P\varphi)$
E,R–S	Past	I saw	$P(i \wedge \varphi)$
R–E–S	Future-in-the-past	I would see	$P(i \wedge F\varphi)$
R–S,E	Future-in-the-past	I would see	$P(i \wedge F\varphi)$
R–S–E	Future-in-the-past	I would see	$P(i \wedge F\varphi)$
E–S,R	Perfect	I have seen	$i \wedge P\varphi$
S,R,E	Present	I see	$i \wedge \varphi$
S,R–E	Prospective	I am going to see	$i \wedge F\varphi$
S–E–R	Future perfect	I will have seen	$F(i \wedge P\varphi)$
S,E–R	Future perfect	I will have seen	$F(i \wedge P\varphi)$

Figure 3. Reichenbach's analysis in hybrid logic

2.9 A note on multidimensionality

One very interesting application of modal logic to semantic analysis is the use of multidimensional modal logic in connection with cross-world comparatives. Consider, for example, sentences like *This article is shorter than it might have been.* One approach to its semantics is to use not just a single world in the semantics, but to move to two or even more worlds. We might have an "actual" world and an "evaluation" world. For applications in semantics related to comparatives, see Cantwell [13]. By now there are also quite sophisticated modelings of tense and aspect; see, for example ter Meulen [94].

2.10 Problems and prospects

Even with the move to a Reichenbachian treatment of tense and aspect, there are remaining stubborn problems. Many of these are especially pertinent to the discussion of the application of possible world semantics; they indeed cause one to either re-think the use of possible worlds, or to propose modifications or extensions of it. Consider, for example, the *present relevance* of the perfect. For example, *Jimmy has lost his mind* intuitively entails that Jimmy has not gotten it back.

It is also important to note that a lot of real-world knowledge goes into judgments about sentences using time and tense. For example

(9) i. ??James McCawley has written many books.

ii. James McCawley wrote many books.

The first is anomalous, but only to one who knows that McCawley died in 1999. For someone who didn't know this, (9i) carries the implicature that McCawley is still alive. The point here is that (9i) and (9ii) are not equivalent, but the difference is due to background knowledge. So the entire system of time/tense/aspect interacts with the knowledge background of speakers and hearers. With this in mind, consider also, and note the difference between

Category	Description	Examples
S	Sentence	*John seek a unicorn*
CN	Common nouns	*man, woman, unicorn*
IV	Intransitive verb phrases	*walk*
S/IV	Noun phrases	*the man, every unicorn, John*
(S/IV)/CN	Determiners	*every, a, one, the*
IV/(S/IV)	Transitive verb phrases	*love, seek*
IV/S	Sentential complement verbs	*believe, hope, doubt*
CN/CN	Adjectives	*red, fake*
S/S	Sentential adverbs	*frequently, necessarily*

Figure 4. Categories and Sample Expressions in a Categorial Grammar

(10) i. The authors have regretted that they never met McCawley.

ii. The authors had regretted that they never met McCawley.

Many recent papers and books in the area emphasize the presence of causality and real-world knowledge in discourse about time; see Steedman [91]. Another book on this topic which emphasizes connections to logic programming and even robotics is van Lambalgen and Hamm [105].

2.11 Montague semantics

As was mentioned above, Montague's application of higher-order intensional logic marked the starting point for applications of modal logic in natural language semantics. Montague developed his theory of natural language semantics over the course of three papers (collected in [99]), each of which differs from the others in some respect. In the following, we give a survey of a "streamlined" approach, taken from Gamut [32].

Montague semantics consists of three parts: syntactic categories, semantic types, and operations on the members of each of these, where each operation on members of syntactic categories has a corresponding operation on the members of the corresponding semantic types. This correspondence is Montague's formalization of the principle of compositionality.

The theory of syntactic categories assumed in Montague semantics is loosely based on categorial grammar. The categories of categorial grammar are either basic categories or derived categories, which are formed by closing the basic categories under two operators: / and \. An expression that has a category of the form A/B is "looking to its right for" an expression of the category B to make an expression of the category A. And an expression of category $B\backslash A$ is looking to its left for an expression of category B to again make one of category A. Thus, derived categories have a functional behavior.

The full set of categories, CAT, is obtained by closing the basic categories, S (for *sentence*), CN (*common noun*), IV (*intransitive verb*), under the / operator. Thus, only one of the two operators of categorial grammar is used by Montague. Figure 4 has examples of the most common categories and some of their expressions.

At this point, we have described the set of syntactic categories and given examples. One forms the full set of expressions of the various categories by juxtaposition following

the categorial rules. For example, *John walks* is an S because *John* is $\mathsf{S/IV}$ and *walks* is an IV. From this, *believes John walks* is an IV. And then *Mary believes John walks* is again an S. This is as it should be, since we have a grammatical sentence.

We return to the syntactic categories and expressions below, after a digression concerning the formal semantics. Let e and t be any distinct objects, and define the set T of *semantic types* by the following inductive definition:

1. $e, t \in T$,
2. if $a, b \in T$, then $\langle a, b\rangle \in T$,
3. if $a \in T$, then $\langle s, a\rangle \in T$.

The idea is that e stands for *entity* and t for *truth value*, s for a set of possible worlds, and $\langle a, b\rangle$ for the set of all functions from a to b (or rather for the set of functions from the set that a stands for to the set b stands for). The difference between syntactic categories and semantic types is that syntactic categories have a notion of "order" built-in. In the following, we will use upper-case letters for syntactic categories and lower-case letters for semantic types.

Given infinite sets of variables for each type a, denoted by VAR_a, and, possibly empty, sets of constants for each type a, denoted by CON_a, we define the well-formed expressions of type a, denoted by WE_a, as follows:

1. $\mathsf{VAR}_a \subseteq \mathsf{WE}_a$ and $\mathsf{CON}_a \subseteq \mathsf{WE}_a$,
2. if $\alpha \in \mathsf{WE}_{\langle a,b\rangle}$ and $\beta \in \mathsf{WE}_a$, then $\alpha(\beta) \in \mathsf{WE}_b$,
3. if $\varphi, \psi \in \mathsf{WE}_t$, then $\neg\varphi \in \mathsf{WE}_t$ and $(\varphi \wedge \psi) \in \mathsf{WE}_t$,
4. if $\varphi \in \mathsf{WE}_t$ and $v \in \mathsf{VAR}_a$, then $\forall v\varphi \in \mathsf{WE}_t$,
5. if $\alpha, \beta \in \mathsf{WE}_a$, then $\alpha = \beta \in \mathsf{WE}_t$,
6. if $\alpha \in \mathsf{WE}_a$ and $v \in \mathsf{VAR}_b$, then $\lambda v\alpha \in \mathsf{WE}_{\langle b,a\rangle}$,
7. if $\varphi \in \mathsf{WE}_t$, then $\Box\varphi \in \mathsf{WE}_t$,
8. if $\alpha \in \mathsf{WE}_a$, then ${}^\wedge\alpha \in \mathsf{WE}_{\langle s,a\rangle}$,
9. if $\alpha \in \mathsf{WE}_{\langle s,a\rangle}$, then ${}^\vee\alpha \in \mathsf{WE}_a$.

We will use other connectives: $\Diamond, \vee, \rightarrow, \leftrightarrow, \exists$, to abbreviate their usual definitions in terms of the connectives above. The reason that these types are referred to as *semantic* types is that each type has a corresponding domain. Given a set of individuals, D, and a set of worlds, W, we define the domain of a type t, denoted by $\mathcal{D}_{t,D,W}$ as follows:

1. $\mathcal{D}_{e,D,W} = D$
2. $\mathcal{D}_{t,D,W} = \{0, 1\}$
3. $\mathcal{D}_{\langle a,b\rangle,D,W} = \mathcal{D}_{b,D,W}^{\mathcal{D}_{a,D,W}}$
4. $\mathcal{D}_{\langle s,a\rangle,D,W} = \mathcal{D}_{a,D,W}^{W}$

where A^B denotes the set of functions from B to A. We now define the interpretation of expressions. A *model*, $\mathcal{M}$, is a triple, (D, W, I), where D is a non-empty set of individuals, W is a non-empty set of worlds, and I is an interpretation of the constants at a world. We define $[\![\alpha]\!]_{\mathcal{M},w,g}$, where $\mathcal{M}$ is a model, $w \in W$ is a world, and g is a variable assignment. As usual, we denote the variable assignment that differs from g at most in that it assigns d to v by $g[v/d]$.

1. if $\alpha \in \mathsf{CON}_a$, then $[\![\alpha]\!]_{\mathcal{M},w,g} = I(w, \alpha)$; if $\alpha \in \mathsf{VAR}_a$, then $[\![\alpha]\!]_{\mathcal{M},w,g} = g(\alpha)$,
2. if $\alpha \in \mathsf{WE}_{\langle a,b\rangle}$ and $\beta \in \mathsf{WE}_a$, then $[\![\alpha(\beta)]\!]_{\mathcal{M},w,g} = [\![\alpha]\!]_{\mathcal{M},w,g}([\![\beta]\!]_{\mathcal{M},w,g})$,
3. if $\varphi, \psi \in \mathsf{WE}_t$, then $[\![\neg\varphi]\!]_{\mathcal{M},w,g} = 1$ iff $[\![\varphi]\!]_{\mathcal{M},w,g} = 0$, and $[\![(\varphi \wedge \psi)]\!]_{\mathcal{M},w,g} = 1$ iff $[\![\varphi]\!]_{\mathcal{M},w,g} = 1$ and $[\![\psi]\!]_{\mathcal{M},w,g} = 1$,
4. if $\varphi \in \mathsf{WE}_t$ and $v \in \mathsf{VAR}_a$, then $[\![\forall v\varphi]\!]_{\mathcal{M},w,g} = 1$ iff for all $d \in \mathcal{D}_a$, $[\![\varphi]\!]_{\mathcal{M},w,g[v/d]} = 1$,
5. if $\alpha, \beta \in \mathsf{WE}_a$, then $[\![\alpha = \beta]\!]_{\mathcal{M},w,g} = 1$ iff $[\![\alpha]\!]_{\mathcal{M},w,g} = [\![\beta]\!]_{\mathcal{M},w,g}$,
6. if $\alpha \in \mathsf{WE}_a$ and $v \in \mathsf{VAR}_b$, then $[\![\lambda v\alpha]\!]_{\mathcal{M},w,g}$ is the function $h \in \mathcal{D}_{\langle b,a\rangle}$, such that for all $d \in \mathcal{D}_b$, $h(d) = [\![\alpha]\!]_{\mathcal{M},w,g[v/d]}$,
7. if $\varphi \in \mathsf{WE}_t$, then $[\![\Box\varphi]\!]_{\mathcal{M},w,g} = 1$ iff for all $w' \in W$, $[\![\varphi]\!]_{\mathcal{M},w',g} = 1$,
8. if $\alpha \in \mathsf{WE}_a$, then $[\![{}^\wedge\alpha]\!]_{\mathcal{M},w,g}$ is the function $h \in \mathcal{D}_{\langle s,a\rangle}$, such that for all $w' \in W, h(w') = [\![\alpha]\!]_{\mathcal{M},w',g}$,
9. if $\alpha \in \mathsf{WE}_{\langle s,a\rangle}$, then $[\![{}^\vee\alpha]\!]_{\mathcal{M},w,g} = [\![\alpha]\!]_{\mathcal{M},w,g}(w)$.

This allows us to have formal terms for what we informally wrote above in (3).

There is a symmetry between λ-abstraction and application (i.e. β conversion), and $^\wedge$ abstraction and $^\vee$ application. However, while the following form of β-conversion can only be applied in the *extensional* fragment of this system, it only holds in restricted cases in the intensional system.

THEOREM 1. *In the extensional fragment of $\lambda x\beta(\gamma)$ is equivalent to $\beta[x \mapsto \gamma]$ if all free variables in γ are free for x in γ.*

However, in the extensional system this equivalence fails. It is possible to extend this equivalence to a restricted set of expressions of the intensional system: the intensionally closed expressions, whose extension does not vary from world to world. The *intensionally closed expressions* in L, denoted by ICE^L, is the minimal subset of WE^L such that

1. If $x \in \mathsf{VAR}_a$, then $v \in \mathsf{ICE}^L$,
2. If $\alpha \in \mathsf{WE}^L_a$, then ${}^\wedge\alpha \in \mathsf{ICE}^L$
3. If $\varphi \in \mathsf{WE}^L_t$, then $\Box\varphi \in \mathsf{ICE}^L$
4. ICE^L is closed under boolean connectives, quantifiers, and λ-abstraction.

The above mentioned symmetry is summarized in the following two theorems:

THEOREM 2. ${}^\vee({}^\wedge\alpha)$ *is equivalent to* α.

THEOREM 3. $\lambda x\beta(\gamma)$ *is equivalent to* $\beta[x \mapsto \gamma]$ *if*

1. *all free variables in* γ *are free for* x *in* γ*; and*
2. *either* $\gamma \in \mathsf{ICE}^L$*, or no free occurrence of* x *in* β *lies within the scope of* $\Box, {}^\wedge$*.*

Now, we associate semantic types with syntactic categories as follows using the following function f:

$$f(\mathsf{S}) = t$$
$$f(\mathsf{CN}) = f(\mathsf{IV}) = \langle e, t\rangle$$
$$f(\mathsf{A/B}) = \langle\langle s, f(\mathsf{B})\rangle, f(\mathsf{A})\rangle$$

With each syntactic category, A, we associate a set of *basic expression* of that category, denoted by B_{A}, and a set of expressions of that category, denoted by P_{A}.

The next step involves the definition of syntactic operations that create complex expressions. In the following, we will use the same rule numbers as [32]. Here are the first three rules:

$$B_{\mathsf{A}} \subseteq P_{\mathsf{A}} \tag{S1}$$

If $\alpha \in P_{\mathsf{S/IV}}$ and $\beta \in P_{\mathsf{IV}}$, then $F_1(\alpha,\beta) \in P_{\mathsf{S}}$, and $F_1(\alpha,\beta) = \alpha\beta'$, where β' (S2)
is the result of replacing the main verb in β by its third-person singular present form.

If $\alpha \in P_{(\mathsf{S/IV})/\mathsf{CN}}$ and $\beta \in P_{\mathsf{CN}}$, then $F_2(\alpha,\beta) \in P_{\mathsf{S/IV}}$, and $F_2(\alpha,\beta) = \alpha\beta$. (S3)

Rule S1 simply makes the basic expressions of category A expressions of category A. Rule S2 combines noun phrases with verb phrases to make sentences, the side condition enforcing subject-verb agreement. Rule S3 combines determiners with common nouns to form noun phrases.

EXAMPLE 4. Here is a derivation for "every man walks":

$$F_2(\textit{every}, \textit{man}) = \textit{every man}$$
$$F_1(\textit{every man}, \textit{walk}) = \textit{every man walks}$$

Since the syntactic derivations in Montague grammar are very straightforward, we will dispense with them in the rest of this article.

We now define a function $\mapsto$ that associates with each expression of category A an expression of type $f(\mathsf{A})$, its *meaning*. First, the translation of most basic expressions will simply be a constant. We will denote the constants corresponding to basic expressions using CAPS. Thus, the constant corresponding to *walk* is WALK. The only exceptions to this rule are noun phrases, determiners, the verb *be*, and *necessarily*.

$$T1:$$
$$John \mapsto \lambda X({}^\vee X(j))$$
$$Mary \mapsto \lambda X({}^\vee X(m))$$
$$he_n \mapsto \lambda X({}^\vee X(x_n))$$
$$every \mapsto \lambda Y \lambda X \forall x({}^\vee Y(x) \rightarrow {}^\vee X(x))$$

$$\text{If } \alpha \in P_{\mathsf{S/IV}}, \beta \in P_{\mathsf{IV}}, \alpha \mapsto \alpha', \text{ and } \beta \mapsto \beta', \text{ then } F_1(\alpha,\beta) \mapsto \alpha'({}^\wedge\beta') \tag{T2}$$
$$\text{If } \alpha \in P_{(\mathsf{S/IV})/\mathsf{CN}}, \beta \in P_{\mathsf{CN}}, \alpha \mapsto \alpha', \text{ and } \beta \mapsto \beta', \text{ then } F_2(\alpha,\beta) \mapsto \alpha'({}^\wedge\beta') \tag{T3}$$

EXAMPLE 5. Here is the translation for "every man walks."

$$\cfrac{\cfrac{\cfrac{\cfrac{\lambda Y \lambda X \forall x({}^{\vee}Y(x) \rightarrow^{\vee} X(x)) \quad \textsc{man}}{\lambda X \forall x(\textsc{man}(x) \rightarrow^{\vee} X(x))}\ T2 \qquad \textsc{walk}}{\lambda X \forall x(\textsc{man}(x) \rightarrow^{\vee} X(x))({}^{\wedge}\textsc{walk})}\ T3}{\forall x(\textsc{man}(x) \rightarrow^{\vee} ({}^{\wedge}\textsc{walk}(x)))}\ \beta\text{-conversion}}{\forall x(\textsc{man}(x) \rightarrow \textsc{walk}(x))}\ {}^{\vee\wedge}\text{-cancellation}$$

Now we will consider transitive verbs. Again, we first give a syntactic rule, followed by a semantic rule:

If $\alpha \in P_{\mathsf{IV/(S/IV)}}$ and $\beta \in P_{\mathsf{S/IV}}$, then $F_6(\alpha, \beta) \in P_{\mathsf{IV}}$, and $F_6(\alpha, \beta) = \alpha\beta'$ (S7)
where $\beta'$is the accusative form of β if β is a syntactic variable; otherwise $\beta' = \beta$.
If $\alpha \in P_{\mathsf{S/IV}}, \beta \in P_{\mathsf{IV}}, \alpha \mapsto \alpha'$, and $\beta \mapsto \beta'$, then $F_6(\alpha, \beta) \mapsto \alpha'({}^{\wedge}\beta')$. (T7)

We will use the following two notational conventions from Gamut [32]. The first is just an instance of what computer scientists call *uncurrying*.

If γ is an expression of type $\langle a, \langle b, t\rangle\rangle, \alpha$ and expression of type a, and β (NC1)
an expression of type b, then we may write $\gamma(\beta, \alpha)$ instead of $(\gamma(\alpha))(\beta)$.

Before discussing the second notational convention ($NC2$), we need to review how Montague proposed to treat transitive verbs. In Montague's system, the meanings transitive verbs are relations between individuals and second-order properties, i.e. they are of type $\langle\langle s, \langle\langle s, \langle e, t\rangle\rangle, t\rangle\rangle, \langle e, t\rangle\rangle$. Thus, since they are not relations between individuals, we can have a statement such as "John seeks a unicorn" be true, without it entailing the existence of unicorns. However, there are certain transitive verbs, so-called *extensional transitive verbs* which entail the existence of their arguments. For these expressions NC2 will allow us to move from Montague's higher-order interpretation of transitive verbs to relations between individuals.

If δ is an expression of type $\langle\langle s, \langle\langle s, \langle e, t\rangle\rangle, t\rangle\rangle, \langle e, t\rangle\rangle$, then we may write δ_* (NC2)
instead of $\lambda y \lambda x \delta(x, {}^{\wedge} \lambda X {}^{\vee} X(y))$.

The expression δ_* refers to the relation that holds between x and y iff the relation δ holds between x and the intension of the set of all properties of y, i.e. ${}^{\wedge}\lambda X {}^{\vee} X(y)$. For further details and discussion, see Gamut [32].

EXAMPLE 6. Here is a derivation for "every man loves a woman."

$$\lambda Y\lambda X\exists x({}^{\vee}Y(x) \to^{\vee} X(x)) \quad \textsc{woman}$$
$$\vdots$$
$$\lambda Y\lambda X\forall y({}^{\vee}Y(y) \to^{\vee} X(y)) \quad \textsc{man} \qquad \dfrac{\textsc{love} \qquad \lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x))}{\textsc{love}({}^{\wedge}\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x)))}\,T7$$
$$\vdots$$
$$\dfrac{\lambda Y\forall y(\textsc{man}(y) \to^{\vee} Y(y)) \qquad \textsc{love}({}^{\wedge}\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x)))}{\lambda Y\forall y(\textsc{man}(y) \to^{\vee} Y(y))({}^{\wedge}\textsc{love}({}^{\wedge}\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x))))}\,T2$$
$$\dfrac{\lambda Y\forall y(\textsc{man}(y) \to^{\vee} Y(y))({}^{\wedge}\textsc{love}({}^{\wedge}\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x))))}{\forall y(\textsc{man}(y) \to^{\vee} ({}^{\wedge}\textsc{love}({}^{\wedge}\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x))))(y))}\,\beta\text{-conversion}$$
$$\dfrac{\forall y(\textsc{man}(y) \to^{\vee} ({}^{\wedge}\textsc{love}({}^{\wedge}\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x))))(y))}{\forall y(\textsc{man}(y) \to (\textsc{love}({}^{\wedge}\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x))))(y))}\,{}^{\vee\wedge}\text{-cancellation}$$
$$\dfrac{\forall y(\textsc{man}(y) \to (\textsc{love}({}^{\wedge}\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x))))(y))}{\forall y(\textsc{man}(y) \to \textsc{love}(y,{}^{\wedge}\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x)))}\,NC1$$
$$\dfrac{\forall y(\textsc{man}(y) \to \textsc{love}(y,{}^{\wedge}\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x)))}{\forall y(\textsc{man}(y) \to \exists x(\textsc{woman}(x) \wedge \textsc{love}_*(y,x)))}\,NC2$$

The following rule schema is used to create different derivations for ambiguous sentences.

If $\alpha \in P_{\mathsf{S/IV}}$ and $\varphi \in P_{\mathsf{S}}$, then $F_{7,n}(\alpha,\varphi) = \varphi'$, where φ' is the result of the following substitution in φ: (S8,n)
(i) if α is not a syntactic variable he_k, then replace the first occurrence of he_n or him_n with α, and the other occurrences of he_n or him_n with the appropriate anaphoric pronoun.;
(ii) if $\alpha = he_k$, then replace every occurrence of he_n and of him_n with him_k.

And the corresponding semantic rule:

$$\text{If } \alpha \in P_{\mathsf{S/IV}}, \varphi \in P_{\mathsf{S}}, \alpha \mapsto \alpha', \text{ and } \varphi \mapsto \varphi', \text{ then } F_{7,n}(\alpha,\varphi) \mapsto \alpha'({}^{\wedge}\lambda x_n\varphi') \qquad \text{(T8,n)}$$

EXAMPLE 7. Here is another derivation of "every man loves a woman." This time, "everybody loves him$_1$" is derived first, and "a woman" is *quantified in.*

$$\lambda Y\lambda X\exists x({}^{\vee}Y(x) \to^{\vee} X(x)) \quad \textsc{woman} \qquad \textsc{love} \quad \lambda X^{\vee}X(x_1)$$
$$\vdots \qquad\qquad\qquad \vdots$$
$$\dfrac{\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x)) \qquad \forall y(\textsc{man}(y) \to \textsc{love}_*(y,x_1))}{\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x))({}^{\wedge}\lambda x_1\forall y(\textsc{man}(y) \to \textsc{love}_*(y,x_1)))}\,T8,1$$
$$\dfrac{\lambda X\exists x(\textsc{woman}(x) \wedge^{\vee} X(x))({}^{\wedge}\lambda x_1\forall y(\textsc{man}(y) \to \textsc{love}_*(y,x_1)))}{\exists x(\textsc{woman}(x) \wedge^{\vee} ({}^{\wedge}\lambda x_1\forall y(\textsc{man}(y) \to \textsc{love}_*(y,x_1))(x)))}\,\beta\text{-conversion}$$
$$\dfrac{\exists x(\textsc{woman}(x) \wedge^{\vee} ({}^{\wedge}\lambda x_1\forall y(\textsc{man}(y) \to \textsc{love}_*(y,x_1))(x)))}{\exists x(\textsc{woman}(x) \wedge (\lambda x_1\forall y(\textsc{man}(y) \to \textsc{love}_*(y,x_1))(x)))}\,{}^{\vee\wedge}\text{-cancellation}$$
$$\dfrac{\exists x(\textsc{woman}(x) \wedge (\lambda x_1\forall y(\textsc{man}(y) \to \textsc{love}_*(y,x_1))(x)))}{\exists x(\textsc{woman}(x) \wedge (\forall y(\textsc{man}(y) \to \textsc{love}_*(y,x))))}\,\beta\text{-conversion}$$

Now we can use quantifying-in to derive multiple interpretations of *believe*-sentences, corresponding to the above-mentioned *de dicto-de re* distinction. Assuming that the syntactic category of *believe* is $\mathsf{IV/S}$, we need new syntactic and semantic rules for such expressions:

$$\text{If } \alpha \in P_{\mathsf{IV/S}} \text{ and } \beta \in P_{\mathsf{S}}, \text{ then } F_{11}(\alpha,\beta) \in P_{\mathsf{IV}}, \text{ and } F_{11}(\alpha,\beta) = \alpha\beta \qquad \text{(S15)}$$
$$\text{If } \alpha \in P_{\mathsf{IV/S}}, \varphi \in P_{\mathsf{S}}, \alpha \mapsto \alpha', \text{ and } \varphi \mapsto \varphi', \text{ then } F_{11}(\alpha,\varphi) \mapsto \alpha'({}^{\wedge}\varphi') \qquad \text{(T15)}$$

EXAMPLE 8. Here are derivations for *John believes that a man walks.* The first gives us the *de dicto* reading:

$$\lambda Y \lambda X \exists x({}^{\vee}Y(x) \wedge {}^{\vee} X(x)) \quad \text{MAN}$$
$$\vdots$$
$$\lambda X \exists x(\text{MAN}(x) \wedge {}^{\vee} X(x)) \qquad \text{WALK}$$
$$\vdots$$
$$\lambda X({}^{\vee}X(j)) \qquad \dfrac{\text{BELIEVE} \qquad \exists x(\text{MAN}(x) \wedge \text{WALK}(x))}{\text{BELIEVE}({}^{\wedge}\exists x(\text{MAN}(x) \wedge \text{WALK}(x))}\ T15$$
$$\vdots$$
$$\text{BELIEVE}(j, ({}^{\wedge}\exists x(\text{MAN}(x) \wedge \text{WALK}(x)))$$

While the quantifying-in version gives the *de re* reading:

$$\lambda Y \lambda X \exists x({}^{\vee}Y(x) \rightarrow {}^{\vee} X(x)) \quad \text{MAN} \qquad \lambda X {}^{\vee} X(x_1) \quad \text{WALK}$$
$$\vdots \qquad\qquad\qquad\qquad \vdots$$
$$\dfrac{\lambda X \exists x(\text{MAN}(x) \wedge {}^{\vee} X(x)) \qquad \text{BELIEVE}(j, ({}^{\wedge}\text{WALK}(x_1))}{\lambda X \exists x(\text{MAN}(x) \wedge {}^{\vee} X(x))({}^{\wedge}\lambda x_1 \text{BELIEVE}(j, ({}^{\wedge}\text{WALK}(x_1)))}\ T8, 1$$
$$\vdots$$
$$\exists x(\text{MAN}(x) \wedge \text{BELIEVE}(j, ({}^{\wedge}\text{WALK}(x))))$$

In addition to epistemic modalities, we can give a treatment of of sentential adverbs, like *necessarily*, using the following two rules:

$$\text{If } \alpha \in P_{\mathsf{S/S}} \text{ and } \beta \in P_{\mathsf{S}}, \text{ then } F_{11}(\alpha, \beta) \in P_{\mathsf{S}}, \text{ and } F_{11}(\alpha, \beta) = \alpha\beta \tag{S20}$$
$$\text{If } \alpha \in P_{\mathsf{S/S}}, \varphi \in P_{\mathsf{S}}, \alpha \mapsto \alpha', \text{ and } \varphi \mapsto \varphi', \text{ then } F_{11}(\alpha, \varphi) \mapsto \alpha'({}^{\wedge}\varphi') \tag{T20}$$

However, we need to distinguish non-logical adverbs, like *rarely*, from logical ones, like *necessarily*, because we want the meaning of the former, but not the latter, to vary across models. This is accomplished through *meaning postulates*, an invention of Carnap's [14], which can be used to relate logical constants with expressions and also to relate expressions with each other, e.g. $\mathsf{bachelor}$ with $\neg\mathsf{married}$. The relevant meaning postulate for *necessarily* would be:

$$\forall p \Box(\text{NECESSARILY}(p) \leftrightarrow \Box^{\vee} p)$$

We conclude this section with the example: *Necessarily, John walks.*

EXAMPLE 9.

$$\lambda X({}^{\vee}X(j)) \quad \text{WALK}$$
$$\vdots$$
$$\dfrac{\dfrac{\dfrac{\text{NECESSARILY} \qquad \text{WALK}(j)}{\text{NECESSARILY}({}^{\wedge}\text{WALK}(j))}\ T20}{\Box^{\vee}({}^{\wedge}\text{WALK}(j))}\ MP}{\Box(\text{WALK}(j))}\ {}^{\vee\wedge}\text{-cancellation}$$

The preceding examples are meant to be illustrative of the way that higher-order intensional logic is used in Montague grammar to model the meanings of natural language

expressions. There are many shortcomings of Montague's framework, some formal and some empirical, the rectification of which can be seen as the motivation for the majority of the current approaches in semantic theory. See [24] and [75] for additional details of Montague grammar and for discussions of its shortcomings.

3 SYNTAX

3.1 Mathematical linguistics

Mathematical linguistics is concerned with models of natural languages and linguistic theories and their formal properties, especially those theories about syntax. The properties of interest are typically those of theoretical computer science, particularly from formal language theory, complexity theory, and learnability theory. Applications of logic to syntax combine the first two by giving tools to assess the complexity of formal languages descriptively. This line of research is related to finite model theory [25] and descriptive complexity theory [40].

We will review the basics of formal language theory as it applies to this setting. For a more detailed introduction see Partee, ter Meulen, and Wall [72], or, at a more advanced level and including many applications of modal logic, Kracht [54]. In order to model natural language syntax mathematically, we use strings. An *alphabet* is a finite set Σ of *symbols*, and a *string* over Σ is a finite sequence of elements of Σ. This includes the empty sequence, denoted by ε. A fundamental operation on strings is *string concatenation* which we will denote by juxtaposition. We denote the set of all strings over Σ by Σ^*, and the set of all non-empty strings by Σ^+. A *(formal) language* is a set of strings; i.e., a subset of Σ^*. In the intended applications, Σ is the set of words (or even morphemes) of a natural language (rather than just letters of some alphabet), however, for the purpose of examples we will frequently just use letters. Mathematical linguistics uses formal languages as models of natural languages: we identify English with the set of English sentences.

The purpose of grammatical theories is to distinguish the well-formed (grammatical) strings from the ill-formed (ungrammatical) strings. This can be achieved in a number of ways, using automata, grammars, algebras, or logic. However, it is an important assumption of linguistic theory, dating back at least to American Structuralism, that sentences of natural languages are not just linear sequences, but that they contain hierarchical structures: constituents. Furthermore, the division of a string into constituents plays an important part in semantics, since the principle of compositionality stipulates that the meaning of a string depends on the meaning of the words and the way they are put together, the latter of which can be captured by the constituent structure. While automata, algebras, and logics can be used to define languages, formal grammars play a central role in mathematical linguistics because they can associate a hierarchical structure with the strings that they generate: the derivation tree. Note that not all formal grammars can associate derivation trees with the strings they generate, but for linguistic applications, grammars that do are typically more interesting. Thus, we distinguish the *weak generative capacity*, the set of strings generated by a grammar, from the *strong generative capacity*, the set of structural descriptions or trees assigned by the grammar to the strings that it generates.

We will be referring frequently to a particular class of grammars and the languages

they generate: the *context-free grammars* (CFGs) and *context-free languages* (CFLs). CFGs are specified in terms of two alphabets, Σ and Γ, which are called the *terminal* and *non-terminal* alphabets, respectively. The terminal alphabet consists of the symbols that make up the strings that the grammar generates; the non-terminal alphabet can be thought of as corresponding to the syntactic categories of traditional grammar. In addition, CFGs are specified in terms of *a finite set of rules*, P, and a distinguished member of Γ, *the start symbol*, denoted by S. The rules in P are of the form $A \to w$, where $w \in (\Sigma \cup \Gamma)^*$. CFGs derive strings of terminal symbols by successively rewriting non-terminal symbols. Let $x, y, z \in (\Sigma \cup \Gamma)^*$, and $A \in \Gamma$. We write $xAz \Rightarrow_G xyz$ to indicate that xyz can be obtained from xAz by using the rule $A \to y$ of G. We use $\Rightarrow^*_G$ to denote the reflexive, transitive closure of $\Rightarrow_G$. The language generated by a CFG, G, denoted by $L(G)$, is defined as

$$L(G) = \{w \mid w \in \Sigma^*, S \Rightarrow^*_G w\}$$

A language, L, is called a CFL if there is a CFG, G, such that $L = L(G)$.

The CFLs play a central role in mathematical linguistics; they are in some sense a yardstick, because they approximate many natural language languages reasonably well [33] and they can be processed efficiently [39]. On the other hand, many formalisms are defined for the explicit purpose of extending the weak generative capacity of CFGs, that is to obtain non-CF languages. The reason for this is that there are natural language phenomena that are not context-free [89]. There are also some proposals which only go beyond CFGs in terms of strong generative capacity, although they are weakly equivalent to CFGs. That is, they are interested in obtaining sets of structures which go beyond the sets of parse trees of CF languages, but which generate CF string languages. Both the Lambek calculus [101] and regular tree languages (see below) are examples of such proposals.

3.2 Preliminary: logics of strings

The logic of strings was first studied by logicians interested in decidability [10]. It was continued within formal language theory, and had an algebraic slant [77, 92]. The case of strings has not found many applications to linguistics, as the more involved settings below have. However, this simpler case is useful in getting an intuition about the more complex cases. For a more detailed introductions to this area see Khoussainov and Nerode [45] and Thomas [98].

First of all, our intended models are what we shall call *string structures*. These are Kripke frames of the form

$$1 \longrightarrow 2 \longrightarrow \quad \cdots \quad \longrightarrow n\ .$$

The idea is that a *string* on some alphabet gives rise to a frame as above. Adding a valuation amounts to specifying subsets of the model. Since we intend the atomic propositions to be the alphabet symbols, the subsets of the frame corresponding to these symbols correspond to the positions in the given word with the given symbols. Thus there is an extra condition that each world in the frame satisfy exactly one atomic sentence. A string model is a pair (W, v) consisting of a string structure W together with a valuation v that meets this extra condition. We usually omit the valuation from our notation. Let

Syntax	**Sentences** φ	$p_i \mid \neg\varphi \mid \varphi \wedge \psi \mid [\rightarrow]\varphi \mid [\rightarrow^*]\varphi$
Semantics	**Main Clauses**	$W, i \models [\rightarrow]\varphi$ iff $W, i+1 \models \varphi$
		$W, i \models [\rightarrow^*]\varphi$ iff for all $j \geq i, W, j \models \varphi$

Figure 5. Modal logic of strings: $\mathcal{L}(\rightarrow, \rightarrow^*)$

Σ be an alphabet, considered also as a set of atomic propositions for our modal language. A set of string models over Σ corresponds to a subset of Σ^+ of non-empty words over Σ. The correspondence associates to the string model (W, v) the string $W_1 \cdots W_n$, where n is the length of W and each W_i is the unique element of Σ satisfied by i in the model W.

Modal Logic of Strings

Figure 5 contains the basic modal logic of strings which we will call $\mathcal{L}(\rightarrow, \rightarrow^*)$. The semantics in Figure 5 defines the relation $W, i \models \varphi$. We say that a string W satisfies a formula φ if $W, 1 \models \varphi$. A language L is *definable* in this (or another language) if there is a sentence φ so that L is exactly the set of strings satisfying a sentence φ.

In order to study the languages definable in $\mathcal{L}(\rightarrow, \rightarrow^*)$, we introduce a class of languages, called the *star-free* languages (the reason for the name will become apparent later). The star-free languages, which are defined in Figure 6, were introduced by McNaughton and Pappert [66] to study first-order (FO) definable languages. It should be noted that star-free languages are sets of strings, and as such might well contain the empty string ε. Since we are going to be interested in classes of models which correspond to strings, and since the carrier sets our models must be non-empty, we are going to be interested in *ε-free* star languages as defined in Figure 7.

Syntax	**Expressions** r	$0 \mid 1 \mid a \mid rs \mid r+s \mid -r$
Semantics		$[\![0]\!] = \varnothing$
		$[\![1]\!] = \{\varepsilon\}$
		$[\![a]\!] = \{a\}$
		$[\![rs]\!] = \{st \mid s \in [\![r]\!], t \in [\![s]\!]\}$
		$[\![r+s]\!] = [\![r]\!] \cup [\![s]\!]$
		$[\![-r]\!] = \Sigma^* - [\![r]\!]$

Figure 6. The syntax and semantics of star-free expressions

Syntax	**Expressions** r	$0 \mid a \mid rs \mid r+s \mid -r$
Semantics	**Main Clause**	$[\![-r]\!] = \Sigma^+ - [\![r]\!]$

Figure 7. The syntax and semantics of ε-free star-free expressions

Here are some examples of formulas in $\mathcal{L}(\rightarrow, \rightarrow^*)$ and the star-free languages that correspond to them (taken from [19]). Notice that we are using *regular expressions* (see below) to describe these star-free languages because they are shorter; these languages can also be described with star-free expressions.

Syntax	**Formulas** φ	$p_i \mid \neg\varphi \mid \varphi \wedge \psi \mid [\rightarrow]\varphi \mid [\rightarrow^*]\varphi \mid \mathcal{U}(\varphi, \psi)$
Semantics	**Main Clause**	$W, i \models \mathcal{U}(\varphi, \psi)$ iff there exists a $j \geq i$, such that $W, j \models \varphi$, and for all $n, i \leq n \leq j, W, n \models \psi$

Figure 8. Temporal logic of strings: PTL

EXAMPLE 10. The language $(ab)^+$ is defined by the formula

$$a \wedge \langle\rightarrow^*\rangle(b \wedge \neg\langle\rightarrow\rangle a \wedge \neg\langle\rightarrow\rangle b) \wedge \neg\langle\rightarrow^*\rangle(a \wedge \langle\rightarrow\rangle a) \wedge \neg\langle\rightarrow^*\rangle(b \wedge \langle\rightarrow\rangle b)$$

Here and in the following, $\langle\cdot\rangle\varphi$ abbreviates $\neg[\cdot]\neg\varphi$. This formula says that the first letter is an a, the last letter is a b, and there are no consecutive a's or b's. Notice that $(aa)^+$ is not $\mathcal{L}(\rightarrow, \rightarrow^*)$ definable; in fact it is not even FO definable.

EXAMPLE 11. Let $A = \{a, b, c\}$. The language $A^*a(a+c)^*$ is defined by the formula

$$\langle\rightarrow^*\rangle(a \wedge \langle\rightarrow\rangle\neg\langle\rightarrow^*\rangle b)$$

The following proposition states the relationship between $\mathcal{L}(\rightarrow, \rightarrow^*)$ definability and star-freeness. There is also an algebraic characterization in Cohen *et al.* [19] which is omitted here.

PROPOSITION 12. *If $L \subseteq \Sigma^+$ is definable in $\mathcal{L}(\rightarrow, \rightarrow^*)$, then L is star-free.*

However, there are star-free languages that are not definable in $\mathcal{L}(\rightarrow, \rightarrow^*)$.

PROPOSITION 13. *The language $a^*b(a+b+c)^*$ is not $\mathcal{L}(\rightarrow, \rightarrow^*)$ definable.*

Proof. We use a version of Ehrenfeucht games for $\mathcal{L}(\rightarrow, \rightarrow^*)$ between word models W and V. The r-round game works exactly as in the standard game for modal logic on Kripke models. There are distinguished points in the two models, and they are updated in each round of a play. The difference from the standard games is that player I may decide at each round to play a standard move or else a $*$-*move*. In the $*$-move, I picks one of the two structures and moves the distinguished point (say w_i) to some w_j with $j \geq i$. Then II does the same in the other structure. If the distinguished points are labelled differently at any round, then I wins the play; otherwise II wins.

To show that $L = a^*b(a+b+c)^*$ is not definable, we show that for each r there are words w and v such that $w \in L$ and $v \notin L$, but player II has a winning-strategy in the r-round game on the string models corresponding to w and v. We take

$$\begin{array}{rcl} w & = & a^{r+1}b(a^r ca^r b)^r \\ v & = & a(a^r ca^r b)^r. \end{array}$$

Let $n_i(b, W)$ be the number of b points strictly greater than the distinguished point in W at the end of round i; similarly for $n_i(b, V)$. The winning strategy for player II is to match a b with a b and a c with a c, and to maintain the assertion that either $n_i(b, W) = n_i(b, V)$, or else both numbers are at least $r - i$ (and similarly for c). ❑

Syntax	**Expressions** r	$0 \mid a \mid rs \mid r+s \mid r^+$
Semantics	**Main Clauses**	$[\![r^+]\!] = \bigcup_{n>0} [\![r]\!]^n$, where $[\![r]\!]^1 = [\![r]\!]$ and $[\![r]\!]^{n+1} = [\![r]\!]^n [\![r]\!]$

Figure 9. The syntax and semantics of ε-free regular expressions

Temporal Logic of Strings

We can define all star-free languages if we add the temporal operator $\mathcal{U}$, called *until*. This logic, which we will call PTL, is defined in Figure 8. We can define the language from Proposition 13 in PTL.

EXAMPLE 14. The language $a^*b(a+b+c)^*$ is defined by the following formula

$$\mathcal{U}(b, a)$$

Thus, adding $\mathcal{U}$ gives us a more expressive language. In fact, Etessami and Wilke [26] have shown that there is an "until hierarchy," based on the nesting depth of $\mathcal{U}$. The following theorem characterizes the expressive power of PTL extending the classical characterization of temporal logic by Kamp [44].

THEOREM 15. *The following are equivalent for a language $L \subseteq \Sigma^+$:*

1. *L is FO definable (over the signature $<$ and monadic predicates corresponding to the alphabet letters).*
2. *L is definable in PTL.*
3. *L is star-free.*

Proof. The equivalence (1) iff (3) is due to McNaughton [66]. For an accessible proof, see [25]. The equivalence (1) iff (2) uses Gabbay's [31] separation method, but can also be proved algebraically [19]. See also [30]. ❏

EXAMPLE 16. The language $(aa)^+$ is not PTL definable.

Proof. See [92]. ❏

We will now consider an extension of the star-free languages, called the *regular languages*, defined in Figure 9.

Propositional Dynamic Logic of Strings

The regular languages were first logically characterized by Büchi who showed that they correspond to the languages definable in the monadic second order logic of strings (MSO). We will use propositional dynamic logic (PDL), defined in Figure 10, to characterize them. First, notice that $(aa)^+$ is definable:

EXAMPLE 17. The language $(aa)^+$ is defined by

$$a \wedge \langle\rightarrow\rangle a \wedge [\rightarrow; a?; \rightarrow; a?]^* \neg\langle\rightarrow\rangle\top$$

We will now define the automata theoretic model of the regular languages: finite automata. A *finite automaton* (FA) M is a structure $(\Sigma, Q, F, q_0, \Delta)$ where Σ is a alphabet, Q is a finite set of states, $F \subseteq Q$ is the set of final states, q_0 is the initial state, and Δ is a finite set of transition rules of the form $(q, a) \rightarrow p$ with $a \in \Sigma$ and $p, q \in Q$. We define the transition relation $\Rightarrow_M \subseteq (Q \times \Sigma^*) \times (Q \times \Sigma^*)$ inductively as follows:

$$(q, \varepsilon) \Rightarrow_M (q, \varepsilon)$$
$$(q, aw) \Rightarrow_M (p, w)$$

where $(q, a) \rightarrow p$ is a transition rule in Δ. We say that M *accepts* a string w if $(q_0, w) \Rightarrow_M^* (p, \varepsilon)$ where $p \in F$ and $\Rightarrow_M^*$ is the reflexive, transitive closure of $\Rightarrow_M$. Given an FA M, the language accepted by M, denoted by $L(M)$, is defined as

$$L(G) = \{w \mid (q_0, w) \Rightarrow_M^* (p, \varepsilon), p \in F\}$$

One interesting observation, using the automata theoretic characterization of regular languages, is that they are closed under complementation (notice that "$-$ " is not included in the definition of regular expressions).

Syntax	**Formulas** φ	$p_i \mid \neg\varphi \mid \varphi \wedge \psi \mid [\pi]\varphi$
	Programs π	$\rightarrow \mid ?\varphi \mid \pi;\sigma \mid \pi \cup \sigma \mid \pi^*$
Semantics	**Main Clauses**	$W, i \models [\pi]\varphi$ iff for all j such that $(i, j) \in [\![\pi]\!]_W, W, j \models \varphi$
		$[\![?\varphi]\!]_W = \{(i, i) : i \in [\![\varphi]\!]_W\}$
		$[\![\pi;\sigma]\!]_W = [\![\pi]\!]_W; [\![\sigma]\!]_W$
		$[\![\pi \cup \sigma]\!]_W = [\![\pi]\!]_W \cup [\![\sigma]\!]_W$
		$[\![\pi^*]\!]_W = ([\![\pi]\!]_W)^*$

Figure 10. Propositional Dynamic Logic (PDL) on string models

THEOREM 18. *The following are equivalent for a language $L \subseteq \Sigma^+$:*

1. *L is definable in PDL.*
2. *L is definable in MSO.*
3. *L is regular.*
4. *L is accepted by a FA.*

Proof. The equivalence (2) iff (3) is Büchi's theorem. Again, see [25] for an accessible proof. The equivalence (3) iff (4) is known as Kleene's theorem, see e.g. [39]. For a proof of the equivalence (1) iff (3), see Kracht [53]. ❑

Two interesting results that use algebraic proofs show that it is decidable whether a regular language is definable in $\mathcal{L}(\rightarrow, \rightarrow^*)$ or in PTL [19]. Since it is decidable for any regular language L whether $L = \Sigma^+$, it is decidable whether a formula in MSO is valid over string models [10].

Variations

Other non-modal logics that have been studied in the context of strings include monadic transitive closure (MTC) [3] and least fixed point (MLFP) logic [79], as well as logics with modular counting quantifiers [93]. The latter are of interest because they allow to extend FO logic so that $(aa)^+$ becomes definable without going to the full power of MSO. The logics MTC and MLFP define precisely the regular languages, since it is easy to see that PDL $\leq$ MTC $\leq$ LFP $\leq$ MSO. The equivalence then follows from theorem 18.

Extensions

The first proof that a natural language is not regular was given by Chomsky [16, 17]. Thus, we would have to find stronger logics to describe natural languages within this framework. This is however not the line of research pursued (Rounds [85] being a notable exception), for two reasons. First, decidability of the logical formalism employed is of some importance, as this line of research ultimately aims to contribute to computational linguistics. However, trying to find *decidable* extensions of PDL or MSO is quite challenging (a point we will revisit later). There exists a characterization of the CFLs in terms of an extension of MSO [58], allowing quantification over special kinds of binary relations, so-called "matchings". Even though the question whether this logic is decidable is not addressed there, validity is undecidable for any logic characterizing CFLs, since the questions whether $L(G) = \Sigma^+$ is undecidable for CFGs. Such logics are also bound to be odd, since CFLs are not closed under complementation. The second problem is that using a logics for *strings* does not give a notion of strong generative capacity: the process of verifying that a formula is true of a string does not assign a structure to that string, as the process of deriving a string using a grammar does.

Digression

One point which should be of interests to modal logicians concerns the sense in which *words* are like *(modal) sentences*. The analogy is neatly captured in coalgebra (see Chapter 6), especially in studies pertaining to *coalgebraic logic*. We are considering several functors on the category of sets. Here $\mathcal{P}$ is the power set functor, and $\mathcal{P}_f$ is the finite power set functor. *AtProp* is a set of atomic propositions, and A is an alphabet. We have the following analogies,

	Kripke semantics	automata
Functor $F(x)$ on sets	$\mathcal{P}(x) \times \mathcal{P}(AtProp)$	deterministic : $x^A \times \{0,1\}$ non-deterministic : $\mathcal{P}_f(x)^A \times \{0,1\}$
coalgebra	Kripke model	deterministic automaton
final coalgebra	canonical model	regular languages
notion of equivalence	bisimulation	bisimulation.

Kripke models, deterministic, and non-deterministic automata are described as coalgebras of the given functors. In both cases, the elements of the carrier of the coalgebra may be thought of as *states*. (However, coalgebras do not include specified "real worlds" or "start states".) In the case of the automata, the state sets might be infinite, but our use of $\mathcal{P}_f$ insures that they will be finitely branching. The set $\{0,1\}$ in the automata functors is there to equip the state set with *accepting* and *non-accepting* states. The final

coalgebra in each case turns out to be an important mathematical object, and the reader can see the sense in which the canonical model is the analog of the regular languages. Indeed, modal sentences might be thought of as the record of "possible observations" on Kripke models in the same way that words are on automata. Finally, from coalgebra we have a very general notion of equivalence, the coalgebraic bisimulation. The special cases of this are bisimulation of Kripke models and also the bisimulation of automata (the largest such is the Myhill-Nerode equivalence relation). See Rutten [86] for more information on the connection between automata and coalgebra.

3.3 Logics of trees

Since extending the logic of strings to capture more complex string languages than the regular languages often leads to undecidability, one approach to extending the coverage of our logic is to describe more complex structures: move from strings to trees. Thus, the Kripke structures we will be considering are trees, and the logics will contain more complicated modalities to describe trees. One immediate advantage of this approach for linguistic purposes is that these logics will automatically be connected to strong generative capacity, since they describe sets of trees. One disadvantage is that the *recognition* or *parsing* problem, which in the string case just amounts to model checking, now involves satisfiability checking (see below).

The extension of the descriptive approach to trees was originally also motivated by decidability questions [97]. Even though the connections to CFLs were pointed out by Thatcher [95], this line of research did not find applications in linguistics until the development of constraint based grammar formalisms which replaced the derivational approach to natural language syntax. The work of Rogers [83], Kracht [54], and others provided formal models for these constraint based grammar formalisms and established formal language theoretic results for them at the same time.

As mentioned above our Kripke structures will now be trees. We will use the concept of tree domains [35] to define such Kripke structures. A (finite, binary) *tree domain*, T, is a finite subset of $\{0,1\}^*$, such that for all $u, v \in \{0,1\}^*$

1. if $uv \in T$, then $u \in T$, and

2. if $u1 \in T$, then $u0 \in T$.

A string in T describes a path from the root to a node, where 0 means "go left" and 1 means "go right". We identify nodes with the path leading to them. Thus, ε is the root. The first condition above says that if there is a path to a node, then there is a path to any node above it (this is called prefix closure). The second condition says that if a node has a right daughter, then it has a left daughter (called left sibling closure).

The main relations between nodes in a tree that are of interest in linguistics are domination and linear precedence. We say that that a node $u \in T$ *dominates* a node $v \in T$ if for some $w \in \{0,1\}^*$, $v = uw$. A special case of domination is the parent-of relation, defined by: u is the parent of v if $v = u0$ or $v = u1$. We say that u *linearly precedes* v if for some $x, y, z \in \{0,1\}^*$, $u = x0y$ and $v = x1z$. Following Rogers [83], we will denote the domination relation by $\triangleleft^*$, the parent-of relation by $\triangleleft$, and linear precedence by $\prec$. Thus, our Kripke frames will be variations of the form $(T, \triangleleft, \triangleleft^*, \prec)$, where T is a tree domain.

Regular tree languages

In order to generalize from strings to labeled trees, we will now consider *ranked alphabets* in which each symbol has an arity or rank. For surveys of tree languages see Gécseg and Steinby [34] or Thatcher [96]. Let Σ be a ranked alphabet. We will denote the set of n-ary symbols in Σ by Σ_n. The set of terms over Σ is denoted by T_Σ. A subset of T_Σ is called a *tree language*.

In a number of settings, trees are considered to be labeled with boolean features, rather than with ranked symbols. We note that these two approaches commensurable using the following representation. Given a finite set of boolean features $F = \{f_1, \ldots, f_n\}$, the *binary ranked alphabet based on* F, Σ^F, is defined as

$$\Sigma^F = \{f_1, \neg f_1\} \times \cdots \times \{f_n, \neg f_n\} \times \{0, 2\}$$

where each $f_i, \neg f_i$ represents whether or not a feature holds at a given node and 0 or 1 represent the arity of the symbol. Thus, $(f_1, \neg f_2, 0)$ would be a leaf symbol, and $(f_1, \neg f_2, 2)$ would be an internal node symbol. The previous definition can be easily generalized to trees of any arity.

The *yield* of a tree, t, is the string over Σ_0 which is obtained by concatenating the symbols at the leaves of t from left to right, or more formally:

$$\begin{aligned} \mathit{yield}(c) &= c, \text{ for } c \in \Sigma_0 \\ \mathit{yield}(f(t_1, \ldots, t_n)) &= \mathit{yield}(t_1) \ldots \mathit{yield}(t_n), \text{ for } f \in \Sigma_n \end{aligned}$$

A (bottom-up, non-deterministic) *finite tree automaton* (FTA) M is a structure of the form (Σ, Q, F, Δ) where Σ is a ranked alphabet, Q is a finite set of states, $F \subseteq Q$ is the set of final states, and Δ is a finite set of transition rules of the form $f(q_1, \ldots, q_n) \to q$ with $f \in \Sigma_n$ and $q, q_1, \ldots, q_n \in Q$. An FTA is *deterministic* if there are no two transition rules with the same left-hand-side. It can be shown that the bottom-up variety of finite tree automata can be determinized, while the top-down variety cannot.

A *context* s is a term over $\Sigma \cup \{x\}$ containing the zero-ary term x exactly once. We write $s[x \mapsto t]$ for the term that results from substituting x in s with t. Given a finite tree automaton $M = (\Sigma, Q, F, \Delta)$ the derivation relation $\Rightarrow_M \subseteq T_{Q\cup\Sigma} \times T_{Q\cup\Sigma}$ is defined by $t \Rightarrow_M t'$ if for some context $s \in T_{\Sigma\cup Q\cup\{x\}}$ there is a rule $f(q_1, \ldots, q_n) \to q$ in Δ, and

$$\begin{aligned} t &= s[x \mapsto f(q_1, \ldots, q_n)] \\ t' &= s[x \mapsto q] \end{aligned}$$

We use $\Rightarrow_M^*$ to denote the reflexive, transitive closure of $\Rightarrow_M$. A finite automaton M *accepts* a term $t \in T_\Sigma$ if $t \Rightarrow_M^* q$ for some $q \in F$. The *tree language accepted* by a finite tree automaton M, $L(M)$, is

$$L(M) = \{t \in T_\Sigma \mid t \Rightarrow_M^* q, \text{ for some } q \in F\}.$$

A tree language, L, is *regular* if $L = L(M)$ for some FTA M.

The following example is concerned with the Circuit Value Problem (CVP), in which the trees labeled with boolean functions are evaluated. It is interesting to note that a number of separation results of logically defined tree languages use trees labeled with boolean functions [79].

EXAMPLE 19. Let $\Sigma = \{\wedge, \vee, 0, 1\}$. The tree language $CVP \subseteq T_\Sigma$ such that each tree in CVP evaluates to true can be accepted by the following FTA, $M = (\Sigma, Q, F, \Delta)$, where

$$\begin{aligned} Q &= \{t, f\} \\ F &= \{t\} \end{aligned}$$

and

$$\Delta = \left\{ \begin{array}{ll} 0 \rightarrow f, & 1 \rightarrow t, \\ \wedge(t,t) \rightarrow t, & \wedge(t,f) \rightarrow f, \\ \wedge(f,t) \rightarrow f, & \wedge(f,f) \rightarrow f, \\ \vee(t,t) \rightarrow t, & \vee(t,f) \rightarrow t, \\ \vee(f,t) \rightarrow t, & \vee(f,f) \rightarrow f \end{array} \right\}$$

Given a finite sets of feature $F = \{f_1, \ldots, f_n\}$ and a feature $f_i \in F$, we define the *projection*, π, that eliminates f_i in the natural way:

$$\pi : \Sigma^F \rightarrow \Sigma^{F-\{f_i\}}$$

This definition can be extended to arbitrary subsets $G \subseteq F$, where

$$\pi : \Sigma^F \rightarrow \Sigma^{F-G}$$

Given a projection $\pi : \Sigma^F \rightarrow \Sigma^{F-G}$, we extend π to a tree homomorphism $\hat{\pi} : T_{\Sigma^F} \rightarrow T_{\Sigma^{F-G}}$ as follows:

$$\begin{aligned} \hat{\pi}(c) &= \pi(c) \\ \hat{\pi}(f(t_1, \ldots, t_n)) &= \pi(f)(\hat{\pi}(t_1), \ldots, \hat{\pi}(t_n)) \end{aligned}$$

with $c \in \Sigma_0$ and $f \in \Sigma_n, n > 0$. For a tree language L, we define $\hat{\pi}(L) = \{\hat{\pi}(t) \mid t \in L\}$.

We will consider the relationship between regular tree languages and the derivation trees of CFGs.

PROPOSITION 20. *(Thatcher [95]) If $L \subseteq T_\Sigma$ is a regular tree language, then*

$$\{yield(t) \mid t \in L\}$$

is a CFL.

While the yields of regular tree languages are CFLs, regular tree languages are more complex than the derivation trees of CFG. In order to compare the regular tree languages to the derivation trees of CFGs, we formalize the latter using the local tree languages.

The *fork* of a tree t, *fork*(t), is defined by

$$\begin{aligned} fork(c) &= \varnothing \\ fork(f(t_1, \cdots, t_n)) &= \{(f, root(t_1), \ldots, root(t_n))\} \cup \bigcup_{i=1}^{n} fork(t_i) \end{aligned}$$

with $c \in \Sigma_0$, $f \in \Sigma_n, n > 0$, and *root* being the function that returns the symbol at the root of its argument. For a tree language L, we define

$$\mathit{fork}(L) = \bigcup_{t \in L} \mathit{fork}(t)$$

The intuition behind the definition of *fork* is that an element of $\mathit{fork}(T_\Sigma)$ corresponds to a rewrite rule of a CFG. Note that $\mathit{fork}(T_\Sigma)$ is always finite, since Σ is finite.

A tree language $L \subseteq T_\Sigma$ is *local* if there are sets $R \subseteq \Sigma$ and $E \subseteq \mathit{fork}(T_\Sigma)$, such that, for all $t \in T_\Sigma, t \in L$ iff $\mathit{root}(t) \in R$ and $\mathit{fork}(t) \subseteq E$.

We quote without proof the following two theorems by Thatcher [95].

THEOREM 21. *(Thatcher [95]) A tree language is a set of derivation trees of some CFG iff it is local.*

THEOREM 22. *(Thatcher [95]) Every local tree language is regular.*

While there are regular tree languages that are not local, the following theorem, also due to [95], demonstrates that we can obtain the regular tree languages from the local tree languages via projections. We will review the main points of the proof, because we will use some of its details later on.

THEOREM 23. *(Thatcher [95]) For every regular tree language L, there is a local tree language L' and a one-to-one projection π, such that $L = \hat{\pi}(L')$.*

Proof. Let L be a regular tree language. Assume that L is accepted by the deterministic FTA $M = (\Sigma, Q, F, \Delta)$. We define L' terms of R and E as follows: $R = \Sigma \times F$ and

$$E = \{((f, q), (f_1, q_1), \ldots, (f_n, q_n)) \mid f(q_1, \ldots, q_n) \to q \in \Delta, f_1, \ldots, f_n \in \Sigma\}$$

We then define $L' = \{t \in T_{\Sigma \times Q} \mid \mathit{root}(t) \in R, \mathit{fork}(t) \subseteq E\}$. Notice that the trees in L' encode runs of M. The tree homomorphisms $\hat{\pi}$ based on the projection $\pi : \Sigma \times Q \to \Sigma$ maps L' to L as can be easily verified.

It should be noted that, since M is deterministic, there exists exactly one accepting run for each tree in $L(M)$ and thus the homomorphism $\hat{\pi} : L' \to L$ is one-to-one. ❑

This rather technical result is of some importance in the context of linguistic application, for it implies that we can use frameworks of lower complexity to describe the same structures as a more complex framework *if we use more complex categories or features.* Since we can also add new categories as names for the more complex ones, we can use a less complex framework to describe the same structures as a more complex framework by adding more categories. Thus, parsimony would seem to imply that we should always use the simpler framework. However from the point of linguistics, the use of complex or additional features needs to be justified. To further elaborate on the previous point, we will have to keep in mind that all of the logics we will consider can define the local tree languages and all the languages they can define are regular. Thus undefinability will always mean undefinability over a fixed finite set of propositional variables, since we can always define a regular, undefinable tree language by using more features.

The basic modal logic of trees: $\mathcal{L}_{core}$

To the best of our knowledge, the first explicit use of modal logic to define tree languages can be found in [7]. Two variations of this logic were considered in [8, 9], of which we

Syntax	**Formulas** φ	$p_i \mid \neg\varphi \mid \varphi \wedge \psi \mid [\pi]\varphi$
	Programs π	$\rightarrow \mid \leftarrow \mid \uparrow \mid \downarrow \mid \pi^*$
Semantics	**Main Clauses**	$[\![\rightarrow]\!]_T = \{(u0, u1) \mid u1 \in T\}$
		$[\![\leftarrow]\!]_T = \{(u1, u0) \mid u1 \in T\}$
		$[\![\downarrow]\!]_T = \{(u, ui) \mid i \in \{0,1\}, ui \in T\}$
		$[\![\uparrow]\!]_T = \{(ui, u) \mid i \in \{0,1\}, ui \in T\}$

Figure 11. Modal logic of trees: $\mathcal{L}_{core}$

will consider the latter. The basic modal logic of trees, $\mathcal{L}_{core}$, is defined in Figure 11. Again, we say that a tree T satisfies a formula φ if $T, \varepsilon \models \varphi$. A language L is *definable* in this (or another language) if there is a sentence φ so that L is exactly the set of trees satisfying a sentence φ.

The following proposition establishes that $\mathcal{L}_{core}$ is expressive enough to define any binary branching, local tree language. The restriction to binary branching is only due to the fact that we defined our tree domains to be binary branching.

PROPOSITION 24. *Let $L \subseteq T_\Sigma$ be a local tree language. There is a sentence φ_G in $\mathcal{L}_{core}$ that defines L.*

Proof. By Theorem 21, there is a CFG G such that L is equal to the derivation trees of G. Let $G = (\Sigma, \Gamma, P, S)$. Since we are only considering binary branching trees, every rule in P is of the form $A \rightarrow BC$ or $A \rightarrow a$ with $A, B, C \in \Gamma$ and $a \in \Sigma$. We can simply encode the rules directly in our logic:

$$A \rightarrow \bigvee_{A \rightarrow BC \in P} \langle\downarrow\rangle(B \wedge \langle\rightarrow\rangle C)$$

and

$$A \rightarrow \bigvee_{A \rightarrow a \in P} (\langle\downarrow\rangle a)$$

This ensures that the models of φ_G are parse trees of G. However, we further need to ensure only the parse trees of G model φ_G. So, we need to express that each node makes exactly one symbol true:

$$[\downarrow^*]\Big(\bigvee_{a \in (\Sigma \cup \Gamma)} a \wedge \bigwedge_{a \neq b} (\neg a \vee \neg b)\Big)$$

that the start symbol of the grammar is true at the root: S, that the terminal symbols are true at the leaves:

$$[\downarrow^*]\Big(\bigvee_{a \in \Sigma} a \rightarrow \neg\langle\downarrow\rangle\top\Big)$$

and that the non-terminal symbols are true at the internal nodes

$$[\downarrow^*]\Big(\bigvee_{A \in \Gamma} A \rightarrow \langle\downarrow\rangle\top\Big)$$

❑

As is observed by Blackburn and Meyer-Viol, this translation of a CFG into logical formulas brings with it a change in perspective. Instead of a *procedural* or *derivational* perspective that considers CFG rules to be rewrite rules, we move to a *declarative* or *descriptive* perspective that considers CFG rules to be *constraints*. This change in perspective is the main motivation for the application of logic in syntax, because of a similar change in perspective that occurred in a number of grammar formalisms proposed by linguists in the 1980s, most notably Chomsky's "Government and Binding" (GB) [18] and Gazdar, Klein, Pullum, and Sag's "Generalized Phrase Structure Grammar" (GPSG) [33].

ID/LP Grammars

The rules of a CFG encode two kinds of information: the categories of a node and its children, and the order in which the categories of the children occur. Thus, a rule of the form $A \to BC$ tells us that a node labeled A can have two children, one labeled B, the other C, and that the node labeled B precedes the node labeled C. Linguists have observed that separating these two notions can lead to more compact grammars. Thus, ID/LP grammars have been proposed that consist of *unordered* rewrite (immediate dominance or ID) rules, $A \to B, C$, and *linear precedence* (LP) rules, $B < C$. Linear precedence rules only apply to sisters, which is why we used $<$ rather than $\prec$ which applies to arbitrary nodes.

ID/LP grammars can be very naturally expressed in $\mathcal{L}_{core}$; in fact ID/LP grammars are, in some sense, a very limited logic for trees. See Gazdar et al. [33] or Shieber [88] for applications and detailed examinations of ID/LP grammars.

Variations of $\mathcal{L}_{core}$

Two additional basic modal logics of trees have been considered by Blackburn and associates [7, 8]. The first includes the connectives $\varphi \Rightarrow \psi$ and $\bullet(\varphi_1, \ldots \varphi_n)$. The latter is used in the context of trees with n children, so we will only consider the case where n is 2. Their semantics are given by $T, v \models \varphi \Rightarrow \psi$ iff for all u, $T, u \models \varphi \to \psi$, and $T, v \models \bullet(\varphi, \psi)$ iff $T, u0 \models \varphi$ and $T, u1 \models \psi$. Notice that the purpose of $\bullet$ is to combine immediate dominance and linear precedence into one connective.

Blackburn and Meyer-Viol [8] define a modal logic of trees that differs from $\mathcal{L}_{core}$ in that it contains modalities for the left and right daughter: $\downarrow_1, \downarrow_2$.

Temporal Logic of Trees

We now move on to an extension of $\mathcal{L}_{core}$, temporal logic. The syntax and semantics of propositional tense logic on trees, $\mathcal{X}_{until}$, is defined in Figure 12. The main application of $\mathcal{X}_{until}$ was given by Palm [70], though with a different formulation which we will consider below. We follow here the formulation of Marx [63], because it lends itself to a more direct proof of equivalence with FO.

THEOREM 25. *[63] The following are equivalent for a tree language $L \subseteq T_\Sigma$:*

1. *L is FO definable.*

2. *L is definable in $\mathcal{X}_{until}$.*

Syntax	$p_i \mid \neg\varphi \mid \varphi \wedge \psi \mid \mathcal{U}_{\rightarrow}(\varphi,\psi) \mid \mathcal{U}_{\leftarrow}(\varphi,\psi) \mid \mathcal{U}_{\uparrow}(\varphi,\psi) \mid \mathcal{U}_{\downarrow}(\varphi,\psi)$
Semantics	$T, u \models \mathcal{U}_{\downarrow}(\varphi,\psi)$ iff there exists a v such that $u \lhd^* v$, $T, v \models \varphi$, and for all w such that $u \lhd^* w \lhd^* v$, $T, w \models \psi$

Figure 12. Temporal logic of trees: $\mathcal{X}_{until}$ (only one clause in the semantics)

Syntax	**Formulas** φ	$p_i \mid \neg\varphi \mid \varphi \wedge \psi \mid [\pi]\varphi$
	Programs π	$\rightarrow \mid \leftarrow \mid \uparrow \mid \downarrow \mid \pi_\varphi \mid \pi^*$
Semantics	**Main Clauses**	$[\![\pi_\varphi]\!]_T = \{(u,v) \mid (u,v) \in [\![\pi]\!]_T, T, u \models \varphi\}$

Figure 13. Conditional path logic of trees: $\mathcal{L}_{cp}$

While the notion of regular expressions can be generalized to trees, the correspondence between star-free expressions and FO (or $\mathcal{X}_{until}$) definability breaks down at this level. In fact, Thomas and Potthoff [81] showed that every regular language that does not contain unary branching symbols is star-free. The question whether FO definability of regular tree language is decidable is still open.

Variations of $\mathcal{X}_{until}$

As was mentioned above, Palm's [70] application of $\mathcal{X}_{until}$ was carried out using a different formulation which he called propositional tense logic and which Afanasiev et al. [1] called conditional path logic, $\mathcal{L}_{cp}$. The syntax and semantics of $\mathcal{L}_{cp}$ are defined in Figure 13.

X-bar theory

As was mentioned above, which non-terminals are used in a natural language grammar matters to linguists. The point again is that the label assigned to a node in a tree signifies the grammatical category of the constituent it dominates. One theory of the organization of non-terminals and their rules is X-bar theory, which provides the foundation for a variety of grammar formalisms, including GB and GPSG. There are many variations of X-bar theory, so the particular formulation discussed here may not agree with those found in other places.

In terms of the organization of the non-terminals of a grammar, X-bar theory stipulates that there is a finite set of *lexical categories*, like $N(oun)$, $V(erb)$, $P(reposition)$, $A(djective)$, $Adv(erb)$, corresponding to the parts of speech, and that all other non-terminals are *projections* of the lexical categories. The idea of a projection is best motivated by the following example. The constituent *tall man* consists of two words, a noun and an adjective. When considering what the category of the constituent should be, we should take into account that *tall man* behaves more like a noun than like an adjective, which can be verified by substituting *tall man* for a noun in a sentence, preserving grammaticality, and substituting it for an adjective in a sentence, not preserving grammaticality. Thus, the category of *tall man* should be derived from the category of *man*. The category that X-bar theory assigns to the phrase is called N' (pronounced N-bar). N' is a projection of N. While X-bar theory within GB considered N and N' as atomic categories, the idea that the bar-level of a node is a syntactic feature is due to GPSG.

While there are various proposal for X-bar theory, we will assume that all rules of an X-bar grammar should be of the form

$$X'' \to X', Y'' \tag{11}$$

$$X' \to X', Y'' \tag{12}$$

$$X' \to X, Y'' \tag{13}$$

The non-terminal Y'' has different roles in the three rule schemata, each of which has a name in X-bar theory. In rule schema (11), Y'' is called the *specifier*; in rule schema (12), it is called the *adjunct*, and in rule schema (13), it is called the *complement*. In each of the rules, the X or X' on the right hand side is called the *head*.

It has been observed in a variety of contexts [48, 51, 70] that it is desirable to dispense with the bar-feature and to define the constraints posed by the X-bar schemata in terms of projections. Thus, we would like to define a constraint that states that every node has a path to a leaf such that the node, the leaf, and all the nodes on the path have the same lexical features. This can expressed in $\mathcal{L}_{cp}$ as follows. First, we state that a feature φ belongs to a head:

$$hd\ \varphi \equiv \varphi \wedge head$$

Then, we state that a feature φ is projected from a leaf:

$$proj\ \varphi \equiv \langle \downarrow^*_{hd\ \varphi} \rangle (hd\ \varphi \wedge leaf)$$

Finally, we can restate the X-bar convention by requiring every node to be a projection, given a finite set of lexical features Lex:

$$[\downarrow^*](\bigvee_{\varphi \in Lex} proj\ \varphi)$$

Notice that we would need a feature to indicate that a node is the head in case two siblings share the same lexical feature. Furthermore, there are certain regularities that this head feature has to observe, such as that no two sisters may both be heads:

$$[\downarrow^*](head \to \neg(\langle \leftarrow \rangle head \vee \langle \rightarrow \rangle head))$$

Dynamic Logic of Trees

The first descriptive characterization of the regular tree languages was obtained by Doner [23], and Thatcher and Wright [97]. They generalized Büchi's theorem to trees.

THEOREM 26. *The following are equivalent for a tree language $L \subseteq T_\Sigma$:*

1. *L is regular.*
2. *L is definable in MSO.*

Kracht [49] introduced PDL on trees in the context of model theoretic syntax.

While the correspondence between $\mathcal{X}_{until}$ and FO continues to hold in the generalization from strings to trees, the same is not true for the correspondence between PDL and MSO on strings, as was shown by Kracht, a topic we shall investigate in detail in the next section.

Syntax	**Formulas** φ	$p_i \mid \neg\varphi \mid \varphi \wedge \psi \mid [\pi]\varphi$
	Programs π	$\rightarrow \mid \leftarrow \mid \uparrow \mid \downarrow \mid ?\varphi \mid \pi;\sigma \mid \pi \cup \sigma \mid \pi^*$

Figure 14. Dynamic logic of trees

Undefinability: Inessential Features

The relationships between the three logics discussed above are well-understood, in that $\mathcal{L}_{core}$ is properly included in $\mathcal{X}_{until}$, which is properly included in PDL, which in turn is properly included in MSO. There is a central property that can be used to describe the languages that can be defined in one logic, but not in another. This property was first introduced by Kracht [50] and it is defined in terms of *inessential features*.

Let F be a finite set of features, $G \subseteq F$, $L \subseteq T_{\Sigma^F}$, and $\pi : \Sigma^F \rightarrow \Sigma^{F-G}$ be a projection. We call the features in G *inessential for* L if the homomorphism $\hat{\pi} : L \rightarrow T_{\Sigma^{F-G}}$ based on π is one-to-one. The intuition for this definition of inessential features is that no two trees in L can be distinguished using features in G. Thus, given a tree t in $\hat{\pi}(L)$, we can recover the features from G in t using $\hat{\pi}^{-1}$, since $\hat{\pi}$ is one-to-one.

EXAMPLE 27. The bar feature of the version of X-bar theory sketched above is inessential. To see that, notice that there is only one head (bar-level 0) which has a maximal projection (bar-level 2) and all projections in between are of bar-level 1.

While being an inessential feature is defined with respect to a language, being eliminable is defined with respect to a logic and a language. Let F be a finite set of features, $G \subseteq F$, $L \subseteq T_{\Sigma^F}$, $\pi : \Sigma^F \rightarrow \Sigma^{F-G}$ be a projection, and $\mathcal{L}$ be a logic. Suppose that L is definable in $\mathcal{L}^F$. We say that G is *eliminable in* $\mathcal{L}$ *for* L if $\hat{\pi}(L)$ is definable in $\mathcal{L}^{F-G}$.

It should be noted that this definition of eliminability does not coincide with Kracht's [50], who defines eliminable as being globally explicitly definable. Kracht's definition implies the definition used here, and thus is stronger. However, since we are interested in *ineliminability*, by contraposition, the definition employed here implies Kracht's definition of ineliminability.

The following, well-known, inclusions follow primarily from the definition of the three modal logics.

THEOREM 28. $\mathcal{L}_{core} \leq \mathcal{L}_{cp} \leq PDL_{tree} \leq MSO$

Proof. The first two inclusions follow from the definitions of these logics. The third inclusion follows from the fact that transitive closure is MSO-definable. ❑

Next, we consider strictness of these inclusions.

PROPOSITION 29. *[87] Let* $F = \{a, b\}$*. The tree language* $L_1 \subseteq T_{\Sigma^F}$ *such that each tree in* L_1 *contains a path from the root to a leaf at which exactly one* a *holds is not* $\mathcal{L}_{core}$*-definable, but is* $\mathcal{L}_{cp}$*-definable.*

PROPOSITION 30. *Let* $\Sigma = \{\wedge, \vee, 0, 1\}$*. The tree language* $CVP \subseteq T_\Sigma$ *such that each tree in* CVP *evaluates to true is not* $\mathcal{L}_{cp}$*-definable, but is* PDL_{tree}*-definable.*

Proof. Potthoff [80] showed that CVP is not definable in an extension of first-order logic with modular counting quantifiers, and since $\mathcal{L}_{cp}$ is equivalent to first-order logic on trees [1], the undefinability follows. That CVP is definable in PDL$_{tree}$ is shown in [1]. ❑

PROPOSITION 31. *[52, 53] Let $F = \{p, q\}$. Let $L_2 \subseteq T_{\Sigma^F}$ where each tree in L is a ternary branching tree such that p is true along a binary branching subtree and q is true at all leaves at which p is true. The language $L_3 \subseteq T_{\Sigma^{\{q\}}}$ obtained from the projection that eliminates p is not PDL_{tree}-definable, but is MSO-definable.*

These three propositions demonstrate the strictness of the inclusion of the three modal logics and MSO. Next, we will consider how languages that are undefinable in one of these logics can be defined with additional features.

THEOREM 32. *[102] There exists a set of features F, a tree language $L \subseteq T_{\Sigma^F}$, and a subset $G \subseteq F$, such that G is ineliminable in $\mathcal{L}_{core}$ (resp. $\mathcal{L}_{cp}$) but eliminable in $\mathcal{L}_{cp}$ (resp. PDL_{tree}).*

Proof. Both of these constructions work the same way. Given two of our logics $\mathcal{L}_1, \mathcal{L}_2$, with $\mathcal{L}_1 < \mathcal{L}_2$, pick a tree language, L, that is not definable in $\mathcal{L}_1$ but is definable in $\mathcal{L}_2$, which exists by propositions 29 and 30.

By Theorem 28, we know that L is regular, and by Theorem 24, we know that any local tree language is definable in $\mathcal{L}_1$. Given a deterministic FTA $M = (\Sigma, Q, F, \Delta)$, with $L = L(M)$, we can use theorem 23 to construct a local tree language $L' \subseteq T_{\Sigma \times Q}$ such that $\hat{\pi}(L') = L$. Now, the features in Q are inessential, since M is deterministic, but ineliminable, since L is undefinable in $\mathcal{L}_1$. However, since L is definable in $\mathcal{L}_2$, the features in Q are eliminable in $\mathcal{L}_2$. ❑

The previous theorem can be strengthened in that it can be used to *characterize* the tree languages that are undefinable in some logic $\mathcal{L}_1$ but definable in some other logic $\mathcal{L}_2$, with $\mathcal{L}_1 \leq \mathcal{L}_2$.

THEOREM 33. *[102] Any tree language that is not definable in $\mathcal{L}_{core}$ (resp. $\mathcal{L}_{cp}$) but is definable in $\mathcal{L}_{cp}$ (resp. PDL_{tree}) can be defined with additional, inessential features in $\mathcal{L}_{core}$ (resp. $\mathcal{L}_{cp}$) that are not eliminable in $\mathcal{L}_{core}$ (resp. $\mathcal{L}_{cp}$).*

Model Theoretic Syntax and Parsing

Recall that we generalized from strings to trees because we wanted to retain decidability and because we wanted to have a formalism that associates grammatical structure to an unstructured string. While decidability has been retained by this move, we need to say a little bit about how model theoretic syntax associates structures with strings. It should be noted that CFGs are formalisms that generate strings and that the structures that they assign to the strings arise in the process of generating the string, i.e. that trees are not a primary but a derived notion for formal grammars, Tree Adjoining Grammars being a notable exception. It should also be noted that, in our move to logics of trees, strings are no longer a primary notion because we are talking about trees directly. However, when we are interested in, say, checking whether a particular sentence is grammatical, we are given a string. So, while parsing, the process of determining whether a given grammar generates a given string, for CFG amounts to checking whether the grammar generates the string, this is not quite as straightforward here. The following quote from [2] gives an outline of how parsing in the logical framework might look like:

> The intent here is to translate a given grammar G into a formula φ_G such that the set of trees generated by the grammar is exactly the set of trees that

satisfy φ_G. Parsing, then, is just identifying the set of models of φ_G that yield a given string.

Following an idea proposed by Cornell [20] in the context of parsing with finite tree automata, we can improve on the above parsing procedure by observing that we can describe the set of all trees that yield a given string w, φ_w, and then simply check whether $\varphi_w \wedge \varphi_G$ is satisfiable. Notice, though, that having moved from logics of strings to logic of trees entails that the complexity of parsing, which in the string case is that of *model checking*, now is that of *satisfiability checking*. For all of the modal logics considered here, satisfiability checking is EXPTIME-complete. This is still significantly better than MSO or even FO with $\triangleleft^*$ both of which are non-elementary. However, model checking for the modal logics considered here is linear. For another approach to parsing and model theoretic syntax, see Palm [71].

Variations

Just as in the case of strings, monadic transitive closure (MTC) and least fixed point (MLFP) logic and logics with modular counting quantifiers have been considered on trees [79], as well as Thomas' chain and anti-chain logics [98]. While, over trees, MLFP is equally expressive as MSO, the question whether this equivalence also holds for MTC is currently open.

Kracht [54] also considers a modal logic with quantifiers ranging over propositions which is equivalent to MSO over trees.

Extensions

While the fact that natural languages are not regular has been known since the 1950s, examples of non-context-free phenomena in natural languages were only found in the 1980s; see Shieber [89]. Thus, we again need to consider how to strengthen the logics employed here if we want this approach to be applicable to all natural languages.

One approach, a generalization of the logical characterization of CFLs to trees, is Langholm's [56] characterization of the indexed languages by an extension of MSO which generalizes the logical characterization of CFLs mentioned above to trees. The indexed languages are located strictly between the CFLs and the context-sensitive languages. However, as was pointed out above, since parsing with tree logics involves testing for satisfiability rather than model checking, using an undecidable logic makes this approach uninteresting to computational linguistics.

Other approaches to extending model theoretic syntax to non-regular tree languages include Rogers' [84] extension of MSO to n-dimensional trees and the approach by Mönnich and colleagues [47] that encodes non-regular tree language in regular tree languages. Both approaches have in common that they introduce a new level of abstraction, since the direct connection between a logical formula and the tree it encodes is only available via a translation, which is explicit only in the latter approach. While this move from trees to more complex structures is analogous to the move from strings to trees, the latter move still corresponds to structures employed by linguists (derivation trees) while the former does not. However, both approaches retain decidability. Whether decidable, non-regular extensions of PDL can be used to define interesting classes of tree languages is, at present, an open problem.

3.4 Assessment: why modal logic for syntax and which one?

The foregoing multitude of tree logics raises two questions: what are the advantages and disadvantages of modal logics over classical logics for the description of trees, and similarly between the different modal logics? With respect to classical logic, the advantage is not, as in the general case, that modal logics are decidable while classical logic is not, since even MSO over trees is decidable. However, there is an advantage in complexity: all the modal logics considered are EXPTIME-complete [1], while MSO and FO with $\triangleleft^*$ are not elementary. One exception is FO with two successors, S_1, S_2 which is elementary [27], but not very expressive, since not even $\triangleleft^*$ is FO definable from S_1, S_2. For further discussions of complexity theoretic aspects of MSO, see [61].

Another more general question: why should logic be used at all to formalize grammatical theories? The first advantage that the approach outlined in this chapter has is that it connects a descriptive approach to grammars to a procedural approach: grammars formalized in these logics can be translated into tree automata which can be implemented. Another issue has to do with methodology in linguistics. While some linguists have become downright hostile towards formalization, the methodological paradigm of Government and Binding theory was to formulate more and more "principles;" i.e., general statements about the structure of sentences that were supposed to be true for all languages. However, it was quite unclear how one would check whether or not any new principle was consistent with all the previously stated principles. Formalizing principles from GB in one of these logics would allow to check whether an adding a given principle would make a particular theory contradictory. For further discussions of methodological issues in GB, see Hintikka and Sandu [38].

4 CONCLUSION AND OPEN PROBLEMS

Like other areas of applied mathematics which use formal tools to model phenomena under consideration, logic in general, and modal logic in particular, is one of the main tools for modeling in mathematical linguistics. As we have seen, modal logic is used in semantics to give a formal model of the meanings of the object language, while it is used in syntax to formalize grammatical theories; i.e., the meta-language. While the use of logic in semantics has considerable history with many significant successes, the logical approach to syntax outlined here is relatively new, although its foundations date back further.

There are many applications of logic in linguistics that we have not discussed here, however, two stand out because they contain applications of modal logic: categorial grammar and feature structures. However, both of these topics have already received authoritative surveys in the *Handbook of Logic & Language* [4].

One area of research in mathematical linguistics that has had considerable success in recent years has been the study of learnability of grammar formalisms, particularly of variations of categorial grammars; see Buszkowski [12]. Similar results for model theoretic syntax have not been obtained yet. While there exist interesting approaches to learning logical theories [62] which would seem to be relevant to extending learnability theory to model theoretic syntax, these approaches depend heavily on properties of their main tool, first-order logic. Thus, a significant amount of groundwork would have to be done before one could extend this approach to model theoretic syntax.

Further open problems in model theoretic syntax include computational implementations, for which some progress has already been made by the existing implementations of monadic second order logic [46]. However similar implementations of modal logics of trees or applications of the existing applications to linguistic problems do not seem to exist. The relationship between the different approaches to extending model theoretic syntax to non-regular tree languages outlined above is also currently open. For example, is there an easy way to translate between Rogers' extension in [84] of MSO to n-dimensional trees and the approach by Mönnich and colleagues [47] that encodes non-regular tree language in regular tree languages? Finally, while the different modal logics in this chapter were separated using the tree languages in Propositions 29, 30 and 31, it would be interesting to find linguistically motivated tree languages that can also separate these logics. Until such examples are found, very little motivation seems to exist to use the more expressive logics.

One interesting property that the logical approaches to both syntax and semantics outlined here have in common is that extending their empirical scope to different natural language phenomena depends on corresponding coverage of these phenomena in some syntactic theory. Since it is the main aim of model theoretic syntax to formalize linguistic theories, instead of *being* a linguistic theory, this dependence is clear here. In the case of semantic theory, coverage of linguistic phenomena depends, because of the principle of compositionality, on syntactic representations from which the semantic representations are built.

ACKNOWLEDGEMENTS

We thank Uwe Mönnich, Patrick Blackburn, Reinhard Muskens, Lawrence Stout, and Johan van Benthem for useful comments and encouragement at various points. Hans-Jörg Tiede would like to acknowledge support from Illinois Wesleyan University in the form of an Artistic/Scholarly Development Grant and a Junior Faculty Leave.

1 INTRODUCTION

Game-theoretic ideas have a long history in logic. A game-theoretic interpretation of quantification goes back at least to C.S. Peirce, and game-theoretic versions for all essential logical notions (truth in a model, validity, model comparison) have been developed subsequently. The connections between game theory and *modal* logic, on the other hand, have been developed only more recently. At the time of writing, the area is still an active one, so active in fact, that one might even argue that it is too early to be included in a handbook of modal logic. In spite of this concern, we believe that the volume of research falling into the category of modal logic and game theory justifies a survey. Our attempt in this chapter is to put some structure on the various strands of research, to create an organisation which highlights what we consider to be the essential lines of research. As with all endeavours of this sort, one cannot include all the research considered valuable, and we are well aware that our choice of topics also reflects our own interests and expertise.

Game theory has developed a wealth of interesting ideas for describing interactions which may involve a conflict of interest. So far, the logic community has restricted its attention to relatively few of these, mainly studying 2-player extensive games of perfect information which are strictly competitive (even win/lose). In fact, even this restricted class of games has turned out to be extremely rich, as set theory and computer science can testify. Still, given this traditionally narrow focus of logic, it is encouraging to see that more recent work in logic has extended the game-theoretic toolbox considerably, introducing, e.g., cooperative game theory, imperfect information and games involving more than 2 players. While even this can only be a beginning, by now the game-theoretic ideas used in logic certainly go beyond the intuitively natural idea of a winning strategy, and hence we will start our chapter with a section explaining the necessary background in game theory.

Having packed our game-theoretic baggage, our tour starts in Section 3 with new sights of a familiar landscape, possibly the most natural way to link games to modal logic. Game trees can be viewed as Kripke models, where the possible moves are modeled by an accessibility relation and additional information about payoffs and turn taking are encoded by propositional atoms. Structural equivalence notions such as bisimulation then turn into game equivalence notions, and we can investigate extensions of the modal language which can capture game-theoretic solution concepts such as the subgame-perfect equilibrium.

Leaving the first three sections together with the concluding Section 12 aside, the rest of this chapter can be divided into three reading tracks, epistemic logics (Sections 4-8), game logic (Section 9), and coalition logics (Sections 10-11), which can be pursued independently. The epistemic logic track describes approaches based on (dynamic) epistemic logic for dealing with imperfect information in games. The section on game logic describes an extension of Propositional Dynamic Logic for reasoning about games, focusing on operations for combining games like programs. The coalition logic track, finally, discusses a range of logics developed for modeling coalitional power in games, possibly also adding temporal or epistemic operators.

In Section 4 we introduce a widely accepted logic for knowledge in the area of games, where the assumptions impose that players are fully introspective and their knowledge is veridical. The more interesting properties are to be found when studying knowledge of

groups of players though, with *common knowledge* being the main and most intriguing notion in this palette. Section 5 introduces *interpreted systems*, a dominant paradigm in computer science to deal with knowledge and time, where time corresponds with steps in a protocol, or, for our purposes, indeed a game.

Such epistemic notions as introduced in Section 4 and 5 play an important role in games of imperfect information, and, as some major results in early game theory indicate, even beyond that (see Section 8). For instance, a procedure that yields a Nash equilibrium in extensive games, called *backward induction*, finds its justification in the assumption about common knowledge about rationality of the players. We will see, however, that nowadays epistemologists put the need for the inherently infinite conjunctions that come along with common knowledge into perspective and a non-trivial analysis of games can be given without falling back on such strong assumptions.

Where the emphasis in Section 4 is on the knowledge that the players have *about* the game, in Sections 7 and 8 the emphasis will be on how knowledge evolves *during* a game. Hiding one's knowledge can be beneficial for a player within a game, but revealing his ignorance can also be disastrous, and may benefit other players. Moreover, in certain games (like *Cluedo* and many card games) the winning conditions are purely epistemic: the game ends in a win for that player who is the first who happens to know some crucial information.

The dynamic logic of games discussed in Section 9 takes Propositional Dynamic Logic as its starting point. By a change in the underlying semantics, programs become 2-player games which can be combined using the old program operations of sequential composition, test, etc. Besides these program operations, a new duality operator is added which interchanges the roles of the players. Using this new operator, nondeterministic choice splits into two versions depending on which player makes the choice. A typical formula $[(a \cap b); (a \cup c)]p$, for instance, expresses that player 2 has a strategy for achieving p in the game where first, player 1 chooses between a and b, and then player 2 chooses between a and c (for details, see Section 9).

Section 10 introduces Coalition Logic, a basic modal logic for reasoning about the ability of groups in different kinds of games. For a set of individuals C, the formula $[C]p$ expresses that the members of C have a joint strategy for achieving p at the next stage of game. In Section 11, this language is extended to Alternating-time Temporal Logic (ATL) by adding operators for talking about the long-term future, where we can state, e.g., that a coalition can achieve p eventually. ATL is a game-theoretic generalisation of Computation Tree Logic (CTL), with applications in the formal verification of multi-agent systems. Further extensions of ATL to ATL*, the alternating μ-calculus and ATEL are presented. ATEL adds epistemic operators to ATL in order to express, e.g., that a coalition has a strategy for getting an agent to know something eventually.

While our focus in this chapter is on *modal logic for games*, there are also many *games for modal logic*. The reader interested in this reverse connection is referred to other chapters of this handbook (i.e., Chapter 12 and 17) for more details. The similarity between programs and games and the relevance of epistemic and temporal issues, on the other hand, suggest that modal logic may provide an interesting new perspective on games, and it is this perspective we would like to present in this chapter.

2 GAME THEORY

The purpose of this section is to introduce the basic game-theoretic notions needed for the logics discussed in later sections. Hence, this section will also give the reader an indication of the size and nature of the game-theoretic territory which has come under logical investigation.

In Sections 2.1 and 2.2, we discuss games in strategic and extensive forms, respectively. We cover some central solution concepts developed for these models, namely Nash equilibria and subgame-perfect equilibria. For a more detailed discussion of these notions, standard texts on game theory (e.g., [56, 11]) can be consulted. Section 2.3 focuses on a game-theoretic model of cooperation (effectivity functions) which has been investigated in social choice theory [52] and which will play a central role in the logics discussed in Sections 9, 10 and 11.

2.1 Games in Strategic Form

One of the most general models for situations of strategic interaction is that of a strategic game. Because of its generality, strategic games form the standard model in non-cooperative game theory. In a strategic game, the different players choose one of their available alternative actions/strategies, and taken together, these actions determine the outcome of the game. Note that we do not distinguish actions from strategies in strategic games; in extensive games, we will distinguish these two notions. Also, note that game *forms* can be conceived of as 'uninterpreted games': they only deal with the structure of the game, determining which moves are possible in which states, but they do not specify which states are 'good' or 'bad' for any player, i.e., they say nothing about winning, losing, a payoff or utility, when a particular state is reached.

DEFINITION 1 (Strategic Game Form). A *strategic game form* $F = (N, \{\Sigma_i | i \in N\}, o, S)$ consists of a nonempty finite set of agents N, a nonempty set of strategies or actions Σ_i for every player $i \in N$, a nonempty set of states S and an outcome function $o : \Pi_{i \in N}\Sigma_i \to S$ which associates to every tuple of strategies of the players (strategy profile) an outcome state in S. $\dashv$

For notational convenience, let $\sigma_C := (\sigma_i)_{i \in C}$ denote the strategy tuple for coalition $C \subseteq N$ which consists of player i choosing strategy $\sigma_i \in \Sigma_i$. Then given two strategy tuples σ_C and $\sigma_{\overline{C}}$ (where $\overline{C} := N \setminus C$), $o(\sigma_C, \sigma_{\overline{C}})$ denotes the outcome state associated with the strategy profile induced by σ_C and $\sigma_{\overline{C}}$. We shall also write $-i$ for $N \setminus \{i\}$.

Figure 1 below provides an example of a strategic game form among three players in the usual matrix depiction. Unless noted otherwise, we will assume that player 1 chooses the row, player 2 the column, and the third player chooses between the left and the right table. In this example, let σ_1 be the strategy where player 1 chooses B, σ_2 the strategy where player 2 chooses M, and let σ_3 be the strategy of player 3 choosing the left table. Then we have $o(\sigma_{\{1,2\}}, \sigma_{\{3\}}) = o((\sigma_1, \sigma_2, \sigma_3)) = s_1$.

To make a strategic game form into a strategic game, we need to add preference relations or utility functions which express the players' preferences over the game's outcomes. In the first case, given a preference relation $\succeq_i \subseteq S \times S$ for every player $i \in N$ and a strategic game form $F = (N, \{\Sigma_i | i \in N\}, o, S)$, we call $G = (F, (\succeq_i)_{i \in N})$ a *strategic game*. We interpret $s \succeq_i t$ to mean that player i prefers outcome s at least as much as outcome t, and one usually assumes that $\succeq_i$ is a linear order (although this assumption

Figure 1. A strategic game form for three players.

shall not be essential for our development later). Similarly, given a strategic game form F and a utility function $u_i : S \to \mathbb{R}$ for every player $i \in N$, we can construct a *strategic game* $G = (F, (u_i)_{i\in N})$ where player i prefers outcome s at least as much as outcome t iff $u_i(s) \geq u_i(t)$. Provided that $\succeq_i$ is indeed a linear order, the two definitions are interchangeable, and we shall freely switch between the two formats.

Figure 2 below shows three well-known 2-player games. The matrices list the players' utilities or payoffs, e.g., the top leftmost entry of the leftmost game, $(-4,-4)$ denotes the pair $(u_1(D,D), u_2(D,D))$.

	D	C
D	$-4,-4$	$0,-8$
C	$-8,0$	$-1,-1$

	B	F
B	$2,1$	$0,0$
F	$0,0$	$1,2$

	H	T
H	$-1,1$	$1,-1$
T	$1,-1$	$-1,1$

Figure 2. Three strategic 2-player games: Prisoner's Dilemma (left), Battle of the Sexes (middle) and Matching Pennies (right)

In the Prisoner's Dilemma, two prisoners are interrogated by the police. If the prisoners cooperate (C) and remain silent, they can only be sentenced for a minor offence and will receive one year in prison each. If both defect and confess (D), each will receive 4 years in prison. Finally, if only one prisoner defects, he will go free in order to be used as a witness against his fellow prisoner who will receive 8 years in prison. In the Battle of the Sexes, a couple needs to decide whether to go see a ballet performance (B) or a football match (F) in the evening. Both of them mainly want to spend the evening together, but she prefers the football match and he prefers the ballet performance. Lastly, in the Matching Pennies example, two children each have a penny, and they decide simultaneously whether to show heads (H) or tails (T). One child wins (payoff 1 for the winner, -1 for the loser) in case the sides match, the other child wins in case they differ. Matching Pennies is an example of a *zero-sum* or *strictly competitive* game: For every outcome state s we have that $u_1(s) + u_2(s) = 0$.

A strategic game allows us to model multi-agent interaction using strategies and preferences. Game theory has developed a number of solution concepts which specify a "predicted" set of outcomes for such a game (views differ as to how exactly such a solution has to be interpreted). The following notion is one of the cornerstones of modern game theory.

DEFINITION 2 (Nash Equilibrium). A strategy profile σ_N is a *Nash equilibrium* of a strategic game $G = (N, \{\Sigma_i | i \in N\}, o, S, (\succeq_i)_{i\in N})$ iff $\forall i \in N\ \forall \tau_i \in \Sigma_i :\ o(\sigma_i, \sigma_{-i}) \succeq_i o(\tau_i, \sigma_{-i})$ $\dashv$

Intuitively, a strategy profile (σ_1, σ_2) is a Nash equilibrium in a 2-player game in case σ_1 is a best response to σ_2 and vice versa; no player can improve his payoff by unilaterally

changing his strategy. In the three examples given in Figure 2, the reader may wish to verify that (D, D) is the only Nash equilibrium in the Prisoner's Dilemma, and that both (B, B) and (F, F) are Nash equilibria in the Battle of the Sexes. There is no Nash equilibrium in Matching Pennies.

While for a given player i, a Nash equilibrium only requires i's action to be optimal given the other players' actions, a *dominant* strategy is optimal regardless of what the other players do. Formally, for two strategies $x, y \in \Sigma_i$, x *strictly dominates* y iff $\forall \sigma_{-i} : o(x, \sigma_{-i}) \succ_i o(y, \sigma_{-i})$. We call a strategy strictly dominated iff it is strictly dominated by some other strategy. In the prisoner's dilemma, cooperation is strictly dominated by defection. No dominated strategies exist in the other games mentioned so far.

Our concern in this chapter is mainly with *pure* strategies which are non-probabilistic. In contrast, a *mixed strategy* allows a player to randomise over his set of strategies, playing each strategy with some probability p where $0 \leq p \leq 1$. In the Matching Pennies game, each player may decide to choose Heads with probability $\frac{1}{2}$. This strategy profile $((\frac{1}{2}, \frac{1}{2}), (\frac{1}{2}, \frac{1}{2}))$ is a Nash equilibrium over mixed strategies, and Nash's celebrated result states that it is no coincidence that Matching Pennies has such an equilibrium.

THEOREM 3 ([53]). *Every strategic game has a Nash equilibrium over mixed strategies.*

The computational complexity of *finding* a mixed strategy Nash equilibrium (from Theorem 3 we are ensured of its existence) for a 2-player strategic game with finite (pure) strategy sets is in NP, but it is presently not known whether the problem is also NP-hard. According to [57], this is one of the most important concrete open questions on the boundary of P today.

2.2 Games in Extensive Form

Strategic games consider strategic interaction as involving only a single choice for every player. There may be situations, however, where we want to model the fine structure of strategic interaction which involves modelling the sequential structure of decision making. Extensive form games provide us with this level of added detail.

Perfect Information

Given a finite or infinite sequence of actions $h = (a_1, a_2, \ldots)$, let $h|k = (a_1, a_2, \ldots, a_k)$ denote the initial subsequence of length k of h.

DEFINITION 4 (Extensive Game Form of Perfect Information). An *extensive game form of perfect information* is a triple $F = (N, H, P)$, where as before, N is the set of players.

H is a set of sequences (finite or infinite) over a set A of actions which we shall call *histories* (or: *runs*, *plays*) of the game. We require that H satisfies three requirements: (1) the empty sequence $() \in H$. (2) H is closed under initial subsequences, i.e., if $h \in H$ has length l, then for all $k < l$ we have $h|k \in H$. If $h \in H$ is infinite, $h|k \in H$ for all k. (3) If all finite initial subsequences of an infinite sequence h are in H, then so is h: given an infinite sequence h such that for all k we have $h|k \in H$, then $h \in H$. Let $Z \subseteq H$ be the set of *terminal histories*, i.e. $h \in Z$ iff for all $h' \in H$ and k such that $h'|k = h$ we have $h' = h$ (so, infinite histories are terminal). $P : H \backslash Z \to N$ is the player function which assigns to every nonterminal history the player whose turn it is to move. $\dashv$

As with strategic games, we turn an extensive game form into an extensive game

by adding preference relations. Formally, let $\succeq_i \subseteq Z \times Z$ be a preference relation on the set of terminal histories Z. As before, we shall sometimes use utility functions u_i instead of preference relations. Given an extensive game form $F = (N, H, P)$, we call $G = (F, (\succeq_i)_{i \in N}) = (N, H, P, (\succeq_i)_{i \in N})$ an *extensive game*. We call an extensive game G *finite* iff its set of histories H is finite. G has a *finite horizon* iff all histories in H have finite length.

Figure 3 shows the tree representation of an extensive game, where the branches are labelled by actions and the payoffs of the players are shown at the terminal nodes.

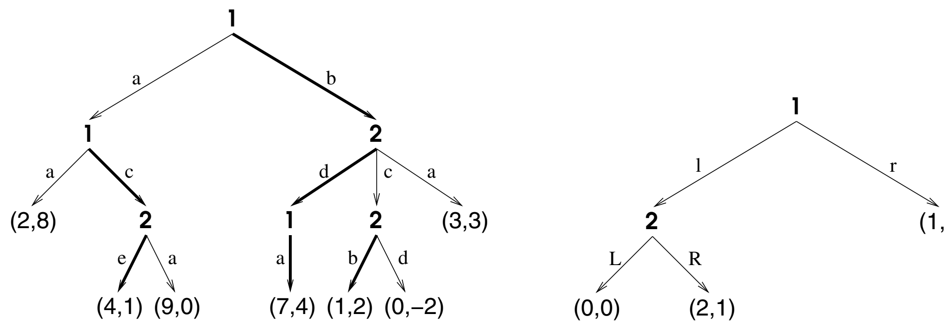

Figure 3. An extensive game for two player with payoffs (left) and an extensive game with an implausible Nash equilibrium (right)

Given a finite history $h = (a_1, \ldots, a_n)$ and an action $x \in A$, let $(h, x) = (a_1, \ldots, a_n, x)$. Furthermore, let $A(h) = \{x \in A | (h, x) \in H\}$ be the set of actions possible after h. Now we can define a strategy for player i as a function $\sigma_i : P^{-1}[\{i\}] \to A$ such that $\sigma_i(h) \in A(h)$ (P^{-1} denotes the pre-image of P). As before, we let Σ_i denote the set of strategies of player i. Given a strategy profile $\sigma = (\sigma_i)_{i \in N}$, let $o(\sigma) \in H$ be the history which results when the players use their respective strategies.

In the game on the left of Figure 3, the strategy for player 1 indicated by bold arrows is given by $\sigma_1(()) = b$, $\sigma_1((a)) = c$ and $\sigma_1((b, d)) = a$. Player 2's strategy indicated in the game is given by $\sigma_2((a, c)) = e$, $\sigma_2((b)) = d$ and $\sigma_2((b, c)) = b$.

The notion of a Nash equilibrium can now be lifted easily from strategic games to extensive games. Given an extensive game $G = (N, H, P, (\succeq_i)_{i \in N})$, a strategy profile σ is a *Nash equilibrium* iff $\forall i \in N\ \forall \tau_i \in \Sigma_i : \quad o(\sigma_i, \sigma_{-i}) \succeq_i o(\tau_i, \sigma_{-i})$. However, it turns out that for extensive games, Nash equilibria often lack plausibility, as shown by the game on the right in Figure 3, taken from [56].

The Nash equilibria of the game are (l, R) and (r, L). The second equilibrium however does not seem reasonable. At the position where player 2 has to move, she will choose R since this will give her a higher payoff. Knowing this, player 1 should choose l at the beginning of the game, and so we would want to advocate only (l, R) as the solution of the game. The strategy profile (r, L) turns out to be a Nash equilibrium because of the threat that player 2 will choose L rather than R, but this threat is not credible since choosing L would hurt her own interest. To rule out such pathological equilibria, we need to strengthen our equilibrium notion. The problem with profile (r, L) is that it prescribes an unreasonable choice in a subgame of the original game, whereas we would want our

equilibrium strategies to be optimal in every subgame.

To obtain a more robust equilibrium notion, we introduce the notion of a subgame more formally. Given two sequences h and h', with h finite, let (h, h') denote the concatenation of h and h'. Consider a history h in the extensive game $G = (N, H, P, (\succeq_i)_{i \in N})$. To isolate the subgame starting after h, we define $G(h) = (N, H|_h, P|_h, (\succeq_i|_h)_{i \in N})$ where $H|_h = \{h' | (h, h') \in H\}$, $P|_h(h') = P(h, h')$ for each $h' \in H|_h$ and finally $h' \succeq_i |_h h''$ iff $(h, h') \succeq_i (h, h'')$. Similarly, strategies σ_i (and strategy profiles) can be restricted to subgames by setting $\sigma_i|_h(h') = \sigma_i(h, h')$.

DEFINITION 5 (Subgame-Perfect Equilibrium). A strategy profile σ is a *subgame-perfect Nash equilibrium* of a game G iff for every history $h \in H$, the restriction $\sigma|_h$ of σ is a Nash equilibrium of $G(h)$. $\dashv$

In the game of Figure 3 (right), only (l, R) is a subgame-perfect equilibrium. Note that all subgame-perfect equilibria are also Nash equilibria. A game is called *generic* if no player is indifferent between any two terminal histories, i.e., for all $i \in N$ and $h, h' \in H$, we have $u_i(h) = u_i(h')$ iff $h = h'$.

THEOREM 6 ([42]). *Every finite extensive game of perfect information has a subgame-perfect equilibrium. Moreover, in any generic game, this equilibrium is unique.*

While the formal proof of this theorem is somewhat technical, the general method used to establish the result is easy to explain and is known as *backward induction*. We build up the equilibrium profile by induction on the length of a game (i.e., the length of its longest history). If a game has length 0, it only consists of a terminal node and there are no strategic decisions to be made. Consider the payoff vector of the terminal node as the backward induction vector (short: bi-vector) of the game. Now if the game G has length $n+1$, assume that player i has to move at the root of G. By induction hypothesis, all the proper subgames of G have a bi-vector and we have associated strategy profiles for them. To get an equilibrium profile for G, let i choose a successor with the highest bi-vector for i, and consider that payoff vector as the bi-vector of G. Starting at the terminal nodes, this backward induction method moves up through the game tree and inductively defines a strategy profile which turns out to be a subgame-perfect equilibrium and a bi-vector which is its associated payoff vector.

Note that the intuitive reasoning which we used to argue against (r, L) as a solution of the game in Figure 3 (right) was already an example of backward induction reasoning. In Figure 3, the backward induction profile in the game to the left has been indicated by boldface arrows. The payoff vector of the backward induction profile is $(7, 4)$.

As a corollary to Theorem 6, we obtain the following well-known result due to Zermelo which (in a slightly generalised version) can be used to show, e.g., that in the game of chess, either black or white must have a strategy which guarantees at least a draw. We say that a 2-player extensive game of perfect information is a *win-loss game* provided that it is strictly competitive and for all histories h, either $u_1(h) = 1$ or $u_2(h) = 1$, i.e., win and loss are the only two possible outcomes. In such a game, a strategy is a *winning strategy* for player i provided it guarantees a history h such that $u_i(h) = 1$.

THEOREM 7 ([107]). *Every finite 2-player win-loss game is determined, i.e., one of the players has a winning strategy.*

One can even show that the problem of determining whether such a game is a win for a specific player can be determined in polynomial time: in fact, it is a ‘canonical P-complete

problem' in the sense that it is a popular candidate to be related to other computational problems (like AND/OR Graph Solvability) in order to show *their* polynomial complexity. See [27, Appendix 11.1].

Almost Perfect Information

Extensive games of perfect information impose a strict order on the moves which take place in a game. As a first generalisation, we may extend the definition of an extensive game to allow for simultaneous moves of the players. These *extensive games of almost-perfect information* (or *extensive games with simultaneous moves*) will be important for our discussion of Coalition Logic and ATL. In these games, players are completely informed about the past, but they may be unsure about the present, i.e., about the actions the other players are simultaneously taking.

Formally, an extensive game of almost-perfect information is a tuple $G = (N, H, P, (\succeq_i)_{i\in N})$ just like an extensive game of perfect information, with the only difference that for every nonterminal history $h \in H$, $P(h)$ is a nonempty subset of N. Furthermore, for each $i \in P(h)$, we have a set $A_i(h)$ of actions possible for player i at h, and we define the set of actions possible after h to be $A(h) = \prod_{i\in P(h)} A_i(h)$. Histories of the game are now sequences of vectors, consisting of the actions chosen simultaneously by the appropriate players. A strategy for player i is now a function σ_i such that $\sigma_i(h) \in A_i(h)$. The definitions of Nash equilibrium and subgame-perfect equilibrium can easily be adjusted to these extensive games with simultaneous moves.

Imperfect Information

So far, we have assumed that the players always know where they are in the game tree. This amounts to assuming that the players are always informed about the actions which have been taken so far, both by the other players and by themselves; in short, we have considered perfect information games where a player has no private information (e.g., cards which only she knows), nor does she ever forget which moves she has made earlier (this is the essence of the game "Memory"). The game model we shall introduce now is an extension of the extensive game model to cover situations of imperfect information.

DEFINITION 8 (Extensive Game of Imperfect Information). An *extensive game of imperfect information* is a tuple $G = (N, H, P, (\mathcal{I}_i)_{i\in N}, (\succeq_i)_{i\in N})$. The only new component $\mathcal{I}_i$ is a partition of the set of histories where i has to move, i.e. of $P^{-1}[\{i\}]$, with the property that for all $h, h' \in I \in \mathcal{I}_i$, $A(h) = A(h')$. ⊣

The elements of $\mathcal{I}_i$ are called *information sets*. If player i has to make a decision in a game at history $h \in I \in \mathcal{I}_i$, she does not know which of the histories in I is the real history, i.e. she considers all histories in I as possible alternatives to h. In order for this interpretation to make sense, we have to assume that the histories in I cannot be distinguished by what actions are possible in the various histories, a requirement which we enforced by demanding that for all $h, h' \in I$, $A(h) = A(h')$. Observe that if all information sets are singletons, we have in fact a game of perfect information.

Since a player cannot distinguish between two histories which are in the same information set, her strategies have to be uniform within every information set. Hence, we define a strategy for an extensive game of imperfect information to be a function $\sigma_i : \mathcal{I}_i \to A$ such that $\sigma_i(I) \in A(I)$. In words, a strategy picks an action for every information set;

since histories within one information set allow for the same actions to be taken, the action prescribed by the strategy can always be executed, no matter where the player really is in the game tree.

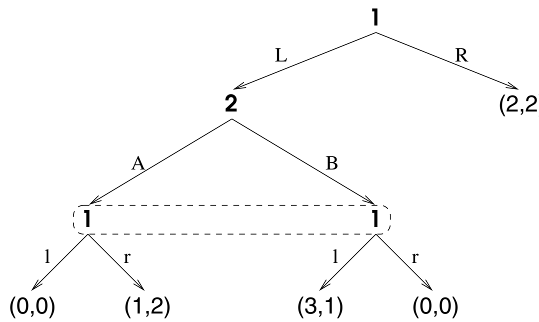

Figure 4. Example of an extensive game of imperfect information

Figure 4 contains an example of an imperfect information game. The information sets which are not singletons have been indicated by drawing a dashed box around the histories which are in the same information set. So in this game, player 1 makes the first move, and assuming she chooses to play L, player 2 moves afterwards. Player 1 however obtains no information about the choice made by player 2, maybe she was not present when the choice was made, maybe she forgot, etc. Her strategy therefore would have to specify either l or r for both cases, since she is unable to distinguish them. Two more examples of imperfect information games are given in Figure 5. The left game exhibits

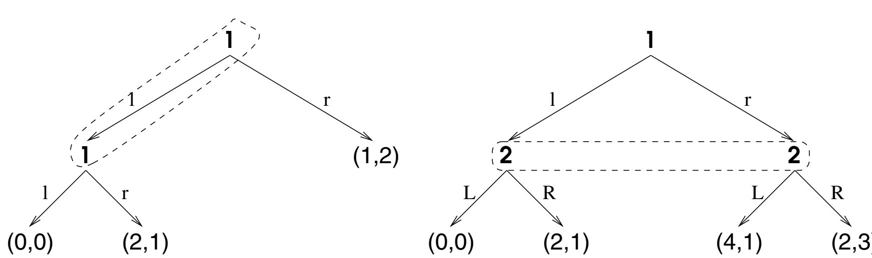

Figure 5. A game with imperfect recall (left) and one with simultaneous moves (right)

imperfect recall: After doing l, player 1 does not know whether she has done l already or not. Since this notion will play a role later, we will define it more formally here. Given game $G = (N, H, P, (\mathcal{I}_i)_{i\in N}, (\succeq_i)_{i\in N})$ and history $h \in H$, let $X_i(h)$ record the experience of player i along history h, i.e., the sequence of information sets the player encounters in h and the actions he takes at that information set. So with the game of Figure 4, we have $X_1(LAr) = (\emptyset, L, \{LA, LB\}, r)$. Then we say that G has *perfect recall* iff for every player i we have $X_i(h) = X_i(h')$ whenever there is some $I \in \mathcal{I}_i$ such that $h, h' \in I$. So while Figure 4 presents a game with perfect recall, the left game of Figure 5 does not, since $X_1(\emptyset) = (\emptyset)$ but $X_1(l) = (\emptyset, l)$.

The right game in Figure 5 shows that the imperfect information game model can also be used to model games with simultaneous moves. After player 1 moves, player 2 has to move without any information about the choice made by the first player. Thus, since player 1 also does not know about the decision that player 2 will make later, we can interpret this game as one where the two players simultaneously choose an action.

The concepts of Nash equilibrium and mixed strategy Nash equilibrium can easily be extended to imperfect information games. The story is more complicated for the subgame-perfect equilibrium. The game in Figure 6 demonstrates the problem that one can run into when wanting to apply backward induction to a game of imperfect information.

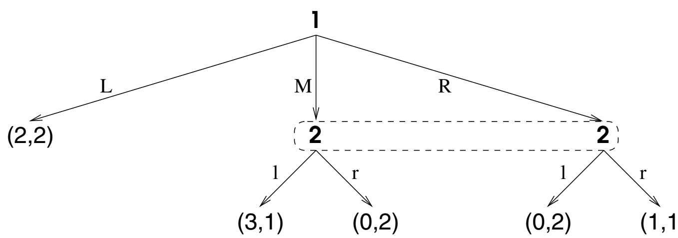

Figure 6. An imperfect information game where backward induction runs into problems

Player 2's only information set contains two subgames. In the left subgame, r is the strategy prescribed by backward induction, whereas in the right subgame, l is optimal. Since both subgames lie in the same information set, the backward induction strategy has to be uniform for both subgames. In order to label one of the two strategies as optimal, player 2 would have to know where she is in the game, but this is exactly what she does not know.

To deal with this problem, one can introduce a belief system which specifies at each information set the probability with which the player believes that a history has happened. The strategy choice can then make use of these probabilities. This leads to the notion of a *sequential equilibrium* which we shall not define formally here. Note simply that for the game in Figure 6, if player 2 believes that it is more likely that player 1 will play M rather than R, strategy r should be preferable to player 2. We refer the reader to [56] for the details.

2.3 Cooperation in Games

So far we have assumed that agents determine individually what strategy they want to follow. We made no attempt to account for the possibility that agents might cooperate in bringing about a desirable state of affairs. Effectivity functions, the model we discuss in this subsection, aim at capturing explicitly the powers which agents can obtain by forming coalitions.

Effectivity functions model the power distribution among individuals and groups of individuals. In social choice theory, they have been used in particular to model voting procedures. The exposition we will give here focuses on providing the necessary background to understand the link between effectivity functions and the neighbourhood

models used in non-normal modal logics like the ones we will discuss in Sections 9, 10 and 11.

Effectivity functions have been studied extensively in game theory and social choice theory [52, 1, 66]. The following exposition is based on [63, 62].

DEFINITION 9 (Effectivity Function). Given the finite nonempty set of players N and a nonempty set of alternatives or states S, an *effectivity function* is any function $E : \mathcal{P}(N) \to \mathcal{P}(\mathcal{P}(S))$ which satisfies the following two conditions: (1) $\forall C \subseteq N : \emptyset \notin E(C)$, and (2) $\forall C \subseteq N : S \in E(C)$. ⊣

The function E associates to every group of players the sets of outcomes for which the group is effective; coalition C is effective for X if it can bring about an alternative in X, even though it may have no control over which alternative of X is realised. The literature differs somewhat in the conditions placed on the function E. The conditions chosen here aim at Theorem 12 and the logics discussed in Sections 10 and 11. Informally, condition (1) of Definition 9 states that no group C can ensure that *nothing* is brought about, while condition (2) expresses that every group C can at least bring about *something* by 'choosing' the complete set of alternatives S, putting no constraints on what the players outside C can achieve.

EXAMPLE 10. Consider the following example from [24] about Angelina, Edwin and the judge: If Angelina does not want to remain single, she can decide either to marry Edwin or the judge. Edwin and the judge each can similarly decide whether they want to stay single or marry Angelina. If we assume that the three individuals live in a society where nobody can be forced to marry against his/her will, this situation can be modelled using effectivity functions as follows: The set of players is $N = \{a, e, j\}$ and the set of alternatives is $S = \{s_s, s_e, s_j\}$, where s_s denotes the situation where Angelina remains single, s_e where she marries Edwin, and s_j where she marries the judge. Angelina (a) has the right to remain single, so $\{s_s\} \in E(\{a\})$, whereas Edwin can only guarantee that he does not marry Angelina; whether she marries the judge or remains single is not up to him. Consequently, we have $\{s_s, s_j\} \in E(\{e\})$ and there is no proper subset X of $\{s_s, s_j\}$ such that $X \in E(\{e\})$. Analogously for the judge, we have $\{s_s, s_e\} \in E(\{j\})$. Angelina and Edwin together can achieve any situation except the one where Angelina marries the judge (since this alternative would require the judge's consent), and hence $\{s_s\}, \{s_e\} \in E(\{a, e\})$. Again, the situation is similar for the judge: $\{s_s\}, \{s_j\} \in E(\{a, j\})$. ⊣

In most situations, coalitional effectivity functions will satisfy some additional properties. Among the central properties are the following:

MONOTONICITY: Since a superset of states places fewer constraints on a coalition's ability, we can usually assume that effectivity functions are *monotonic*: For every coalition $C \subseteq N$, if $X \subseteq X' \subseteq S$, $X \in E(C)$ implies $X' \in E(C)$.

MAXIMALITY: An effectivity function E is *C-maximal* if for all X, if $\overline{X} \notin E(\overline{C})$ then $X \in E(C)$. E is *maximal* iff for all coalitions C it is C-maximal. Instantiating this condition for 2 players over $S = \{win_1, win_2\}$, $\{1\}$-maximality expresses that the game is determined: if one player does not have a winning strategy, then the other player does.

SUPERADDITIVITY: The most interesting principle governs the formation of coalitions. It states that coalitions can combine their strategies to (possibly) achieve more: E is *superadditive* if for all X_1, X_2, C_1, C_2 such that $C_1 \cap C_2 = \emptyset$, $X_1 \in E(C_1)$ and $X_2 \in E(C_2)$ imply that $X_1 \cap X_2 \in E(C_1 \cup C_2)$.

Given utility functions $(u_i)_{i \in N}$ for the players, effectivity functions also allow us to define solution concepts. Given an effectivity function $E : \mathcal{P}(N) \to \mathcal{P}(\mathcal{P}(S))$, call an alternative $s \in S$ *dominated* if there is a set $X \subseteq S$ and a coalition C such that $X \in E(C)$ and for all $i \in C$ and $x \in X$ we have $u_i(x) > u_i(s)$.

DEFINITION 11 (Core). Given an effectivity function $E : \mathcal{P}(N) \to \mathcal{P}(\mathcal{P}(S))$ and utility functions $(u_i)_{i \in N}$, the *core* of $(E, (u_i)_{i \in N})$ is the set of undominated alternatives. $\dashv$

In connection with the core, it is usually also assumed that for all sets $X \neq \emptyset$, we have $X \in E(N)$, so in particular, any state can be achieved by the grand coalition of all players.

An effectivity function E is *stable* if for any set of utility functions $(u_i)_{i \in N}$, the core of $(E, (u_i)_{i \in N})$ is nonempty. Given E and $(u_i)_{i \in N}$, one can determine in polynomial time whether the core of $(E, (u_i)_{i \in N})$ is nonempty. Determining whether E is stable, however, is an NP-complete problem [50].

From Strategic Games to Effectivity Functions

Effectivity functions can be derived from a strategic game form in a number of different ways. Given a strategic game form G, a coalition $C \subseteq N$ will be *α-effective* for a set $X \subseteq S$ iff the coalition has a joint strategy which will result in an outcome in X no matter what strategies the other players choose. Formally, for a strategic game form $G = (N, (\Sigma_i)_{i \in N}, o, S)$, its *$\alpha$-effectivity function* $E^\alpha_G : \mathcal{P}(N) \to \mathcal{P}(\mathcal{P}(S))$ is defined as follows:

$$X \in E^\alpha_G(C) \text{ iff } \exists \sigma_C \forall \sigma_{\overline{C}} \;\; o(\sigma_C, \sigma_{\overline{C}}) \in X.$$

We say that an effectivity function $E : \mathcal{P}(N) \to \mathcal{P}(\mathcal{P}(S))$ *α-corresponds* to a strategic game G iff $E = E^\alpha_G$.

Analogously, a coalition $C \subseteq N$ will be *β-effective* for a set $X \subseteq S$ iff for every joint strategy of the other players, the coalition has a joint strategy which will result in an outcome in X. Hence, in contrast to α-effectivity, the coalition's strategy may depend on the strategy of the other players. Formally, the *β-effectivity function* $E^\beta_G : \mathcal{P}(N) \to \mathcal{P}(\mathcal{P}(S))$ of a game form G is defined as follows

$$X \in E^\beta_G(C) \text{ iff } \forall \sigma_{\overline{C}} \exists \sigma_C \; o(\sigma_C, \sigma_{\overline{C}}) \in X.$$

It is easy to see that $E^\alpha_G \subseteq E^\beta_G$, i.e. α-effectivity implies β-effectivity, but the converse does not hold, as the example in Figure 7 illustrates. In that game G, player 1 chooses the row, player 2 the column, and the third player chooses between the left and the right table. For every joint strategy of players 1 and 3, player 2 has a strategy which yields outcome s_2. Note, however, that this strategy depends on the strategies chosen by players 1 and 3, i.e., player 2 has no strategy which will guarantee outcome s_2 independent of the strategies of players 1 and 3. In terms of α- and β-effectivity, we have $\{s_2\} \in E^\beta_G(\{2\})$, but $\{s_2\} \notin E^\alpha_G(\{2\})$. The coalition consisting of players 1 and 2 on the other hand does

	l	m	r
l	s_1	s_2	s_1
r	s_2	s_1	s_3

	l	m	r
l	s_3	s_1	s_2
r	s_2	s_3	s_3

Figure 7. A strategic game where α- and β-effectivity differ

have a joint strategy (r, l) which guarantees s_2 independent of player 3's strategy, i.e. $\{s_2\} \in E^{\alpha}_{G}(\{1, 2\})$.

While this discussion shows that every strategic game form can be linked to an effectivity function via α-correspondence, not every effectivity function will be the α-effectivity function of a strategic game form. The properties required to obtain a precise characterisation result are the following.

THEOREM 12 ([63]). *An effectivity function $\mathcal{P}(N) \to \mathcal{P}(\mathcal{P}(S))$ α-corresponds to a strategic game form if and only if it is monotonic, N-maximal and superadditive.*

3 GAME FORMS AND KRIPKE MODELS

Figure 3 invites the modal logician to apply his tools and analysis as provided in especially Chapter 1 of this handbook in a natural way: games in extensive form are just models over time or processes in disguise [85]. In other words, if one is interested in the moves and their outcomes, extensive games can be conceived of as Kripke models for dynamic logic: see also Section 9. We take this perspective in this section, swiftly moving the focus of our analysis from the area of games to that of logic. To start with, we abstract from the specific actions, and reason about what specific agents can achieve. We do this in an example driven, and semantic way, in Section 3.1. When combining the players' powers with their preferences, modal logic can help to shed light on solution concepts, an exercise we will undertake in Section 3.2. In these two subsections, it is not the extensive form of the game that matters for the modal analysis so much, but more which end-nodes can be reached. We make some remarks concerning equivalence and expressivity taking the full structure of the extensive game into account, in Section 3.3. Yet another point of view takes the strategies, or, rather, the paths in an extensive game as first class citizens: see Section 11.

Games in Strategic Form

However, before exploiting the modal structure of games in extensive form, let us follow the structure of Section 2.1 and point out that the applicability of modal logic also extends to games in strategic form. The contribution [13] introduces a dynamic relation R_i for every player i, with intended meaning that sR_it holds iff from state s, player i can unilaterally bring about state t. States are states of the game, and σ assigns to every state the strategy profile that is being played in any state: e.g., $\sigma_i(s) = s_i$ denotes that i plays strategy s_i in s. Regarding the atomic propositions, [13] assumes to have atoms $q \leq p$ for any natural numbers p and q (with straightforward interpretation), and, for every player i and number p, an atom $u_i = p$ denoting i's utility (or pay-off) at any state: such an atom is true at s iff $u_i(\sigma(s)) = p$, where u_i assigns a utility $p \in \mathbb{N}$ to

every strategy profile σ. We assume to only need finitely many values $Val = \{p, q, \dots\}$. Finally, the atom $Nash$ is true at all the profiles at which this equilibrium is played.

For instance, using a suggestive name for states, in our representation of the Prisoner's Dilemma (see Figure 2), in state (D, D) it is true that $u_1 = -4 \wedge u_2 = -4$ and, everywhere in the game, we have

$$\Box_2 \Diamond_1 \Big(\bigvee_{q \in Val} (u_1 = q) \wedge (q \geq -4) \Big) \wedge \Diamond_2 \Box_1 \Big(\bigwedge_{p \in Val} (u_1 = p) \rightarrow (p \leq -4) \Big) \tag{1}$$

Equation (1) expresses that, no matter what player 2 does, player one can guarantee himself a payoff of -4, but at the same time, he can do not better than that: 2 can play a move such that the best that 1 can achieve is -4. Note that we *do* have, in the game of Figure 2, that $\Diamond_1 \Diamond_2 ((u_1 > -4) \wedge (u_2 > -4))$ (if the players were to cooperate, they could achieve more than -4 each). Let $p_1, \dots, p_n$ be a set of n payoff values. The following is valid in every strategic game G:

$$\bigwedge_{i \in N} \left((u_i = p_i) \wedge \Box_i \bigwedge_{q \in Val} (u_i = q \rightarrow (q \leq p_i)) \right) \leftrightarrow \left(\bigwedge_{i \in N} (u_i = p_i) \wedge Nash \right) \tag{2}$$

This formula is equivalent to saying that, given that every player i's outcome is p_i, the strategy played is a Nash-outcome if and only if no player i can unilaterily deviate and achieve something (q) that is better than p_i.

3.1 Players and Outcomes

Given an extensive game form $F = (N, H, P)$, we straightforwardly associate with it a *game frame* $\mathcal{F}_F^N = \langle W, R_{i \in N} \rangle$ with the obvious addition that $H = W$ and $R_i st$ iff $P(s) = i$ & $t = (s, a)$ for some action a, i.e., if player i is to move in s and he can choose a move that leads to t. Such a frame is *generated* from a root and, moreover, *turn-based*: if $R_i st$ then for no other j and for no u also $R_j su$. Basic propositions like $\mathbf{turn_i}$ (player i is to move) and **end** (we are in a leaf) can easily be defined, as $\Diamond_i \top$ and $\bigwedge_{i \in N} \Box_i \bot$, respectively. We can also start from an extensive game G and then obtain $\mathcal{F}_G^N$ by augmenting the frame with a preference relation. Moreover, we can assume to have atoms $u_i = p_i$ or $\mathbf{win_i}$ in the language, and interpret them in an appropriate manner in a model $\mathcal{M}_F^N$ or $\mathcal{M}_G^N$. For instance, in the game on the right of Figure 3, we have in the root that $\Diamond_1 (\Box_2 (u_2 \leq 2) \wedge \Diamond_2 \top) \wedge \Diamond_1 \Box_2 \bot$: player 1 can enforce a state such that player 2 can move but is unable to obtain more than 2 units, but player 1 can also move to a state in which player 2 cannot make any move anymore.

The paper [13] argues that modal logic not only is a useful tool to *describe* the rational behaviour of players (see Section 3.2), but also when it comes to *prescribing* the players how to act. To do so, [13] adds a relation R_* to a game frame $\mathcal{F}^N$ representing (paths according to) a *recommendation* that the players are given, i.e., $R_* \subseteq R^N$, where R^N is the transitive closure of $N^T = (\bigcup_{i \in N} R_i)$ with the following properties: (1) R_* is transitive, (if it is recommended to reach w_2 from w_1 and w_3 from w_2, then it is recommended to reach w_3, in w_1); (2) if for some w^T, $N^T w w^T$ (i.e., w is a decision node $\in T = H \setminus Z$), then also $R_* w w_*$ for some w_* (if a player is to move at w, then a recommendation must be made); and, finally (3) if $R_* w_1 w_3$ and at the same time

$R^N w_1 w_2$ and $R^N w_2 w_3$, then we have both $R_* w_1 w_2$ and $R_* w_2 w_3$ (if it is recommended in w_1 to reach w_3, then any path to do that is a recommended path).

Moreover, [13] allows for atomic propositions $(q \leq p)$ and $u_i = p_i$, the latter only being true in a state s iff s is a leaf, with $u_i(s) = p_i$. Now consider the following scheme:

$$\Diamond_*(u_i = p_i) \rightarrow \Box_i\left(\left(\left(u_i = q_i\right) \vee \Diamond_*(u_i = q_i)\right) \rightarrow q_i \leq p_i\right) \tag{3}$$

[13] refers to (3) as *internal consistency* of a recommendation, "in the sense that no player can increase his payoff by deviating from the recommendation, *using the recommendation itself* to *predict his future payoff after the deviation*" ([13, page 17]).

Of course, it is up to the game theoretician to come up with the 'right recommendation', but an obvious choice would be that they play a Nash equilibrium. In a generic game (cf Theorem 13), the backward induction algorithm determines for every decision node a unique immediate successor: let us call this the backward induction relation BI. We say that a recommendation relation R_* is the backward induction recommendation if it is the transitive closure of BI. The next Proposition tells us that scheme (3) can be understood as characterising backward induction.

THEOREM 13. *[13, Proposition 4.8] Let G be a generic perfect information game and $\mathcal{F}_G^N$ its associated Kripke model, with a recommendation relation R_*. Then the following are equivalent:*

(1) R_* is the backward induction recommendation

(2) scheme (3) is valid in $\mathcal{F}_G^N$

3.2 Formalising Solution Concepts in Modal Languages

The aim of [35] is also to formalise solution concepts in a modal logic. We again start with frames $\mathcal{F}_G$ based on a game G with preference relations $\succeq_{i_{i\in N}}$. It assumes that every $\succeq_i$ is reflexive, transitive and connected (i.e., for all u, v, $u \succeq_i v$ or $v \succeq_i u$). Every $\succeq_i$ gives rise to an operator $[i]$, with intuitive reading of $[i]\varphi$: "φ holds in all states at least as preferable to the present one".

The other first class citizens in [35] are *strategy profiles* in the game G. For any such profile σ, let $R_\sigma st$ iff following σ in s would eventually lead to the end state t. Thus, $[\sigma]\varphi$ reads "if from here all players adhere to σ, the play will eventually end in a state in which φ holds". Finally, for every player i and strategy profile σ, recall that (τ_i, σ_{-i}) is the profile where all players stick to σ, except for i who deviates and plays τ_i. We use this to define a third accessibility relation: $R_{(i,\sigma)}st$ iff for some τ_i, $R(\tau_i, \sigma_{-i})st$. Hence, the meaning of $[i,\sigma]\varphi$ in s becomes that "φ holds in all the states that will be reached if all the players except possibly i play the strategy σ". Given an extensive game $G = (N, H, P, (\succeq_i)_{i\in N})$ we now define $\mathcal{F}_G$ as $\langle H, (\succeq_i), (R_\sigma), R_{(i,\sigma)}\rangle$, where $i \in N$ ranges over the players, and σ over the strategy profiles. Note that the binary relations R_σ, and $R_{(i,\sigma)}$ on such a frame have the leaves as their co-domain (cf. Figure 8). By decorating such a frame with a valuation $\pi : H \rightarrow 2^A$ for some set of atoms A, we obtain a *game model* M_G for G.

Now, before stating a result about these relations, we first recall a result from *correspondence theory* (see Chapter 5).

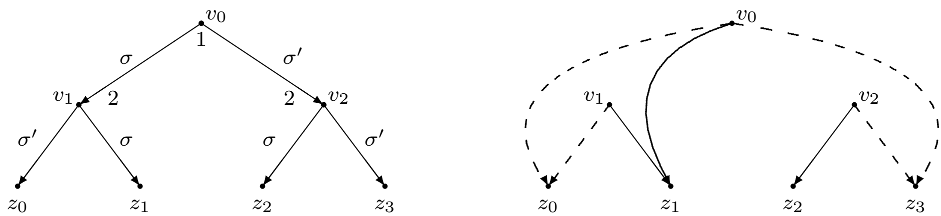

Figure 8. Transformation of an extensive game (left) to a game-frame (right) with respect to two strategy profiles σ and σ' and their corresponding accessibility relations R_σ and $R_{(1,\sigma')}$ (dashed). Reflexive arrows at the leaves are omitted.

THEOREM 14. *Suppose we have three accessibility relations R_k, R_l and R_m with corresponding modalities. Then the scheme $\langle k\rangle[l]\varphi \to [m]\varphi$ characterises frames satisfying (k,l,m)-Euclidicity, i.e., frames in which $\forall s,t,u((R_k st \;\&\; R_m su) \Rightarrow R_l tu)$.*

Remember that a Nash-equilibrium in an extensive game is a strategic profile σ such that for all players i and profiles τ, we have $o(\sigma_i,\sigma_{-i}) \succeq_i o(\tau_i,\sigma_{-i})$, i.e. no player can improve his situation by unilaterally deviating from σ. The profile σ is said to be a *best response* for player i iff for all profiles τ, we have $o(\sigma_i,\sigma_{-i}) \succeq_i o(\tau_i,\sigma_{-i})$. This is an individual pendant of Nash-equilibrium: clearly, a strategy profile σ is a Nash-equilibrium iff it is a best response for all players.

THEOREM 15 ([35], Theorem 3.1). *Let $\mathcal{F}_G$ be obtained from the extensive game G as indicated above, and let v_0 be its root-node. Let 's.p.' stand for 'sub-game perfect'.*

$$\begin{array}{lrl}
(i) & \sigma \text{ is a best response for } i \text{ in } G \text{ iff} & \mathcal{F}_G, v_0 \models \langle i,\sigma\rangle[i]\varphi \to [\sigma]\varphi \\
(ii) & \sigma \text{ is an s.p. best response for } i \text{ in } G \text{ iff} & \mathcal{F}_G \models \langle i,\sigma\rangle[i]\varphi \to [\sigma]\varphi \\
(iii) & \sigma \text{ is a Nash equilibrium in } G \text{ iff} & \mathcal{F}_G, v_0 \models \bigwedge_{i\in N}\left(\langle i,\sigma\rangle[i]\varphi \to [\sigma]\varphi\right) \\
(iv) & \sigma \text{ is an s.p. (Nash) equilibrium in } G \text{ iff} & \mathcal{F}_G \models \bigwedge_{i\in N}\left(\langle i,\sigma\rangle[i]\varphi \to [\sigma]\varphi\right)
\end{array}$$

Note that the first item, together with Theorem 14 says that σ is a best strategy for i in v_0 iff when σ leads us to a leaf z, and any deviation by i from σ leads to a leaf z', then in z' player i is not better off. Also note that the sub-game perfect notions are the global variants of the notions that hold in the root.

Taut	any classical tautology	$D!_\sigma$	$[\sigma]\varphi \leftrightarrow \langle\sigma\rangle\varphi$
K	$[\beta](\varphi \to \psi) \to ([\beta]\varphi \to [\beta]\psi)$	$F1$	$[\sigma,i]\varphi \to [\sigma]\varphi$
T_i	$[i]\varphi \to \varphi$	$F2$	$[\sigma,i]([\sigma',i']\varphi \leftrightarrow \varphi)$
4_i	$[i]\varphi \to [i][i]\varphi$	$F3$	$[\beta][\beta']([i]\varphi \to \psi) \vee [\beta''][\beta'''](([i]\psi \to \varphi)$
MP	$\vdash \varphi \to \psi,\ \vdash \varphi\ \Rightarrow \vdash \psi$	*Nec*	$\vdash \varphi \Rightarrow \vdash [\beta]\varphi$

Table 1. Axioms for Extensive Game Logic. The variables $\beta, \beta' \ldots$ range over the modalities $[i], [\sigma]$ and $[i,\sigma]$

The logic that comes with the semantics described here is dubbed *Extensive Game*

Logic in [35] (see Table 1). The axioms $Taut$ and K and the rules MP and Nec denote that we have a normal modal logic; T_i and 4_i reflect that the preference relation $\succeq_i$ is reflexive and transitive. Axiom $D!_\sigma$ says that R_σ is functional: any strategy profile σ prescribes a unique outcome. $F1$ expresses that if any deviation by i from σ leads to a result φ, then this is in particular the case if i sticks to σ_i, i.e., does not deviate. Property $F2$ reflects that any strategy $(\tau_i, \sigma_{\text{-}i})$ takes us to a leaf. And from any leaf, any further moves are void, i.e., $[\sigma', i']\varphi \leftrightarrow \varphi$ holds in it. Finally, $F3$ denotes a kind of *connectivity*. Correspondence theory (cf. Chapter 5) tells us that the modal scheme $\Box_1(\Box_3\varphi \to \psi) \vee \Box_2(\Box_3\psi \to \varphi)$ corresponds to the property that all R_1 and R_2-successors are R_3-connected: $\forall w, u, v : ((R_1wu \& R_2wv) \Rightarrow (R_3uv \text{ or } R_3vu))$. Hence $F3$ expresses that all $R_{\beta'} \circ R_\beta$ and $R_{\beta'''} \circ R_{\beta''}$-successors are $\succeq_i$-connected. By connectivity of $\succeq_i$, this axiom is sound; the fact that we are in the realm of game frames makes $F3$ also ensure this connectivity.

THEOREM 16. *([35, Theorem 4.1]) Extensive Game Logic as presented in Table 1 is strongly complete with respect to the semantics based on game models as defined on page 1092.*

3.3 Games as Process Models

Although [35] takes games in extensive form as its starting point, a little reflection on Figure 8 should convince the reader that the language only allows to reason about the *outcomes* of the game, not about *intermediate states*. Modal logic provides a wide range of languages, allowing to discriminate graphs, and hence games, on many levels of abstraction. This section discusses ideas from [85], by which also the following games G_1 and G_2 are inspired.

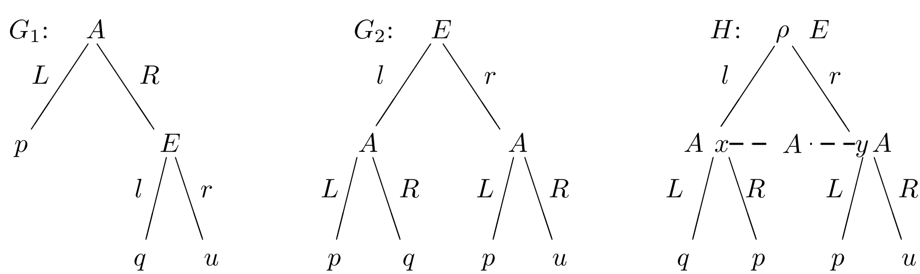

Figure 9. Two 'similar' games G_1 and G_2. H is an imperfect information game: see Section 6

Figure 9 represents two extensive game forms G_1 and G_2 for two players E and A, to which some propositional information has been added to the leaves. The question put forward in [85] is when two games are the same. When looking at the power of players, encoded in α-effectivity functions (cf. Section 2), the games G_1 and G_2 of Figure 9 *are* the same: the powers of E are $\{\{p, q\}, \{p, u\}\}$ while A is effective for $\{\{p\}, \{q, u\}\}$. Also, the two games represent *evaluation games* (cf. [37]) for two formulas that are equivalent, viz., $p \wedge (q \vee u)$ and $(p \wedge q) \vee (p \wedge u)$: verifier has a winning strategy for both formulas in exactly the same models. Hence, if we are interested in the outcomes of games only,

the games G_1 and G_2 can be coined the same. (We come back to the 'power level' for describing games in Section 10.)

On the other hand, there is admittedly a difference between the two games, if alone for the feeling that A can hand over control to E to achieve u in the left hand figure, whereas in the right hand side the converse looks more an appropriate description. Also, the two games differ by the mere fact that different players start in each. A property true in G_1 but not in G_2 for instance is that, if E is ever to move, he can guarantee u. Following [85], we see that when the turns and the moves of the players are at stake, the two extensive game models above are not equivalent.

When notions relating to the *process* of a game are important, formalisms, mainly arising from computer science, like process algebra, the Hoare-Dijkstra-Floyd calculus, dynamic modal logic and temporal logics naturally come to surface, each with its own semantic notions concerning equality of structures, like (finite) trace equivalence, observational equivalence or bisimulation. Although also the more recent *BDI-logics* (logics addressing Beliefs, Desires and Intentions, see also Chapter 18) for reasoning about multi-agent systems have similar concerns, at this moment there is not yet a dominant framework in which actions of agents (or moves of players), the powers of coalitions and the informational and motivational attitudes of the players are all treated on a par. We restrict ourselves to some semantical observations here.

Taking moves as atomic actions in a PDL-like logic (see also Chapter 12) a property true in the root of G_2 would be $\langle l \cup r\rangle[L \cup R](p \vee q)$: indicating that there is an execution of the choice $l \cup r$ so that every execution of the choice $L \cup R$ leads to either p or q. Apart from the choice operator $\cup$, one usually also has the constructs ; and * between programs, denoting sequential and iterative composition, respectively, and the test ? for propositions. To stay close to the previous section, where there are no labels for the player's choices, let us first mention that [35] assumes the following *atomic* actions (in our notation). For every player $i \in N$ we add an action $\mathbf{mo}_i$, where $R_{\mathbf{mo}_i}st$ is true iff if i is to move at s, he has a choice that leads to t. Next, for every strategy profile σ, relation $R_{\mathbf{step}(\sigma)}$ denotes the *one-step* transitions of σ, that is, $R_{\mathbf{step}(\sigma)}st$ iff $\sigma(s) = t$.

We now can distinguish the two models G_1 and G_2 with for instance the formula $[\mathbf{mo}_E][\mathbf{mo}_A \cup \mathbf{mo}_E]\bot$ which is only true in G_1, expressing that there are no moves possible after E has played. Following and specialising for instance [12], we can even identify formulas Φ_1 and Φ_2 such that Φ_i is true in a model M_i iff M_i is *bisimular* to G_i above. The idea is simple, constructing a formula $\varphi_{G,s}$ for every state s in a finite G inductively as follows. If s is a leaf, let $\varphi_{G,s}$ be the finite conjunction of literals over atoms true in s, together with the property that there are no moves to be made, i.e., $\varphi_{G,s} = \bigwedge_{G,s\models p} p \wedge \bigwedge_{G,s\not\models p} \neg p \wedge \bigwedge_{i\in N}[\mathbf{mo}_i]\bot$. Next, let t be a node such that for all its successors $s_1, \ldots s_k$ in the tree, φ_{G,s_h} $(h \leq k)$ is already defined, and suppose that i is to move in t. Then

$$\varphi_{G,t} =_{\text{def}} \bigwedge_{G,t\models p} p \wedge \bigwedge_{G,t\not\models p} \neg p \wedge \bigwedge_{j\neq i}[\mathbf{mo}_j]\bot \wedge \bigwedge_{h\leq k} \langle \mathbf{mo}_i\rangle\varphi_{G,s_h} \wedge [\mathbf{mo}_i](\bigvee_{h\leq k} \varphi_{G,s_h})$$

It will be clear from this construction, that for any extensive finite game G with root r_0 we have that for any model M and state s, $M, s \models \varphi_{G,r_0}$ iff M, s is bisimular to G, r_0. On game models, bisimulation boils down to *isomorphism*, but the notion is useful when reasoning about games as *graph automata* (see also Chapter 12 and [44]).

Observing that $\neg\langle\mathbf{step}(\sigma)\rangle\top$ characterises the leaves in the game tree, and using `while` φ `do` π as shorthand for $(\varphi? \ ; \ \pi)^*;\neg\varphi?$ ('as long as φ, perform π'), we can define, for every coalition $M = \{i_1, \ldots, i_m\} \subseteq N$ a program that, given σ, $N \setminus M$ adheres to it, but M is allowed to deviate:

$$\Pi(\sigma, M) =_{df} \texttt{while}\langle \mathit{step}(\sigma)\rangle\top \ \texttt{do} \ (\mathit{step}(\sigma) \cup \mathbf{mo}(i_1) \cup \cdots \cup \mathbf{mo}(i_m))$$

The operator $[\sigma]$ of the previous section can now be defined as $[\Pi(\sigma, \emptyset)]$, whereas $[\sigma, i]$ becomes $[\Pi(\sigma, \{i\})]$, enabling us to express the characterisations of (s.p.) Nash equilibrium and best response, as in the previous section.

But one does not have to reason about just one strategy. Let us define **end** as being in a leaf: $\mathbf{end} =_{\text{def}} \bigwedge_{i\in N}[\mathbf{mo}_i]\bot$. We can then express that, when every player i adheres to his strategy σ_i, the game will terminate in a state satisfying φ, using the formula $[(\bigcup_{i\in N}(\mathbf{mo}_i)?;\mathbf{step}(\sigma_\mathbf{i}))^*](\mathbf{end} \rightarrow \varphi)$. Every player i playing strategy σ_i of course induces a strategy profile σ, and as such, π can also be expressed in the framework of [35], but we can now also express properties of intermediate states. Let us define $\mathbf{plays}(i, \sigma_i)$ as $(\mathbf{mo}_i)?;\mathbf{step}(\sigma_\mathbf{i})$, and, for a set of strategies Σ_M, one σ_i for each $i \in M \subseteq N$, $\mathbf{Plays}(M, \Sigma_M)$ as $\bigcup_{i\in M}((\mathbf{mo}_i)?;\mathbf{step}(\sigma_\mathbf{i}))$, meaning that every agent i in M will play his strategy σ_i. Let us denote each agent j's atomic actions (or choices) with Ac_j. Also, let $\mathbf{any}(j)$ mean $(\mathbf{mo}_j)?;\bigcup_{a_j\in Ac_j}$, whereas $\mathbf{Any}(M) =_{\text{def}} \bigcup_{j\in M}\mathbf{any}(j)$. Then,

$$[(\mathbf{Plays}(M, \Sigma_M) \cup \mathbf{Any}(N \setminus M))^*]\varphi \tag{4}$$

expresses that coalition M can, by choosing the strategies Σ_M, ensure that, no matter what the other players $j \in N \setminus M$ will do, φ will invariantly be true. This implies that M has a strategy to ensure φ, which, as we will see in Section 11, is the basic expression of *ATL*. When abbreviating (4) as $\langle M, \Sigma_M\rangle\varphi$, that basic expression of *ATL* can be expressed as $\bigvee_{\Sigma_M}\langle M, \Sigma_M\rangle\varphi$, where Σ_M ranges over sets of strategies for players in M. It is interesting to note that every strategy in a finite game model is definable in *PDL*, using the characteristic formulae $\varphi_{G,s}$ for G, s: simply observe that every transition labelled with choice a_i from s to t can be denoted by $(\varphi_{G,s})?;a_i(\varphi_{G,t})?$. However, since in general there will be exponentially many strategies, this is arguably more of technical interest than of practical value.

3.4 Other Issues

Until now we have focused mainly on (Nash) equilibria and best response strategies. Recall from Zermelo's theorem (Theorem 7) that in every finite win-loss game for two players, exactly one player has a winning strategy. Let us denote player's i win by $\mathbf{win_i}$. Following [85] once more, we can define predicates $\mathbf{Win_i}$, meaning that, at the current node, i has a winning strategy (let $i \neq j$):

$$\mathbf{Win}_i \equiv (\mathbf{end} \wedge \mathbf{win}_i) \vee (\mathbf{turn}_i \wedge \langle\mathbf{any}(i)\rangle\mathbf{Win_i}) \vee (\mathbf{turn}_j \wedge [\mathbf{any}(j)]\mathbf{Win_i})$$

This hints at an inductive definition for $\mathbf{Win_i}$ using a *least fixed-point* schema

$$\mathbf{Win_i} =_{def} \mu P \cdot (\mathbf{end} \wedge \mathbf{win}_i) \vee (\mathbf{turn}_i \wedge \langle\mathbf{any}(i)\rangle P) \vee (\mathbf{turn}_j \wedge [\mathbf{any}(j)]P)$$

The reader immediately recognises the above as a formula in the *μ-calculus*, which is the topic of Chapter 12 of this handbook. As another example, the expression $\mu P \cdot (\mathbf{end} \wedge \varphi) \vee (\mathbf{turn}_i \wedge \langle \mathbf{any}(i) \rangle P) \vee (\mathbf{turn}_j \wedge [\mathbf{any}(j)]P)$ says that i has a strategy for guaranteeing a set of outcomes in which φ is true. Note that this is already expressible in a *PDL*-like logic: just choose $N = M = \{i, j\}$ in equation (4). In Section 11 we will discuss the logic *ATL* which is specifically designed to reason about what agents, and indeed, *coalitions* can guarantee to hold.

Still, the relation between the $\mu-$calculus and games is an interesting one. The calculus provides a very natural way, using its fixed point definitions, to reflect the equilibrium character of game-theoretic notions. Specifically the connections between the μ-calculus and games of possibly infinite duration are appealing: going back to an idea of [16], we know that *any* formula of the μ-calculus expresses the existence of a strategy in a certain game.

As seen above, if the goal of a player is to reach some desirable position in finite time, the set of positions that guarantee the win can be computed as a *least fixed point.* However, when the aim is to stay forever within a set of some safe positions, the winning set can be presented as a *greatest fixed point.* (This is very reminiscent of the distinction between *liveness* and *safety properties* used in computer science, as first introduced in [43]. See also [40] for a survey and Chapter 12 of this handbook.) More sophisticated winning conditions arise naturally in games modelling potentially infinite behavior of reactive systems. In general, mutually dependent least and greatest fixed point operators are necessary. [55] (from which the current two paragraphs borrow heavily), suggests that this interplay between least and greatest fixed points may well be the secret of the success of the μ-calculus: "... in contrast to first-order or temporal logic, the μ-calculus did not emerge by a formalization of the natural language". The μ-calculus also can benefit from game theory, since the game semantics reduces μ-calculus model checking to solving (parity) games: for more on this, see Chapter 12 of this handbook. A first impression of the complexity of such problems is given in Section 11. Another example of using games to settle complexity issues is provided in [12], where a *two person corridor tiling game* is used to prove the EXPTIME-hardness of PDL.

4 EPISTEMIC LOGIC

We saw in Section 2 that it makes sense to be explicit about the amount of information that each player has, at a given state of the game. Epistemic logic studies the notion of knowledge, and since [36], a mainstream in formal approaches to knowledge and belief is grounded in a possible world semantics. In the 1990's, these approaches were further developed in areas like computer science, cf. [21] – originally motivated by the need to reason about communication protocols – and artificial intelligence, cf. [49] and [51] – to reason about epistemic preconditions of actions. From the early days of game theory (cf. [4]) it has been recognised that the amount of knowledge that agents have is crucial in many solution concepts. But the formalisation of knowledge in game theory only took off since the late nineties, partially due to the TARK and LOFT events ([77, 45]).

The monograph [11] distinguishes between the notions of perfect/imperfect information on the one hand, and those of complete/incomplete information on the other. A game is of *perfect information* if the rules specify that the players always know 'where they are': for games in extensive form this means that each player is free in every node

	axioms and rules for $\mathbf{S}5_m$, where $i \leq m$		multi-agent notions

Table 2.

to make a decision independent of that in other nodes. A game is of *complete information* if everything is known about the circumstances under which the game is played, like the probability that nature chooses a certain outcome, and who the opponent is and how risk-averse he is. In a game with incomplete information, players do not necessarily know which game they are playing, or who the other players are. Such games, although realistic, are up to now mainly the domain of a research area called *evolutionary game theory*, utilising theories of learning and evolutionary computation (see for an overview, [79]). Epistemic logic is nowadays widely used to express various degrees of imperfect information in a game; assumptions about the completeness of information are still often made on a meta-level.

Modal epistemic logic, the logic of knowledge, provides a very natural interpretation to the accessibility relation in Kripke models. For an agent i, two worlds w and v are connected (written R_iwv), if the agent cannot (epistemically) distinguish them. In other words, we have R_iwv if, according to i's information at w, the world might as well be in state v, or that v is compatible with i's information at w. Using this interpretation of access, R_i is obviously an equivalence relation. Readers familiar with game theory may be best acquainted with epistemic notions in this field as summarised in [5]. In that terminology, our set of states S is a space Ω of states of the world, our equivalence relation R_i is [5]'s partition $\mathcal{F}_i$ of Ω, and our *formulas* correspond to [5]'s *events*. Also, our equivalence relations connect in an obvious way to the partitions mentioned in Definition 8.

The epistemic modal language for m agents is obtained by allowing a modal operator K_i for every agent $i \leq m$, with $K_i\varphi$ meaning: agent i knows φ. The corresponding Kripke models are $M = \langle W, R_1, R_2, \ldots R_m, \pi\rangle$, with each R_i being an equivalence relation. Thus, we are in the realm of the multi-modal logic $\mathbf{S}5_m$, of which the axioms are summarised in Table 2. They express that knowledge is *closed under consequences* ($A2$), it is *veridical* ($A3$) and agents are both *positively* and *negatively* introspective ($A4$ and $A5$, respectively). Moreover, all agents know the $\mathbf{S}5_m$-theorems. Clearly, these properties represent *logically omniscient* agents (see also Chapter 18), and hence adopting this particular logic for the knowledge of players assumes an ideal case of perfect reasoners. For an overview of weakening the axioms to tackle logical omniscience, we refer the reader to [21, 49].

THEOREM 17. *We have the following facts for* $\mathbf{S5_m}$*, which is the logic summarised in*

the left hand side of Table 2.

1. *The system* $\mathbf{S5_m}$ *is sound and complete with respect to Kripke models in which every* R_i *is an equivalence relation. The complexity of the satisfiability problem for* $\mathbf{S5_m}$ *if* $m > 1$ *is* PSPACE-*complete (cf. [21]).*

2. *Taking* $m = 1$*, the logic* $\mathbf{S5_1}$ *is also sound and complete for the semantics where* R *is the* universal relation. *The complexity of the satisfiability problem for* $\mathbf{S5_1}$ *is the same as for propositional logic: it is NP-complete. Moreover, every formula* φ *is equivalent in* $\mathbf{S5_1}$ *to a formula without any nesting of modal operators (cf. [49]).*

EXAMPLE 18. Let us, as an example, consider the $S5_3$ model hexa, taken from [98], which focuses on the knowledge and ignorance of players in games with imperfect information, by introducing the notion of *knowledge games*, games in which the knowledge of the players, and the effect of their moves upon this knowledge, is described. In hexa, we have three players (1, 2 and 3) and three cards, each with a neutral side and a coloured face: r (red), w (white) or b (blue). If a player holds a card, he is the (initially only) player that knows its colour. See Figure 10 for the Kripke model hexa representing the knowledge of the players after the three cards have been dealt. The state rwb represents the deal where player 1 holds r, 2 holds w, and 3 holds b; this distribution is denoted in the object language as $\delta_{rwb} = r_1 \wedge w_2 \wedge b_3$. From now on, we will underline the 'actual' state of the model: hexa thus represents the knowledge of the players given that the actual deal is rwb. Reflexive access is not represented, thus it is understood that both rwb and rbw are 1-accessible from rwb: given that 1 has the red card, he does not know whether the deal is rwb or rbw.

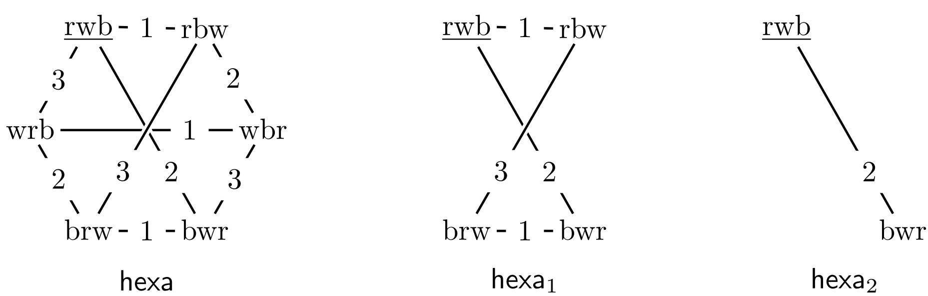

Figure 10. The initial model hexa; hexa$_1$ and hexa$_2$ are obtained using updates (cf. Section 7)

Interestingly, hexa not only tells us that every agent knows its own card (we have for instance hexa, $rwb \models K_1 r_1$, and, more generally, hexa, $c_1c_2c_3 \models K_i c_i$ ($c_i \in \{r, w, b\}, i \leq 3$), but also that everybody knows this. So, for instance, we have, and this is independent of the actual deal, hexa $\models K_1 \bigwedge_{c_2,c_3 \in \{r,w,b\}}((c_2 \rightarrow K_2 c_2) \wedge (c_3 \rightarrow K_3 c_3))$. And again, it is also the case that player 3 knows this. The aim of the game initiated by hexa is to find out the distribution of the cards, and we will return to the model when studying the dynamics of epistemics, in Section 7. $\dashv$

Indeed, the description of the situation that we gave is *common knowledge*, which is an intriguing multi-agent epistemic notion. Let us define 'everybody knows' ($E\varphi$) as is done in axiom $A6$ in Table 2 then the remaining axioms and rule on the right side of this table capture the intuition that common knowledge of φ models $E\varphi \wedge EE\varphi \wedge EEE\varphi \wedge .....$ Indeed, if we denote the axiom system represented in Table 2 by $\mathbf{S}5C_m$, then one easily checks that $\vdash_{\mathbf{S}5C_m} C\varphi \rightarrow E^n\varphi$, for arbitrary $n \in \mathbb{N}$, and, conversely, that $\{E^n\varphi \mid n \in \mathbb{N}\} \models C\varphi$: Semantically, the accessibility relation for R_E, with respect to which E-knowledge is the necessity, is $\bigcup_{i \leq m} R_i$, and then R_C (the relation for common knowledge) is the transitive closure R_E^* of R_E. We will denote any dual operator $\neg X \neg$ of X with $\hat{X}$.

EXAMPLE 19 (The muddy children). In this example the principal players are a father and k children, of whom m (with $m \leq k$) have mud on their foreheads. The father calls all the children together. None of them knows whether it is muddy or not, but they can all accurately perceive the other children and judge whether they are muddy. This all is common knowledge. Now the father has a very simple announcement (5) to make:

At least one of you is muddy. If you know that you are muddy, step forward. (5)

After this, nothing happens (except in case $m = 1$). When the father notices this, he literally repeats the announcement (5). Once again, nothing happens (except in case $m = 2$). The announcement and subsequent silence are repeated until the father's m-th announcement. Suddenly all m muddy children step forward!

Let us analyse the muddy children problem semantically, where we have 3 children. In Figure 11, the initial situation is modelled in twomud (we come back to a formal analysis of the story in Section 7). Worlds are denoted as triples xyz. The world 110 for instance denotes that child a and b are muddy, and c is not. Given the fact that every child sees the others but not itself, we can understand that agent a 'owns the horizontal lines' in the figure, since a can never distinguish between two states $0yz$ and $1yz$. Similar arguments apply to agents b and c.

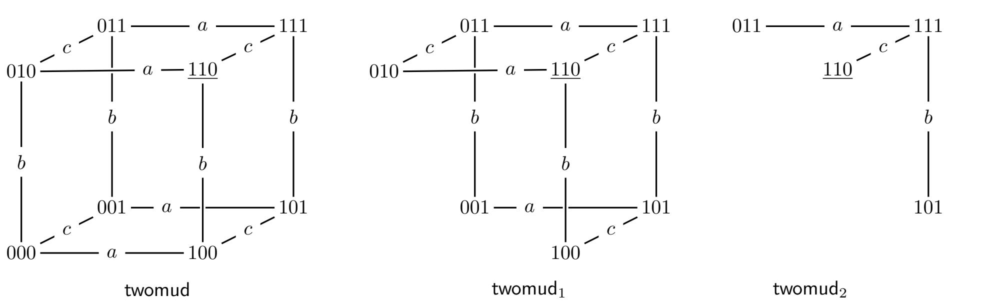

Figure 11. Muddy Children: initial situation twomud and after two updates (twomud$_1$ and twomud$_2$)

Let us see what epistemic truths we have in the state (twomud, s), with $s = 110$. The only propositional atoms we use are m_i ($i = a, b, c$) with meaning 'child i is muddy'. In state s, we then have for instance $\neg(K_a m_a \vee K_a \neg m_a)$ (agent a does not know whether it is muddy), and also $K_a(m_b \wedge \neg K_b m_b) \wedge K_a(\neg m_c \wedge \neg K_c \neg m_c)$ (a knows that b is muddy

without knowing it, and also that c is mudless without knowing that). Regarding group notions, we observe the following, in s. Let ℓ denote that at least one child is muddy ($\ell \equiv m_a \vee m_b \vee m_c$).

1. $E\ell \wedge \neg Em_a \wedge \neg Em_b \wedge \neg Em_c$; everybody knows that there is at least one muddy child, but nobody is known by everybody to be muddy

2. $K_c E\ell \wedge \neg K_b E\ell$; c knows that everybody knows that there is at least one muddy child, but b does not know that everybody knows at least one child to be muddy. To see the second conjunct, note that $\mathsf{twomud}, 100 \models \neg E\ell$, hence $\mathsf{twomud}, s \models \neg K_b E\ell$.

3. $\neg C\ell$; It is not common knowledge that there is at least one muddy child! This follows immediately from the previous item, but also directly from the model: one can find a path from $s = 110$ via 010 to 000, the latter state being one at which no child is muddy. One easily verifies that we have even $\mathsf{twomud} \models \neg C\ell$. $\dashv$

THEOREM 20 ([21]). *Let the logic* $\mathbf{S5C_m}$ *be summarised in Table 2. Then,* $\mathbf{S5C_m}$ *is sound and complete with respect to Kripke models in which every* R_i *is an equivalence,* R_E *(the relation for 'everybody knows') is* $\bigcup_{i \leq m} R_i$ *and* R_C *(the relation for common knowledge) is* R_E^**, i.e., the reflexive transitive closure of* R_E*. The complexity of the satisfiability problem for* $\mathbf{S5C_m}$ *if* $m = 1$ *is* PSPACE*-complete, and the complexity for* $\mathbf{S5C_m}$ *with* $m > 1$ *is* EXPTIME*-complete.*

As observed in [12, Chapter 6.8], the presence of a pair of modalities, one for a relation and the other for its reflexive transitive closure (in our case: E and C, respectively) is often –not always– an indication for entering the realm of EXPTIME-complexity results, since it enables one to force exponentially deep models, and to code the corridor tiling problem.

5 INTERPRETED SYSTEMS

Whereas the properties of knowledge as summarised in Table 2, especially that of negative introspection, have been under continuous debate and critique, the *Interpreted Systems* approach to knowledge as advocated by [21] in fact gives a *computationally grounded semantics* to the $\mathbf{S}5_m$ properties of knowledge. Rather than assuming the equivalence relation to be somehow given, in an interpreted system they naturally arise from the way a system is modeled. The idea is simple: in an interpreted system $\mathcal{I}$ we have m agents, or processors, each with its own local state s_i. A processor is aware of its own local state: two global states $\mathbf{s}$ and $\mathbf{s}'$ are the same for i if its local states in both coincide. And this notion of 'sameness' is an equivalence relation, yielding the $\mathbf{S}5_m$ properties in a natural way.

To formally define an interpreted system for m agents $\mathcal{I}_m$ we first give the notion of a global state. Let us assume that every agent i can be in a number of states L_i. Apart from the agents' local states, there is also a set of environment states L_e, which keeps track of, e.g., whether a communication line is up or down, or what the actual deal of cards is. A global state $\mathbf{s}$ is then a tuple $\langle s_e, s_1, s_2, \ldots s_m \rangle \in L_e \times L_1 \times L_2 \times \cdots \times L_m$. The set of global states of interest will be denoted $\mathcal{G} \subseteq L_e \times L_1 \times L_2 \times \cdots \times L_m$. Local states, both that of the agents and that of the environment, may change over time. A priori, there are no constraints on how the system may evolve: a *run* over $\mathcal{G}$ is a sequence

of states, or, rather, a function r from time $\mathbb{N}$ to global states. The pair (r, n) of a run and a time point is also referred to as a point. Let $r(n) = \langle s_e, s_1, s_2, \ldots s_m \rangle$ be the global state at time n in run r, then with $r_j(n)$ we mean s_j, where j ranges over $e, 1, \ldots, m$. Now, a *system* $\mathcal{R}$ over $\mathcal{G}$ is a set of runs over $\mathcal{G}$.

In general, formulas are now going to be interpreted in a point (r, n) in an interpreted system $\mathcal{I}$. To do so, we need to take care of atomic formulas and the epistemic operators. An *Interpreted System* $\mathcal{I} = (\mathcal{R}, \pi)$ over $\mathcal{G}$ is a system $\mathcal{R}$ over $\mathcal{G}$ with an interpretation π which decides for each point (r, n) and atom $p \in At$, whether p is true in (r, n) or not. Moreover, two points (r, n) and (r', n') are indistinguishable for i, written $(r, n) \sim_i (r', n')$, if $r_i(n) = r'_i(n')$, or, in other words, if i's local states in both points are the same. Definition (6) expresses that agent i knows φ in a point in $\mathcal{I}$ if φ is true *given agent* i's local information:

$$(\mathcal{I}, r, n) \models K_i\varphi \text{ iff } (\mathcal{I}, r', n') \models \varphi \text{ for all } (r', n') \sim_i (r, n) \tag{6}$$

We assume here that the interpretation function π only depends on the global state $r(n)$, and not the history of the point (r, n). This is in line with [21], but deviates from [30]. In the context of knowledge and linear time, the valid formulas are the same with and without this assumption: see [31] for an explanation of this. In practice, π will depend on just local information of a global state, denoting, e.g., whether a variable of processor i has a certain value, or whether player j holds the ace of hearts in a card game.

Of course, one may want to study epistemic logic for multi-agent systems in a static model $M_{\mathcal{G}} = \langle \mathcal{G}, \sim_1, \ldots, \sim_m, \pi \rangle$ based on a set of global states $\mathcal{G}$, and interpret formulas in global states themselves, rather than in a point in a run. If $\mathcal{G}$ equals the full Cartesian product $L_e \times L_1 \times L_2 \times \cdots \times L_m$, such models are called *hypercubes* in [47]. If we ignore the environment and only require that every combination of individual local states occurs we have a *full system*. Note that hexa of Figure 10 is a full system, whereas hexa_1 is obviously neither full nor a hypercube.

Full systems are appropriate classes of models to specify initial configurations of multi-agent systems, in which no agent has any information about any other agent, or about the environment. They are obviously $\mathbf{S5}_m$-systems, but interestingly enough they satisfy an additional property. It is not hard to see that the operator E for *everybody knows* from Section 4 semantically corresponds to interpreting E as the necessity operator of the relation that is the *union* of all the individual relations R_i: everybody knowns φ if nobody thinks it possible that $\neg\varphi$ is true. Note that $\hat{E}\varphi$ means that some agent considers it possible that φ: for some state that is $R_E = \cup_{i=1\ldots m} R_i$-accessible, φ is true. Axiom 7 then, on top of the axioms of $\mathbf{S5}_m$, is needed to axiomatise hypercubes and full systems (cf. [47]):

$$\bigwedge_{i=1\ldots m} \hat{E}\varphi_i \rightarrow \hat{E}\hat{E} \bigwedge_{i=1\ldots m} \varphi_i \tag{7}$$

In this scheme, φ_i is an i-local formula, to which we will come back shortly. Roughly, an i-local formula φ_i characterises i's knowledge: its truth value is constant within i's reachable states. The scheme then says that if we can reach, using R_E, a knowledge state for every agent, we can reach the 'combined knowledge state' in two steps.

When having more involved group notions of knowledge, full systems and hypercubes share some other specific properties. For instance, consider *distributed knowledge* $D\varphi$, in

which D is the necessity operator for the *intersection* of the individual relations R_i. This notion of knowledge arises when all agents would communicate with each other: if one agent rules out that s is a possible state, after communication nobody would consider s anymore. Obviously, in $\mathbf{S}5_m$, nobody rules out the current state, so that distributed knowledge in $\mathbf{S}5_m$ satisfies $D\varphi \to \varphi$. But in a full system with an empty environment, we also have the converse: $\varphi \to D\varphi$. This is easy to see: the only global state that is i-similar to $\mathbf{s} = \langle \emptyset, s_1, s_2, \ldots s_m \rangle$ is $\mathbf{s}$ itself!

Regarding common knowledge, in hypercubes and full systems it is either absent or else globally present: common knowledge is the same in all local states! This is easy also: if $C\varphi$ would hold in $\mathbf{s} = \langle s_e, s_1, s_2, \ldots s_m \rangle$ but not in $\mathbf{s}' = \langle s'_e, s'_1, s'_2, \ldots s'_m \rangle$, since the system is full, we find a state $\mathbf{t} = \langle \cdot, s_1, s'_2, \ldots, \cdot \rangle$. Recalling that R_C is the transitive closure of the R_i's, and that $R_1\mathbf{st}$ and $R_2\mathbf{ts}'$, we see that $\langle s_e, s_1, s_2, \ldots s_m \rangle$ and $\langle s'_e, s'_1, s'_2, \ldots s'_m \rangle$ must agree on $C\varphi$.

The logic of *local propositions* introduced in [20] connects the notion of accessibility in a system $M_{\mathcal{G}}$, in fact, in any epistemic model $M = \langle W, R_1, \ldots, R_m, \pi \rangle$, with a syntactic one. Let a proposition U in M just be a subset of W. It is an i-local proposition if for all $u, w \in W$ with $R_i uw$, we have $u \in U$ iff $w \in U$. In words: an i-local proposition is determined by i's local state, as is his knowledge. (In hexa for instance, r_1, denoting that 1 holds a red card, is 1-local.) For an atom p, say that $M \sim_p M'$ if the only difference between M and M' can be $\pi(p)$ and $\pi'(p)$. Define $M, w \models \exists_i p(\varphi)$ iff for some M' with $M' \sim_p M$, we have $M, w \models \varphi$, where p is an i-local propositional atom, i.e., $\pi(p)$ is an i-local proposition in M. Let $\Box$ be the universal operator, denoting what is true globally. Let q not occur in φ. Then:

$$M, w \models K_i\varphi \text{ iff } M, w \models \exists_i q(q \wedge \Box(q \to \varphi)) \tag{8}$$

(A similar 'reduction' can be given for distributed and common knowledge, see [20].) We have seen above in (7) that local propositions play a role in axiomatising hypercubes and full systems. But they have greater use: note that (8) implies that if the object language is rich enough to describe the local state of the agents, we can replace epistemic operators by occurrences of $\Box$ and local propositions. This idea is applied in [38] to 'reduce' model-checking of epistemic temporal properties to properties that can be handled by a 'conventional' model-checker SPIN that does not address knowledge explicitly: for a knowledge property $K_i\varphi$ to be checked in s, the user provides a local proposition q_i and the problem is then reduced to (1) checking whether q_i is indeed i-local, (2) whether it is true in s, and (3) whether the implication $q_i \to \varphi$ globally holds. To illustrate this, in hexa for instance, rather than saying, that $\mathsf{hexa}, rwb \models K_1(w_2 \vee w_3)$ (1 knows that the white card is owned by either player 2 or 3) we can stipulate: $\mathsf{hexa}, rwb \models r_1 \wedge \Box(r_1 \to (w_2 \vee w_3))$ (currently, player 1's local state reads 'red card', and globally, in such a situation either 2 or 3 holds the white card).

Let us now return to interpreted systems, where the dynamics is modelled through the notion of runs. Runs may look rather abstract, but following [21] one can think about them as being brought about by the agents while following a *protocol*, in which agents take certain *actions*. This is reminiscent of our notion of *strategies* in an extensive game: they restrict the space of all possible evolutions of the system. Having a language with operators for individual, distributed and common knowledge is still too poor to reason about interpreted systems: one easily shows that any two points (r, n) and (r', n') with the same global states $r(n) = r'(n')$ verify the same epistemic properties. Indeed, it is

natural to add *temporal* operators $\bigcirc$ (next time), $\square$ (always), $\diamondsuit$ (eventually) and $\mathcal{U}$ (until), with truth conditions like (for the formal interpretation of the other temporal operators, and a more extensive treatment of temporal logic, we refer to Chapters 11 and 17 of this Handbook):

$$(\mathcal{I}, r, n) \models \bigcirc\varphi \text{ iff } (\mathcal{I}, r, n+1) \models \varphi \tag{9}$$

With these operators, one *can* in general distinguish different points with the same global state: given a specific deal of cards for instance, it is perfectly well possible that in one play of the game player 1 will win, when in another play he will not: we can have $r(n) = r'(n')$, and $\mathcal{I}, r, n \models \diamondsuit\mathsf{win}_1$ but $\mathcal{I}, r', n' \not\models \diamondsuit\mathsf{win}_1$. In the temporal language, one can express that a certain property φ will occur infinitely often ($\square\diamondsuit\varphi$) or almost always ($\diamondsuit\square\varphi$). But the full character of the language of course comes to the fore in temporal-epistemic properties. Examples include $not\_cross\,\mathcal{U}\,K_i safe$, and $K_i\square((\neg K_j p \wedge \bigcirc K_j p) \rightarrow \bigcirc\bigcirc K_h K_j p)$ expressing that i will not cross the street until he knows it is safe, and that i knows that as soon as j learns that p, this will immediately be communicated to h.

Axioms for Linear Temporal Logic are given in Table 3: the operators $\diamondsuit$ and $\square$ can be defined in terms of $\bigcirc$ and $\mathcal{U}$. Regarding the soundness of the inference rule $R\mathcal{U}$, assume that $\mathcal{I} \models \varphi \rightarrow (\neg\psi \wedge \bigcirc\varphi)$. Since every occurrence of φ guarantees its truth in the next time, it is easy to see that we have $\mathcal{I} \models \varphi \rightarrow \square\varphi$. And, since φ comes with $\neg\psi$ we also have $\mathcal{I} \models \varphi \rightarrow \square\neg\psi$. Now, for an arbitrary χ, note that $\chi\,\mathcal{U}\,\psi$ being true would imply that ψ becomes true some time. But given φ, we just saw that ψ is always false, so we cannot have $\chi\,\mathcal{U}\,\psi$ when we have φ, hence $\mathcal{I} \models \varphi \rightarrow \neg(\chi\,\mathcal{U}\,\psi)$.

$T1$	$(\bigcirc\varphi \wedge \bigcirc(\varphi \rightarrow \psi)) \rightarrow \bigcirc\psi$	$T2$	$\bigcirc\neg\varphi \leftrightarrow \neg\bigcirc\varphi$
$T3$	$\varphi\,\mathcal{U}\,\psi \leftrightarrow \psi \vee (\varphi \wedge \bigcirc(\varphi\,\mathcal{U}\,\psi))$		
Nec	$\vdash \varphi \;\Rightarrow \vdash \bigcirc\varphi$	$R\mathcal{U}$	$\vdash \varphi \rightarrow (\neg\psi \wedge \bigcirc\varphi) \;\Rightarrow \vdash \varphi \rightarrow \neg(\chi\,\mathcal{U}\,\psi)$

Table 3. Axioms for Linear Temporal Logic **LTL.**

Note that in definition (6) in general we do not require that $n = n'$, so agents are not assumed to know what time it is. More generally, our definition allows the environment to change without any agent noticing this: two global states $\langle s_e, s_1, s_2, \ldots s_m\rangle$ and $\langle s'_e, s_1, s_2, \ldots, s_m\rangle$ look the same for all agents, but still may have a different environment. In fact, the definition of an interpreted system is so general that some agents i may sense changes in the environment (e.g., when $L_e \subseteq L_i$), while other agents j may not (when their local state L_j has 'nothing to do' with L_e).

Although in the general case no agent knows the time, in games it is usually assumed that all players at least know how many moves have been played. Indeed, this is, more often than not, assumed to be common knowledge. Games, and many other forms of competition and cooperation in multi-agent systems often assume that such a system is *synchronous*. To capture this, since the agents' knowledge is determined by their local state, we must encode a clock, or the number of passed 'rounds', in such local states. A system $\mathcal{R}$ is *synchronous* if each agent can distinguish different time points: if $n \neq n'$ then $(r, n) \not\sim_i (r', n')$, for any run r and r'. In other words, the local state of any agent must be different at different time points.

If we think of a run r as a sequence of global states in which each agent i is aware of its own local state $r(n)$ at time n, the question arises how much an agent *memorises* when going from $r_i(n)$ to $r_i(n+1)$. In the ideal case, i would 'remember' all local states $r_i(k)$ with $k \leq n$ when the time is currently n. In principle, this is the situation in games like chess and many other board and card games: each player has *perfect recall* of what he experienced during the game (although in practice, of course, humans and even machines may not have 'enough memory' for this). In a similar way as the requirement that i knows how many rounds have passed made us add this information to his local state, if we want the agent to remember exactly what has happened, from his perspective up to time n, we have to encode his previous local states $r_i(k)$ $(k < n)$ in his current local state at time n. Let therefore agent i's *local-state sequence* at the point (r, n) be his stutter-free local past $sflp_i(r, n) = \langle r_i(0), \pm r_i(1), \dots, \pm r_i(n-1)\rangle$, where $\pm r_i(x)$ means that $r_i(x)$ appears in the sequence iff it is different from its immediate predecessor in the sequence. Then, we say that i has *perfect recall in the system* $\mathcal{R}$ if $(r, n) \sim_i (r', n')$ implies that $sflp_i(r, n) = sflp_i(r', n')$, that is, if the agent remembers his local-state sequence, he has no uncertainty about what happened. We abstract from stuttering, since if the agent does not notice a change in his local state, he does not know 'how much is happening'— except in the synchronous case, when $sflp_i(r, n)$ is the complete sequence $\langle r_i(0), r_i(1), \dots, r_i(n-1)\rangle$.

Does perfect recall for agent i mean that $K_i\varphi \rightarrow \Box K_i\varphi$ is valid? Not in general, and mainly not because φ might refer to the current time. Knowing that 'today is Wednesday' does and should not imply that you always know that 'today is Wednesday'. Likewise, ignorance need not persist over time, and hence neither should the knowledge about it: even with perfect recall, $K_i\neg K_i p \rightarrow \Box K_i\neg K_i p$ should not hold: it would be equivalent to $\neg K_i p \rightarrow \Box\neg K_i p$ (note that in $\mathbf{S5}_m$, $\neg K_i\varphi$ is equivalent to $K_i\neg K_i\varphi$). Indeed, $\mathcal{I}, r, n \models K_i\neg K_i\varphi$ 'only' means that i knows to be ignorant in r at time n, this need not persist over time. Perfect recall would only require that at every point $(r, n+k)$, the agent knows that he *did not know* φ 'when the time was n'. A modal logic for belief revision in which one distinguishes operators B_0 for 'initial' belief (holding before the revision) and B_1 for 'new' beliefs (kept after the revision) is explored in [15]. The modal formulation of perfect recall of ignorance then becomes $\neg B_0\varphi \rightarrow B_1\neg B_0\varphi$. When we cannot distinguish between what *was* known and what *is* known, one might want to characterise the *stable* formulas for which $K_i\varphi \rightarrow \Box K_i\varphi$ holds in systems with perfect recall (see [21] and also discussions of 'only knowing' [91] and of (Un-)Successful Updates in Section 7). We will return to the property of perfect recall in Section 6: to capture perfect recall in synchronous systems we need the following property:

$$\textbf{PR} \qquad K_i\bigcirc\varphi \rightarrow \bigcirc K_i\varphi \quad (i = 1 \dots m)$$

We now give some technical results concerning the classes of systems discussed, in Theorem 21. To do so, let $\mathbf{S5}_m \oplus \mathbf{LTL}$ be the axioms for individual knowledge from Table 2, together with those for linear time from Table 3. This system assumes no interaction between knowledge and time. Also, let $\mathbf{S5}_m^C \oplus \mathbf{LTL}$ add the axioms for common knowledge (r.h.s. of Table 2) to this. Let $\mathcal{C}_m$ be the class of all interpreted systems for m agents, $\mathcal{C}_m^{sync}$ those that are synchronous, $\mathcal{C}_m^{pr}$ those that satisfy perfect recall, and let $\mathcal{C}_m^{sync,pr}$ be those synchronous interpreted systems that satisfy perfect recall.

THEOREM 21. *All the following results are from [21, Chapter 8], except for the first part of item 3, which is from [93]. Unless stated otherwise, assume $m \geq 2$.*

1. *$\mathcal{C}_m$ has $\mathbf{S5}_m \oplus \mathbf{LTL}$ as a sound and complete axiomatisation. The complexity of the validity problem for this class is PSPACE-complete. Adding common knowledge, $\mathbf{S5}_m^C \oplus \mathbf{LTL}$ completely axiomatises $\mathcal{C}_m$, but the validity moves to being EXPTIME-complete.*

2. *$\mathcal{C}_m^{sync}$: synchrony does not add anything in terms of axiomatisation or the validity problem: they are exactly as for $\mathcal{C}_m$.*

3. *$\mathcal{C}_m^{pr}$ is completely axiomatised by $\mathbf{S5}_m \oplus \mathbf{LTL} + \{\mathbf{KT}\}$, where $\mathbf{KT}$ is defined as $(K_i\varphi_1 \wedge \bigcirc(K_i\varphi_2 \wedge \neg K_i\varphi_3)) \rightarrow \hat{K}_i[K_i\varphi_1 \,\mathcal{U}\,(K_i\varphi_2 \,\mathcal{U}\, \neg\varphi_3)]$ (for a discussion, we refer to [93]). For $m = 1$, validity in $\mathcal{C}_m^{pr}$ is doubly-exponential time complete, otherwise non-elementary time complete. Adding common knowledge to the language makes the validity problem Π_1^1-complete. Hence, when common knowledge is present there is no finite axiomatisation for $\mathcal{C}_m^{pr}$; indeed, in this case there is not even a recursively enumerable set of axioms that is complete for validity in $\mathcal{C}_m^{pr}$.*

4. *$\mathcal{C}_m^{sync,pr}$ is completely axiomatised by $\mathbf{S5}_m \oplus \mathbf{LTL} + \{\mathbf{PR}\}$. The complexity of validity is non-elementary time complete. Adding common knowledge, we again get a complexity of Π_1^1 for the validity problem, and a negative result concerning finite axiomatisability for $\mathcal{C}_m^{sync,pr}$*

Our discussion of interpreted systems can only be limited. Rather than linear time, one may consider branching time logic, and apart from synchrony and perfect recall, one may consider properties with or without assuming a unique *initial state*, and with or without the principle of *no learning*– the 'converse of perfect recall'. Only these parameters all together yield 96 different logics: for a comprehensive overview of the linear case we refer to [31], and for the branching time case, to [97]. Moreover, where this section's exposition is mainly organised along the ideas in [21], there have been several other but related approaches to knowledge and time, or even knowledge and computation, of which we here only mention the distrtibuted processes approach of [60]. The recent paper [89] provides a general picture of different logics for knowledge and time, by giving a survey of decidability and undecidability results for several logics.

Although in general, the *model checking* problem is computationally easier than that of validity checking, for logics of knowledge and time, in particular those with perfect recall, the complexity of both tasks is often the same (see [94]). Work still progresses, both in the theoretical and the practical realm. We already mentioned an approach that 'reduces' epistemic temporal properties to temporal ones in order to use a 'standard' model checker. But model checkers that explicitly deal with an epistemic language are now rapidly emerging. Systems to model-check knowledge and time include the system MCK ([22]), DEMO ([104]) and the system MCMAS ([46]).

Recently, there has been a broad interest in model checking dynamics of knowledge in specific scenarios, like in [95] ('the dining philosophers'), and in [100] ('the sum and product problem'). Apart from model checking *epistemic properties*, it is also interesting to address the *realisability problem* (does there exist a *protocol* such that a given property is satisfied) and the *synthesis problem* (generate a protocol that satisfies a given constraint, if it exists). Space prohibits us to go into the details, we refer to [96].

6 GAMES WITH IMPERFECT INFORMATION

Now that we have seen how Kripke models are perfectly fit to represent games (Section 3) and imperfect information (Sections 4 and 5), let us spend some words on representing and reasoning about the combination of the two. In games with imperfect information, on which we will focus in this section, players *do* know what the rules of the games are, and who they play against, but they do not necessarily know 'where they are in the game'. In the game models of Section 3, this can be conveniently represented by using an indistinguishability relation for every player, as explained in Section 4. Game theorists call the members of each partition of such an $S5$-equivalence relation usually *information sets*. A game of perfect information would then just be the special case in which every information set contains exactly one node.

As a simple example of an imperfect information game, let us consider game H of Figure 9. We assume that we have the standard knowledge assumptions of $S5$, which semantically mean that the indistinguishability relation in that figure is an equivalence relation: however, we do not represent reflexive arrows, so that the only uncertainty in the game is represented by the dotted line labelled with player A. So, what is modelled in H is that player E makes a first move (l or r), and after that, A has to move, without knowing E's decision. In particular, we have $H, x \models K_A(\langle R\rangle p \vee \langle L\rangle p) \wedge \neg K_A\langle R\rangle p \wedge \neg K_A\langle L\rangle p$, in words: A knows he can guarantee p, but he does not know how! Recall that since a player is supposed to base his decision on the information at hand, we only consider *uniform strategies*, i.e., strategies σ which satisfy the following condition:

$$\forall s, t \in P^{-1}[\{i\}](R_i st \Rightarrow \sigma(s) = \sigma(t)) \tag{10}$$

Without this constraint on strategies, we would have that player A can enforce the outcome p in game H of Figure 9: $H, \rho \models [l, r]\langle L \cup R\rangle p$, which is counterintuitive: in order to achieve p, player A must play a different move in two situations that he cannot distinguish. Concluding: A has a strategy to ensure p in H, although we cannot expect him to play it, because the strategy is not uniform. But there is more to say about this. Suppose that in game H player E makes his move, and *then* we ask ourselves whether A has a uniform strategy to win. Surprisingly, he has! If E would play l, then A can use the uniform strategy σ_1, with $\sigma_1(x) = \sigma_1(y) = R$, and were E to play r, player A can fall back on the uniform strategy $\sigma_2(x) = \sigma_2(y) = L$. So, rather than just requiring uniform strategies for players to be used, we need an additional feature to distinguish winning situations from others. The notion that we are after seems to be closely related to the notions of *knowing-de dicto* and *knowing-de re*. The former expresses that player i knows that he has a winning strategy (if Ac_i represents i's set of actions, this would mean $K_i \bigvee_{a \in Ac_i}\langle a\rangle\mathbf{win_i}$), whereas the latter expresses he knows how to achieve it: $\bigvee_{a \in Ac_i} K_i\langle a\rangle\mathbf{win_i}$. For a further discussion on knowing-*de re* and knowing-*de dicto* in the context of extensive games (applying this to full strategies, rather than actions), see also [39].

The important difference between these two notions of knowledge, and its consequences for a theory of action, was already made in 1990 in [51] (and it goes back to the question what it means that 'A knows who B is', [36] and the general problem of 'quantifying in' into a knowledge formula, [69]). In the context of reasoning about knowledge and action [51] has been very influential, as it is still in the area of decision making in multi-agent systems. In order to cope with examples like 'in order to open a safe, you have to know

its key', [51] demonstrates the value of a possible world semantics, under the assumptions that terms are *rigid designators*. Although the language used in [51] is that of first order logic, one easily recognises properties like *perfect recall* and *no learning* (see Section 5 and 6.1) in [51]'s *noninformative action*.

[51] argues that the assumption of perfect information has been the prominent one in planning in Artificial Intelligence up to the nineties. What is missing, in the first place, is an analysis of *epistemic pre-conditions* before executing a plan: does the agent have the information necessary to carry out (the next step of) the plan? This question has been taken up by computer scientists by coming up with the notion of *knowledge programs*, (cf. [21, Chapter 7]) in which objective test conditions in a program are replaced by epistemic conditions. Apart from specifying epistemic pre-conditions, [51] argues to include *epistemic post-conditions*, in order to facilitate the agent to reason about how to acquire the information that is lacking to execute a sequential plan successfully. All these notions are crucial in the context of game playing, as well.

Where we thus far 'only' imposed the $S5$ principles on imperfect information games, [83] mentions several properties that one could require 'on top' of this, some even related to incomplete information games, like $\mathbf{turn_i} \rightarrow C\mathbf{turn_i}$ (it is common knowledge whose turn it is) and $\langle a \rangle \top \rightarrow C\langle a \rangle \top$ (it is common knowledge which moves can be played, in any node).

If information sets were only used to impose players to stick to uniform strategies (10) one only needs to specify knowledge-accessibility for player i at i's decision nodes. But, although this seems indeed to be common practice in game theory, the full machinery of $S5$ allows for much finer structure. And there are many more assumptions in game theory that seem dominant (but maybe easily relaxed), like the one that made us draw a *horizontal* line as indistinguishability in Figure 9, suggesting that players know how long the game has been played for. In general, we can require that agents don't know what has happened, or whose turn it is. Rather than systematically describe all the options, in the next section we focus on one specific property, and show how a modal analysis may be of help.

6.1 Case study: Perfect Recall

The principle of perfect recall in a game captures that players have some memory about what happened. Formally, in a dynamic logic setting, it is expressed as (see [83] for further details):

$$\begin{array}{llr} (i) & (\mathbf{turn_i} \wedge K_i[a]\varphi) \rightarrow [a]K_i\varphi & \quad and \\ (ii) & (\neg\mathbf{turn_i} \wedge K_i[\cup_{b\in B}]\varphi) \rightarrow [\cup_{b\in B}]K_i\varphi & \end{array} \tag{11}$$

where a is any action of player i, and B is the union of all actions of the other players. In words: if player i knows that doing a will lead to φ, then after having done a, he knows φ. Note that clause (i) of (11) is not realistic for *specific* moves of the opponent: in game H of Figure 9 for instance, we have $H, \rho \models K_A[l]\langle R\rangle p$, but not $H, \rho \models [l]K_A\langle R\rangle p$. Also, it assumes that players are aware when others make their move (cf. synchrony in Section 5).

Semantically, the subformula $K_i[a]\varphi \rightarrow [a]K_i\varphi$ of (11) corresponds to the following (which is even more apparent from the dual of (11), i.e. $\langle a\rangle\hat{K}_i\varphi \rightarrow \hat{K}_i\langle a\rangle\varphi$):

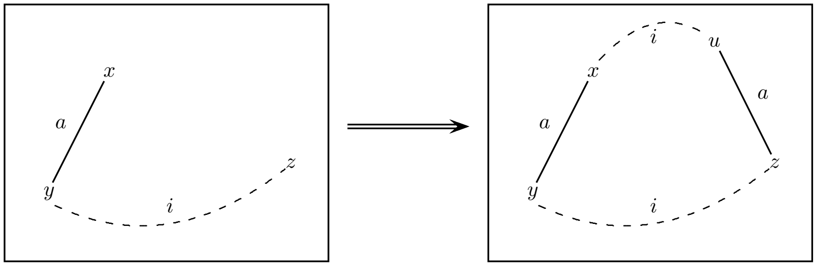

Figure 12. The commuting condition pictured. The arrow stands for implication

$$\forall xyz((R_a xy \ \&\ R_i yz) \rightarrow \exists u(R_i xu \ \&\ R_a uz)) \tag{12}$$

This 'commutation property' is also depicted in Figure 12, and guarantees that ignorance, or better indistinguishability, cannot be generated spontaneously: if a player i cannot distinguish, after doing action a, between state z and y, then both states must be the result of performing a in indistinguishable states.

For illustrative purposes, let us now look how [14] generalises these notions (over more than just actions), to characterise *von Neumann games*. Let $s \prec t$ in a game tree denote that there is a path (labelled with choices) from s to t. Next, let $\ell(x)$ denote the number of predecessors of node x according to $\prec$. Then, an extensive game is called von Neumann if

$$\forall xy(R_i xy \ \&\ x, y \in P^{-1}[\{i\}] \Rightarrow \ell(x) = \ell(y)) \tag{13}$$

This implies that in a von Neumann game, a player who has to move knows how many moves have already been played. A game satisfies *Memory of Past Knowledge* (MPK) if

$$\forall xyz((x \prec y \ \&\ R_i yz) \rightarrow \exists u(R_i xu \ \&\ u \prec z)) \tag{14}$$

Note that MPK is weaker than perfect recall in that it abstracts from the specific action taken. In [14] it is shown that perfect recall is equivalent to the conjunction of Memory of Past Knowledge and Memory of Past Actions (in which a player remembers which actions he has taken in the past, not necessarily in which order).

THEOREM 22. *Let G be an extensive form game. Then, the following are equivalent:*

1. *G satisfies MPK*
2. $\forall i, \forall x, y(R_i xy \Rightarrow \ell(x) = \ell(y))$

Note that condition 2 says that it is in fact common knowledge that G is a von Neumann game. The direction (1) $\Rightarrow$ 2 is proven in [14], the other direction in [9]. The modal characterisation of MPK is given in [14] by using temporal operators. The Past operator P is for instance interpreted as follows: $G, s \models P\varphi$ iff for all t for which $t \prec s$, we have $G, t \models \varphi$. Similarly, the operator $\Box$ refers to the future (for more on temporal modal logic, we refer the reader to Chapter 11 of this handbook). Then, MPK is characterised by

$$PK_i\varphi \rightarrow K_i PK_i\varphi \tag{15}$$

As a scheme, (15) is equivalent to $K_i\varphi \rightarrow \Box K_i PK_i\varphi$.

6.2 Outlook

The upshot of the exercise in the previous section is not so much the specific correspondence results, but rather to demonstrate the elegance and suitability of the modal machinery to reason about notions such as perfect recall. The latter notion also has received considerable attention in the computer science literature, where, in the context of synchronous systems, it is defined as $K_i \bigcirc \varphi \rightarrow \bigcirc K_i \varphi$, see Section 5. (Perfect recall is called 'no-forgetting' in the seminal paper [29]). The other direction of non-forgetting, i.e., $\bigcirc K_i \varphi \rightarrow K_i \bigcirc \varphi$ is called 'no learning', and comes with a similar commutation diagram as that in Figure 12.

Unfortunately, such commuting diagrams that enforce regularities on the underlying models have in general an adverse effect on the complexity of checking satisfiability for such logics. Having a grid-like structure in models for a logic enables one to encode Tiling Problems in them, which then can be used to demonstrate that in the worst case satisfiability becomes undecidable (see also Chapters 3 on complexity and 7 on decision problems). In fact, [29] shows that only assuming no-learning (in a context of at least two knowers and allowing common knowledge), the validity problem is highly undecidable. In words of [89]: "Trees are safe" and "Grids are Dangerous". We refer to that paper for a survey of several (un-)decidability results for temporal epistemic logics. For a restricted set of related results, we refer to Theorem 21 in this Chapter and its succeeding paragraphs.

7 DYNAMIC EPISTEMIC LOGIC

The framework for epistemic logic as presented in Section 4 elegantly allows for reasoning about knowledge (and, in particular, higher order knowledge: knowledge about (other's) knowledge), but as such it does not allow to deal with the *dynamics of epistemics*, in which one can express how certain knowledge changes due to the performance of certain actions, which by itself can be known or not. The notion of run in an interpreted system (Section 5) explicitly allows for such dynamics. In this section, we look at dynamic epistemic logic where the actions themselves are epistemic, like a revision due to a public announcement or a secret message. The famous paper [2] put the *change of information*, or belief revision, as a topic on the philosophical and logical agenda (cf. Chapter 18). This AGM tradition typically studies how a belief or knowledge set should be modified, given some new evidence. Well-studied examples of such modification are *expansion*, *contraction* and *revision*, which are of type $2^{\mathcal{L}} \times \mathcal{L} \rightarrow 2^{\mathcal{L}}$, i.e., they transform a belief set K given new evidence φ into a new belief set K', where the belief sets are subsets of the propositional language. The publication of [2] generated a large stream of publications in belief revision, investigating the notion of epistemic entrenchment, the revision of (finite) belief bases, the differences between belief revision and belief updates, and the problem of iterated belief change (for more on belief revision, refer to Chapter 18 in this handbook).

However, in all these approaches the dynamics are studied on a level *above the informational level*: the operators for modification are not part of the object language, and they are defined on (sets of) propositional formulas in $\mathcal{L}$. Hence, it is impossible to reason about change of agents' knowledge and ignorance within the framework, let alone about the change of other agents' information. This section describes approaches where the changing epistemic attitudes find their way into the object language.

The notion of a run in an interpreted system, together with the availability of temporal operators in the language (Section 5) facilitates reasoning about the dynamics of an agent's knowledge. A run is typically generated by a protocol, which usually represents a standard computer program. The pioneering work in [51] also studies the relation between actions and knowledge: there the emphasis is on epistemic preconditions that are needed to perform certain actions in the world, such as knowing a key-combination in order to open a safe. From the point of view of expressivity, one can say that the work on interpreted systems enables one to reason about the (change of) knowledge over time, and adding actions to the language, one can also reason about the change of knowledge brought about by performing certain plans. This enables one to express properties like *perfect recall* and *no learning* discussed in previous sections.

This section sketches approaches that not only "dynamise the epistemics", but also "epistemise the dynamics": the actions that (groups of) agents perform are epistemic actions. Different agents may have different information about which action is taking place, including higher-order information. Perfect recall would then rather look like $K_i[\alpha]\varphi \rightarrow [K_i\alpha]K_i\varphi$: "if player i knows that when j chooses 'right' this offers i a possible win, only after i *knows* that j *does* move 'right', i is aware of his profitable situation"! The rather recent tradition often referred to as *Dynamic Epistemic Logic*, treats all of knowledge, higher-order knowledge, and its dynamics on the same level. Following a contribution of 1997 [23], a stream of publications appeared around the year 2000 ([48, 98, 84]) and a general theory only now and partially emerges. In retrospect, it appeared that an original contribution of [68] from 1989 was an unnoticed ancestor of this stream of publications. This section is too short to discuss all those approaches, we will, for homogeneity, mainly follow [102, 101], and [7]. We start by considering a special case of updates.

7.1 Public Announcements

Public announcements are a simple and straightforward, but still interesting epistemic action: the idea behind a public announcement of φ is that all players are updated on φ, and they all know this, and they all know that they know this, etc. Given a group of players N, the language $\mathcal{L}_N^{pa}$ for public announcements adds a modality $[\chi]\psi$ on top of the epistemic language with operators $K_i(i \in N)$. If the common knowledge operator C is also allowed, we refer to the language as $\mathcal{L}_N^{pa}(C)$. The interpretation of $[\chi]\psi$ reads: "after truthful public announcement of χ, it holds that ψ". Note that both χ and ψ are typical members of $\mathcal{L}_N^{pa}$ or $\mathcal{L}_N^{pa}(C)$: announcements can be nested.

The semantics of $[\chi]\psi$ is rather straightforward: it is true in (M, s) if, given that χ is true in (M, s), ψ is true in s if we 'throw away' all the states in which χ is false. To achieve this, we define $M_{|\chi}$ as that submodel of M that consists of all points in which χ is true. More formally, given $M = \langle W, R_1, R_2, \ldots R_m, \pi\rangle$, the model $M_{|\chi} = \langle W', R'_1, R'_2, \ldots R'_m, \pi'\rangle$ has as its domain all the χ states: $W' = \{w \in W \mid (M, w) \models \chi\}$, and the primed relations and valuation in M' are the restrictions of the corresponding relations and valuation in M to W'. Then, we define

$$M, s \models [\chi]\psi \text{ iff } (M, s \models \chi \Rightarrow M_\chi, s \models \psi). \tag{16}$$

EXAMPLE 23. (Example 18 ctd.) In the miniature card game hexa (Example 18), suppose that in (hexa,rwb), player 1 publicly announces that he does not possess card w, i.e.,

$\varphi = \neg w_1$. Then, the resulting model is $\mathsf{hexa}_{|\varphi} = \mathsf{hexa}_1$ of Figure 10: all the deals in which 1 *does* have the white card are removed. Note that we have: $\mathsf{hexa}, rwb \models [\neg w_1]K_3 r_1$, and even $\mathsf{hexa}, rwb \models [\neg w_1]K_3(r_1 \wedge w_2 \wedge b_3)$, saying that after 1's announcement, player 3 knows the exact deal. Note that this is not true for player 2: $\mathsf{hexa}, rwb \models [\neg w_1]\neg K_2 r_1$, since, after the announcement $\neg w_1$, player 2 still considers it possible that 1 has b. Player 2 knew already the truth of the announcement. Still, he 'learns' from it:

$$\mathsf{hexa}, rwb \models K_2 \neg K_3(r_1 \wedge w_2 \wedge b_3) \wedge [\neg w_1]K_2(K_3(r_1 \wedge w_2 \wedge b_3) \vee K_3(b_1 \wedge w_2 \wedge r_3))$$

This expresses that initially, in rwb, 2 knows that 3 does not know the current deal (described by $r_1 \wedge w_2 \wedge b_3$), but after 1's announcement $\neg w_1$, 2 knows that 3 knows the deal. Note that 1 does not learn the same as 2: player 1 cannot be sure that 3 learns the deal from the announcement $\neg w_1$, since, according to 1, it might be the case that 3 holds w, in which case 3 would not learn the deal from the announcement.

Public announcements can be made iteratively: the model hexa_2 is obtained from hexa_1, by letting 3 make the public announcement "I know the deal!". More formally, let $\mathsf{knowsdeal}(i)$ be $\bigvee_{c,d,e \in \{r,w,b\}} K_i(c_1 \wedge d_2 \wedge e_3)$. Then, 1 learns the deal after 3 announces that he learned, but 2 does not (let δ be the actual deal $(r_1 \wedge w_2 \wedge b_3)$):

$$\mathsf{hexa}, rwb \models [\neg w_1][\mathsf{knowsdeal}(3)](K_1\delta \wedge \neg K_2\delta)$$

This can be formally verified by inspecting Figure 10, but is also intuitively correct: if 1, holding r, announces that he does not possess w, then he knows that this is either informative for 2 (in case 3 has w, i.e., in rbw) or for 3 (in rwb). Since 3 subsequently announces he learned the deal, 1 finds out the real situation is rwb. Similarly, 2 does not learn the deal from this "dialogue", he conceives it still possible that the real deal is bwr. However, as we saw above, 2 still learns something (i.e., about the knowledge of others: after the first announcement 2 learns that 3 knows the deal and after the second 2 learns that also 1 knows the deal). $\dashv$

As for an axiomatisation of public announcements, the logic $\mathbf{S5}_N^{pa}$ is obtained by adding the left-hand side of Table 4 to $\mathbf{S5}_m$. The logic $\mathbf{S5}_N^{pa}(C)$, which also incorporates common knowledge, is axiomatised by the union of Tables 2 and 4.

	axioms and rules for $\mathbf{S5}_N^{pa}$		additional rule for $\mathbf{S5}_N^{pa}(C)$
A11	$([\chi]\varphi \wedge [\chi](\varphi \rightarrow \psi)) \rightarrow [\chi]\psi$		
A12	$[\chi]p \leftrightarrow (\chi \rightarrow p)$	*R5*	From $\vdash \varphi \rightarrow [\chi]\psi$
A13	$[\chi]\neg\psi \leftrightarrow (\chi \rightarrow \neg[\chi]\psi)$		and $\vdash \varphi \wedge \chi \rightarrow E\varphi$
A14	$[\chi]K_i\psi \leftrightarrow (\chi \rightarrow K_i[\chi]\psi)$		infer $\vdash \varphi \rightarrow [\chi]C\psi$
R4	$\vdash \varphi \Rightarrow \vdash [\chi]\varphi$		

Table 4. Public announcements without (left) and with common knowledge

Axiom $A11$ and rule $R4$ characterise $[\chi]$ as a normal modal operator. The other axioms have the general form $[\chi]\varphi \leftrightarrow (\chi \rightarrow \varphi')$; the second appearance of χ indicates that only behaviour of *successful updates* is specified. Note that the general form is equivalent to $(\chi \wedge ([\chi]\varphi \leftrightarrow \varphi')) \vee (\neg\chi \wedge [\chi]\varphi)$, which, by the fact that $\vdash \neg\chi \rightarrow [\chi]\varphi$, is equivalent to $(\chi \wedge ([\chi]\varphi \leftrightarrow \varphi')) \vee \neg\chi$.

Keeping this in mind, axiom $A12$ (also called *atomic persistence*) assures that atomic facts (and, hence, objective properties, not involving any knowledge) are not affected by public announcement: they do not change the world. According to $A13$, public announcements are partial functions: under the condition that the announced formula is true, its announcement induces a unique outcome. Finally, axiom $A14$ relates individual knowledge to public announcements: from right to left it is a variant of the earlier mentioned *perfect recall*, the other direction is a conditionalised *no learning* property.

The straightforward generalisation of $A14$ to a logic with common knowledge would read $[\chi]C\psi \leftrightarrow (\chi \to C[\chi]\psi)$. However, such a principle is not valid. Consider the models M and M' of Figure 13 (taken from [101]). First of all, let 10 denote a world in which p is true, and q is false, and similarly for 11 and 01. Then, in model M of Figure 13, we have $M, 11 \models [p]Cq$, since in the updated model $M' = M_{|p}$, we have $M', 11 \models Cq$ (in M', world 11 is only $a-$ and $b-$ accessible to itself). At the same time, we have $M, 11 \not\models (p \to C[p]q)$, in particular $M, 11 \not\models C[p]q$. This is so since in 11 there is a world R_C-accessible (to wit, 10), in which a public announcement of p would lead us to the disconnected part 10 of M', where we have $M', 10 \not\models q$, so that $M, 10 \not\models [p]q$, which justifies the claim $M, 11 \not\models C[p]q$.

Figure 13. A counter model for $[p]Cq \leftrightarrow (p \to C[p]q)$

In order to obtain common knowledge through a public announcement, rule $R5$ from Table 4 must be used. The soundness of this rule is typically proven using induction on the R_C-path to ψ in an updated model $M_{|\chi}$.

THEOREM 24 ([68, 8]). *The logics* $\mathbf{S5}_N^{pa}$ *(without common knowledge) and* $\mathbf{S5}_N^{pa}(C)$ *(with common knowledge) as defined in Table 4 are sound and complete with respect to the semantics with key condition (16) on top of the epistemic semantics as given in Section 4.*

In fact, dynamic epistemic logic $\mathbf{S5}_N^{pa}$ can be reduced to its static counterpart $\mathbf{S5}_{|N|}$, by employing the following translation T:

$$
\begin{array}{lcl}
T([\chi]p) & = & T(\chi) \to p \\
T([\chi](\varphi \wedge \psi)) & = & T([\chi]\varphi) \wedge T([\chi]\psi) \\
T([\chi]\neg\psi) & = & T(\chi) \to \neg T([\chi]\psi) \\
T([\chi]K_i\psi) & = & T(\chi) \to K_i T([\chi]\psi)
\end{array}
$$

The equivalence between φ and $T(\varphi)$ follows immediately from the axioms of Table 4, and it is also easy to see that $T(\varphi)$ has no occurrences of the $[\chi]$ operator: they are all replaced by implications $\chi \to p$ for certain atoms p. This feature can be used to obtain completeness of $\mathbf{S5}_N^{pa}$ ([68]), but for the case of $\mathbf{S5}_N^{pa}(C)$, the completeness proof is much more involved ([8]).

Unsuccessful Updates

The intuition of a public announcement $[\chi]$ is that it produces common knowledge of the announced fact χ. Remarkably enough, it is not always the case that $[\chi]C\chi$. As an example, take the model M of Figure 13, where in 11 the atom p holds, but a is ignorant about it. The public announcement of this very fact (i.e., $p \wedge \neg K_a p$, which could be uttered by player b, since he knows it) however, leaves a with a difficult, if not impossible task to update his knowledge; it is hard to see how to simultaneously incorporate p and $\neg K_a p$ into his knowledge.

DEFINITION 25 ((Un-)successful Formulas and Updates). A formula χ is *successful* if $\models [\chi]\chi$. Otherwise, it is *unsuccessful.* Moreover, χ is a *successful update* in M, s if $M, s \models (\chi \wedge [\chi]\chi)$, it is an *unsuccessful update* if $M, s \models (\chi \wedge [\chi]\neg\chi)$. An update with χ is *publicly successful* in M, s if $M, s \models \chi \wedge [\chi]C\chi$. $\dashv$

Which formulas are unsuccessful, and which are successful? This question was raised in [82], and some first answers are given in [86] and [99]. Typically, only formulas involving ignorance can be unsuccessful. Hence, propositional formulas, involving no epistemic operators are always successful. Secondly common knowledge formulas are successful, by merits of the validity $\vdash [C\varphi]C\varphi$. The paper [99] identifies a fragment of the language, $\mathcal{L}_N^{u0}$ that is preserved under 'deleting states':

$$\varphi \in \mathcal{L}_N^{u0} ::= p \mid \neg p \mid \varphi \wedge \psi \mid \varphi \vee \psi \mid K_i\varphi \mid C\varphi \mid [\neg\varphi]\psi$$

The fragment $\mathcal{L}_N^{u0}$ is preserved under submodels, from which it follows that for any $\varphi \in \mathcal{L}_N^{u0}$ and any ψ, $\vdash \varphi \rightarrow [\psi]\varphi$. As a consequence, the language $\mathcal{L}_N^{u0}$ is successful. After presenting these partial results, and before giving an example of (un-)successful updates, we mention the following fact about updates:

THEOREM 26 ([86]). *In every model, every public announcement is equivalent to a successful one.*

EXAMPLE 27. (Example 19 ctd., [99]) Consider model twomud from Figure 11. Let us abbreviate $(m_a \vee m_b \vee m_c)$ to muddy. Then model $(\mathsf{twomud}_1, 110)$ is the model that one obtains when publicly announcing muddy in $(\mathsf{twomud}, 110)$, i.e., after (5) is announced. One easily checks that muddy is a publicly successful update in this state: $\mathsf{twomud}, 110 \models [\mathsf{muddy}]C\mathsf{muddy}$ (note that, since muddy is a member of the submodel-preserving language $\mathcal{L}_N^{u0}$, it is even a successful *formula*).

Note that $\mathsf{twomud}, 100 \models [\mathsf{muddy}]K_a m_a$: if a is the only muddy child, he knows about his muddiness after the announcement (5) that there is at least one muddy child. Let $\mathsf{knowmuddy} = \bigvee_{i \in \{a,b,c\}}(K_i m_i \vee K_i \neg m_i)$ (at least one child knows about its muddy state). Now, although we have $\mathsf{twomud}_1, 110 \models \neg\mathsf{knowmuddy}$, we have $\mathsf{twomud}_1, 110 \models [\neg\mathsf{knowmuddy}]\mathsf{knowmuddy}$. In other words, when the father makes his announcement (5) for the second time, we interpret this as an announcement of $\neg\mathsf{knowmuddy}$ (since father makes his remark for the second time, this is a public announcement that no child stepped forward after the first utterance of (5), or, in other words, no child knows yet about its muddiness). Since $\mathsf{knowmuddy}$ is true in twomud_1 in the states 001, 010 and 100, these states are removed after the announcement $\neg\mathsf{knowmuddy}$, giving us model twomud_2 of Figure 11.

To further explain the story, one easily verifies $\mathsf{twomud}_2, 110 \models C\mathsf{atleasttwomuddy}$, with $\mathsf{atleasttwomuddy}$ having its obvious interpretation $\bigvee_{i,j \in \{a,b,c\}}^{i \neq j}(m_i \wedge m_j)$. But if this

is common knowledge in $\mathsf{twomud}_2, 110$, in particular children a and b know this: since they only see one other muddy child, they conclude that they are muddy themselves and hence step forward. We have seen that $\mathsf{twomud}, 110 \models \mathsf{muddy} \wedge [\mathsf{muddy}]\mathsf{Cmuddy}$, and also that $\mathsf{twomud}, 110 \models [\mathsf{muddy}]\ [\neg\mathsf{knowmuddy}]C\mathsf{knowmuddy}$. In other words, $\neg\mathsf{knowmuddy}$ is an unsuccessful update in $\mathsf{twomud}_1, 110$. Note that this is indeed a local notion: the same announcement $\neg\mathsf{knowmuddy}$ would have been successful in $(\mathsf{twomud}_1, 111)$. ⊣

7.2 General Updates

Public announcements play an important role in games: putting a card on the table, rolling a die, and moving a pawn on the chess board can all be considered as examples. However, in many situations much more subtle communication takes place than a public announcement. Consider the card game hexa in which player 1 shows player 2 his card. Obviously, this is informative for 2: he even learns the actual deal. But, although 3 does not see 1's card, he certainly obtains new information, viz. that 2 learns the deal. And 1 and 2 also get to know that 3 learns this!

The following – possibly simplest – example in the setting of multi-agent systems (two agents or players, one atom) attempts to demonstrate that the notions of higher-order information and epistemic actions are indeed non-trivial and may be subtle.

> *Anne and Bert are in a bar, sitting at a table. A messenger comes in and delivers a letter that is addressed to Anne. The letter contains either an invitation for a night out in Amsterdam, or an obligation to give a lecture instead. Anne and Bert commonly know that these are the only alternatives.*

This situation can be modelled as follows: There is one atom p, describing 'the letter invites Anne for a night out in Amsterdam', so that $\neg p$ stands for her lecture obligation. There are two agents 1 (Anne) and 2 (Bert). Whatever happens in each of the following action scenarios, is publicly known (to Anne and Bert). Also, assume that in fact p is true.

SCENARIO 28 (tell). Anne reads the letter aloud.

SCENARIO 29 (read). Bert sees that Anne reads the letter.

SCENARIO 30 (mayread). Bert orders a drink at the bar so that Anne may have read the letter.

SCENARIO 31 (bothmayread). Bert orders a drink at the bar while Anne goes to the bathroom. Both may have read the letter.

After execution of the first scenario (which is in fact a public announcement), it is common knowledge that p: in the resulting epistemic state Cp holds. This is not the case in the second scenario, but still, some common knowledge is obtained there: $C(K_1p \vee K_1\neg p)$: it is commonly known that Anne knows the content of the letter, irrespective of it being p or $\neg p$. Does this higher-order information change in Scenario 30? Yes, in this case Bert does not even know if Anne knows p or knows $\neg p$: $\neg K_2(K_1p \vee K_1\neg p)$. In Scenario 31 something similar is happening, that may best be described by saying that the agents concurrently learn that the other may have learnt p or $\neg p$. Note that in this case, both agents may have learnt p, so that p is generally known: $E_{12}p$, but they are in that case unaware of each other's knowledge, $\neg C_{12}p$, and *that* is commonly known.

Scenarios 30 and 31 are interesting, since semantically, they indicate that one cannot simply rely on the strategy of deleting states. The scenarios not only provide the agents with certainty, but also some doubts arise. After Scenario 30 for example, Bert must find an alternative state possible, in which Anne knows the contents of the letter, but also one in which Anne does not know. This is in a nutshell the main challenge in the semantics of these general updates.

Language

To a standard multi-agent epistemic language with common knowledge for a set N of agents and a set P of atoms, we add dynamic modal operators for programs that are called knowledge actions or just actions. Actions may change the knowledge of the agents involved. The formulas $\mathcal{L}_N$, the actions $\mathcal{L}_N^{\mathsf{act}}$, and the group gr of an action are defined by simultaneous induction:

DEFINITION 32 (Formulas and actions). The *formulas* $\mathcal{L}_N^{gu}(P)$ are defined by

$$\varphi ::= p \mid \neg\varphi \mid (\varphi \wedge \varphi) \mid K_n\varphi \mid C_B\varphi \mid [\alpha]\psi$$

where $p \in P$, $n \in N$, $B \subseteq N$, $\alpha \in \mathcal{L}_N^{\mathsf{act}}(P)$, and $\psi \in \mathcal{L}_{gr(\alpha)}^{gu}(P)$. The *actions* $\mathcal{L}_N^{\mathsf{act}}(P)$ are defined by

$$\alpha ::= ?\varphi \mid L_B\beta \mid (\alpha \; ! \; \alpha) \mid (\alpha \; ¡ \; \alpha) \mid (\alpha \; ; \; \beta') \mid (\alpha \cup \alpha) \mid (\alpha \cap \alpha)$$

where $\varphi \in \mathcal{L}_N^{gu}(P)$, $B \subseteq N$, $\beta \in \mathcal{L}_B^{\mathsf{act}}(P)$, and $\beta' \in \mathcal{L}_{gr(\alpha)}^{\mathsf{act}}(P)$, and where the *group* $gr(\alpha)$ of an action $\alpha \in \mathcal{L}_N^{\mathsf{act}}(P)$ is defined as: $gr(?\varphi) := \emptyset$, $gr(L_B\alpha) := B$, and $gr(\alpha \bullet \alpha') := gr(\alpha) \cap gr(\alpha')$ for $\bullet = \; ! \;, \cap, \cup, \; ; \;$. $\dashv$

The program constructor L_B is called *learning.* Action $?\varphi$ is a *test*, $(\alpha \; ; \; \alpha')$ is *sequential execution*, $(\alpha \cup \alpha')$ is *nondeterministic choice*, $(\alpha \; ! \; \alpha')$ is called *(left) local choice* and $(\alpha \; ¡ \; \alpha')$ is called *(right) local choice*, and $(\alpha \cap \alpha')$ is *concurrent execution.* The construct $L_B?\varphi$ is pronounced as 'B learn *that* φ'. Local choice $\alpha \; ! \; \alpha'$ may, somewhat inaccurately, be seen as 'from α and α', choose the first.' Local choice $\alpha \; ¡ \; \alpha'$ may be seen as 'from α and α', choose the second.' The interpretation of local choice '!' and '¡' depends on the context of learning that binds it: in $L_B(\alpha \; ! \; \alpha')$, everybody in B but not in learning operators occurring in α, α', is unaware of the specific choice for α. That choice is therefore 'local'.

EXAMPLE 33. The description in $\mathcal{L}_{12}^{\mathsf{act}}(\{p\})$ of the actions in the introduction are:

tell	$L_{12}?p \cup L_{12}?\neg p$
read	$L_{12}(L_1?p \cup L_1?\neg p)$
mayread	$L_{12}(L_1?p \cup L_1?\neg p \cup ?\top)$
bothmayread	$L_{12}(\; (L_1?p \cap L_2?p) \cup (L_1?\neg p \cap L_2?\neg p)$
	$\cup L_1?p \cup L_1?\neg p \cup L_2?p \cup L_2?\neg p \cup ?\top)$

For example, the description of read (Anne reads the letter) reads as follows: 'Anne and Bert learn that either Anne learns that she is invited for a night out in Amsterdam or that Anne learns that she has to give a lecture instead.' $\dashv$

By replacing all occurrences of '!' and '¡' in an action α by '$\cup$', except when under the scope of ?, we get the *type* $t(\alpha)$ of that action. By replacing all occurrences of '$\cup$'

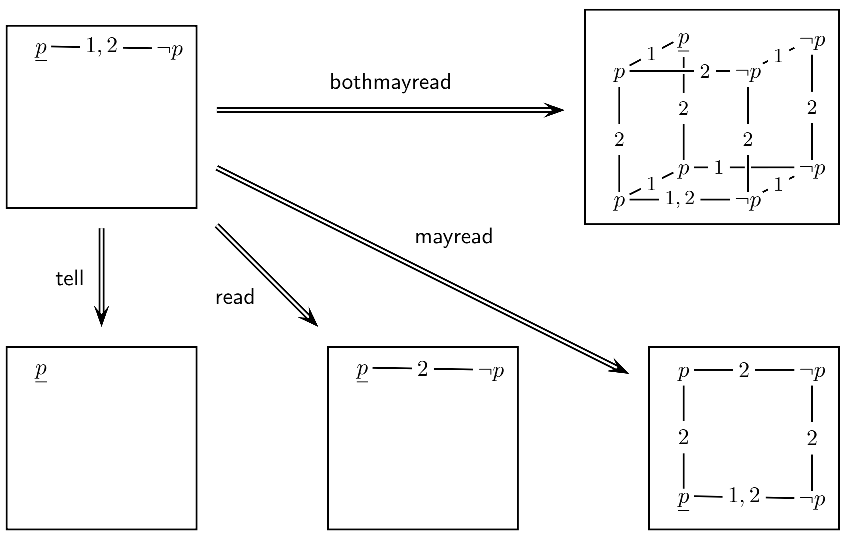

Figure 14. Epistemic states resulting from the execution of actions described in the four action scenarios. The top left figure represents (Let, u), in which it is common knowledge that both 1 and 2 are ignorant about p. For mayread and bothmayread only one of more executions is shown: namely the one in which actually nothing happens, and the one in which both 1 and 2 find out that p, respectively.

in an action α by either '!' or '¡', except when under the scope of ?, we get the set of *instances* $I(\alpha)$ of that action. Informally we write: $I(\alpha) := \{\alpha[\cup/!, ¡]\}$ If $t(\alpha) = t(\beta)$ we say that α and β are the same type of action. Furthermore, if α and β are identical modulo swapping of occurrences of '!' for '¡' or vice versa, we say that α, β are *comparable* actions. The idea here is that in the scope of an L_B operator, the agents of B know which action is executed, but the agents not in B consider all actions of the same type possible. Instead of $\alpha\ !\ \alpha'$ we also write $!\alpha \cup \alpha'$. This expresses more clearly that given choice between α and α', the agents involved in those actions choose α, whereas that choice remains invisible to the agents that learn about these alternatives but are not involved. Similarly, instead of α ¡ α' we write $\alpha\cup\ !\alpha'$.

EXAMPLE 34. The action read where Bert sees that Anne reads the letter is different from the instance of that action where *Anne is actually invited for a night out* and Bert sees that Anne reads the letter. The latter is described as $L_{12}(!L_1?p \cup L_1?\neg p)$: of the two alternatives $L_1?p$ and $L_1?\neg p$, the first is chosen, but agent 2 is unaware of that choice. The description read is its *type*. The other instance of read is $L_{12}(L_1?p\cup\ !L_1?\neg p)$. Actions $L_{12}(!L_1?p \cup L_1?\neg p)$ and $L_{12}(L_1?p\cup\ !L_1?\neg p)$ are *comparable* to each other. ⊣

Semantics and Axioms

Concerning the semantics of $\mathcal{L}_N^{gu}(P)$ (on epistemic models), we refer to Chapter 12 for the treatment of the dynamic operators, and focus here on the learning operator. Although our object language is that of [102], we focus on the semantics as explained in [7], which we coin *action model semantics*. The appealing idea in the action model semantics is that both the uncertainty about the state of the world, and that of the action taking place, are represented in two independent Kripke models. The result of performing an epistemic action in an epistemic state is then computed as a 'cross-product'. We give some more explanation by way of an example: see also Figure 15.

Model N in this figure is the model *Let*, but now we have given names s and t to the states in it. The triangular shaped model N is the *action model* that represents the knowledge and ignorance when the instance $L_{12}(L_1?p \cup L_1?\neg p \cup !\top)$ of $\mathsf{mayread}$ is carried out. The points $\mathsf{a}, \mathsf{b}, \mathsf{c}$ of the model N are also called actions, and the formulas accompanying the name of the actions are called *pre-conditions*: the condition that has to be fulfilled in order for the action to take place. Since we are in the realm of *truthful information transfer*, in order to perform an action that reveals p, the pre-condition p must be satisfied, and we write $\mathsf{pre}(\mathsf{b}) = \mathsf{p}$. For the case of nothing happening, only the precondition $\top$ need be true. Summarising, action b represents the action that agent 1 reads p in the letter, action c is the action when $\neg p$ is read, and a is for nothing happening. As with 'static' epistemic models, we omit reflexive arrows, so that N indeed represents that p or $\neg p$ is learned by 1, or that nothing happens: moreover, it is commonly known between 1 and 2 that 1 knows which action takes place, while for 2 they all look the same.

Now let $M, w = \langle W, R_1, R_2, \ldots R_m, \pi\rangle, w$ be an epistemic static state, and M, w an action in a finite action model. We want to describe what $M, w \oplus \mathsf{M}, \mathsf{w} = \langle W', R_1', R_2', \ldots R_m', \pi'\rangle, w'$, looks like — the result of 'performing' the action represented by M, w in M, w. Every action from M, w that is executable in any state $v \in W$ gives rise to a new state in W': we let $W' = \{(v, \mathsf{v}) \mid v \in W, M, v \models \mathsf{pre}(\mathsf{v})\}$. Since epistemic actions do not change any objective fact in the world, we stipulate $\pi'(v, \mathsf{v}) = \pi(v)$. Finally, when are

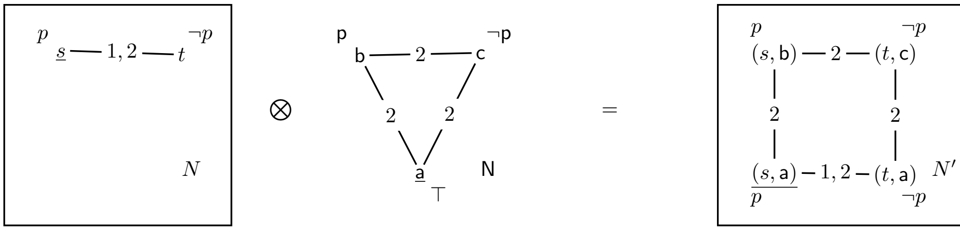

Figure 15. Multiplying the epistemic state Let, s with the action model (N, a) representing the action instance $L_{12}(L_1?p \cup L_1?\neg p \cup\, !\top)$ of $\mathsf{mayread}$

two states (v, v) and (u, u) indistinguishable for agent i? Well, he should be both unable to distinguish the originating states $(R_i uv)$, and unable to know what is happening $(\mathsf{R_i uv})$. Finally, the new state w' is of course (w, w). Note that this construction indeed gives $N, s \oplus \mathsf{N}, \mathsf{a} = N', (s, \mathsf{a})$, in our example of Figure 15. Finally, let the action α be represented by the action model state M, w. Then the truth definition under the action model semantics reads that $M, w \models [\alpha]\varphi$ iff $M, w \models \mathsf{pre}(\mathsf{w})$ implies $(M, w) \oplus (\mathsf{M}, \mathsf{w}) \models \varphi$. In our example: $N, s \models [L_{12}(L_1?p \cup L_1?\neg p \cup\, !\top)]\varphi$ iff $N', (s, \mathsf{a}) \models \varphi$.

Note that the accessibility relation in the resulting model is defined as

$$R_i(u, \mathsf{u})(v, \mathsf{v}) \;\Leftrightarrow\; R_i uv \;\&\; \mathsf{R_i uv} \tag{17}$$

As a consequence, perfect recall does not hold for $[\alpha]$: Let α be $L_{12}(L_1?p \cup L_1?\neg p \cup\, !\top)$. We then have $N, s \models K_2[\alpha]\neg(K_1 p \vee K_1 \neg p)$ (2 knows that if nothing happens, 1 will not find out whether p), but not $N, s \models [\alpha]K_2\neg(K_1 p \vee K_1 \neg p)$. We *do* have in general the following weaker form of perfect recall, however. Let M, w be a static epistemic state, and α an action, represented by some action state M, w. Let A be the set of actions that agent i cannot distinguish from M, w. Then we have

$$M, w \models \bigwedge_{\beta \in A} K_i[\beta]\varphi \rightarrow [\alpha]K_i\varphi \tag{18}$$

In words, in order for agent i to 'remember' what holds after performance of an action α, he should already now in advance that it will hold after *every epistemically possible execution* of that action. In the card example of hexa: if player 1 shows player 2 his card (which is red), than player 3 'only' knows that 2 learned that 1 holds red or white, because he cannot distinguish the action in which 1 shows red from the action in which 1 shows white. The perfect recall version (18) is a consequence of the '$\Rightarrow$'-direction of (17), the other direction gives the following generalized and conditionalised version of 'no learning': $[\alpha]K_i\varphi \rightarrow (\mathsf{pre}(\alpha) \rightarrow \bigwedge_{\beta \in A} K_i[\beta]\varphi)$. This implies that, everything that is known after a *specific* execution of an action, was already known to hold after any *indistinguishable* execution of that action.[1]

Concerning axiomatisations for dynamic epistemic logic, we provide some axioms in Table 5. These have to be added on top of $\mathbf{S}5_m$ and the usual axioms for the dynamic operators. Let us call the resulting system $\mathbf{DEL(S}5)_m$

[1] We have oversimplified the treatment of [7], in particular we have not discussed what it means that an action α is represented by an action state M, w. For further discussion, see [7], or [101], where both semantics discussed here are dealt with.

	some axioms of $\mathbf{DEL(S5)}_m$		some rules of $\mathbf{DEL(S5)}_m$
$A15$	$\langle L_B\alpha\rangle\top \leftrightarrow \mathsf{pre}(L_B\alpha)$	$R6$	$\vdash \varphi \to \psi \Rightarrow \vdash [\alpha]\varphi \to [\alpha]\psi$
$A16$	$[\alpha \,!\, \alpha']\varphi \leftrightarrow [\alpha]\varphi$	$R7$	If: for all β with $\alpha \sim_B \beta$
$A17$	$[\alpha]p \leftrightarrow (\mathsf{pre}(\alpha) \to p)$		there is a χ_β such that
$A18$	$[\alpha]\varphi \leftrightarrow \bigwedge_{\beta\in I(\alpha)}[\beta]\varphi$		(1) $\vdash \chi_\beta \to [\beta]\varphi$, and
$A19$	$\bigwedge_{\beta\sim_i\alpha} K_i[\beta]\varphi \to [\alpha]K_i\varphi$		(2) $\beta \sim_n \alpha'$ implies
$A20$	$[\alpha]K_i\varphi \to$		$\vdash (\chi_\beta \wedge \mathsf{pre}(\beta)) \to E_B\chi_{\alpha'}$
	$(\mathsf{pre}(\alpha) \to \bigwedge_{\beta\sim_i\alpha} K_i[\beta]\varphi)$		Then: $\chi_\alpha \to [\alpha]C_B\varphi$

Table 5. Epistemic axioms and rules: $i \leq m$

We elaborate shortly on the axioms: for further details we refer to [7, 102]. For any action α, a formula $\mathsf{pre}(\alpha)$ can be defined which is true exactly when α can be executed. Axiom $A15$, also called 'Learning', says that this is well-defined for learning actions, and $A17$ ('Atomic permanence') says that, like public announcement, general updates do not change the objective statements, given that the update is executable. Axiom $A16$ ('Local choice') determines the meaning of ! . Axiom $A18$ ('Action instances') formalises that the effect of an action is a combined effect of all its instances. One might have expected a distribution axiom for $[\alpha]$, but this is not sound. Such an axiom is unsound in any dynamic logic with concurrency (see Chapter 12), for the same reason: the interpretation of actions are relations between epistemic states and sets of epistemic states. The modality $[\alpha]$ corresponds to a $\forall\exists$ quantifier for which distribution does not hold. We do have a weaker form of distribution in the form of the action facilitation rule $R7$. This is all we need in the completeness proof.

Note that axioms $A19$ and $A20$ are variants of the earlier discussed principles of 'recall' and 'no learning', respectively. They give what one could call a 'compositional analysis' of pre- and post-conditions of epistemic events. Axiom $A19$ expresses that, in order to know, after α has happened, that φ, one has to know in advance that, no matter which action happens that looks like α, property φ will result. In a simple card game example: if I know after you show Ann a card that she has to know the full deal of cards among us, I should know in advance that Ann knows the deal after every card that I imagine you showing Ann. Often a contrapositive of such an axiom is appealing, in this case it reads $\langle\alpha\rangle\hat{K}_i\varphi \to \bigvee_{\beta\sim_i\alpha}\hat{K}_i\langle\beta\rangle\varphi$: if there is an execution of α after which I still consider φ a possibility, then for some action that looks the same to me as α, I imagine it possible that there is an execution which leads to φ. If you only have two cards, and you show them in a sequence to her (α), but I only see you show her a card twice, I still think it conceivable that she does not know both of your cards (φ), since I take into the consideration that you showed her twice the same card (β), after which she would not know both your cards. We leave elaboration about $A20$ to the reader.

Even the soundness of inference rule $R7$ is not easy to grasp. It mimics an induction rule where the χ formulas are used as induction hypotheses. It uses a notion of indistinguishability of actions: $\alpha \sim_B \beta$ means that group B cannot distinguish the execution of α from that of β. Also, the completeness proof of this logic is not easy, since in the canonical model one has to prove that $[\varphi]C_B\psi$ is in a maximal consistent set Γ iff for every path that runs from Γ along steps from one of the agents in B and in which φ is

true, also $[\varphi]\psi$ holds, and the right hand side of this iff has no counterpart in the object language. This motivated [90] to introduce a *relativised common knowledge operator* $C_B(\varphi, \psi)$ which exactly captures the right hand side of the mentioned equation. Both the inference rule $R7$ and the completeness proof of the logic based on this notion of common knowledge has a much more natural appearance.

8 EPISTEMIC FOUNDATIONS OF SOLUTION CONCEPTS

We now turn to the characterisation of solution concepts in games, formalised using epistemic constructs. To set the scene, let us consider the game in extensive form, depicted on the left hand side of Figure 16. It supposes we have two players, A and B, and A has to decide in the nodes labelled a, e, i and u, whereas B decides in b and d. The leaves of the tree are labelled with payoffs, the one in the left-most leaf for instance denoting that A would receive 1, and B would get 6.

A natural question now is: "suppose you are agent A. What would your decision be in the top node a?" The obvious backward induction procedure determines A's 'best' move starting from the leaves. Suppose the game would end up in node u. Since A is *rational*, he prefers an outcome of 4 over 1, and hence he would move 'left' in u; this is illustrated using the thick lines in the game on the right hand side of Figure 16. Now, B is *rational* as well, and he moreover *knows that A is rational*, so, when reaching node d, player B *knows* he has in fact a choice between a payoff of 4 (going 'left' in d) and 3 (going right, and *knowing what A will do in u*). We do the same reasoning over nodes e and i, and end up with the choices with a thick line in the figure: A would go 'right' and 'left', respectively. Again, since B is *rational and knows that A is rational*, his payoffs in node b are 4 and 3, respectively, and he will choose 'left'. Continuing in this fashion, note that A's choice for going left in a is based on (i) the fact that he is *rational*; (ii) the fact that he *knows that B is rational* and (iii) the fact that *he knows that B knows that he (A) is rational.* In short, knowledge of each other's rationality, and indeed, *common knowledge* thereof, seems to play a crucial role in rational strategic decision making.

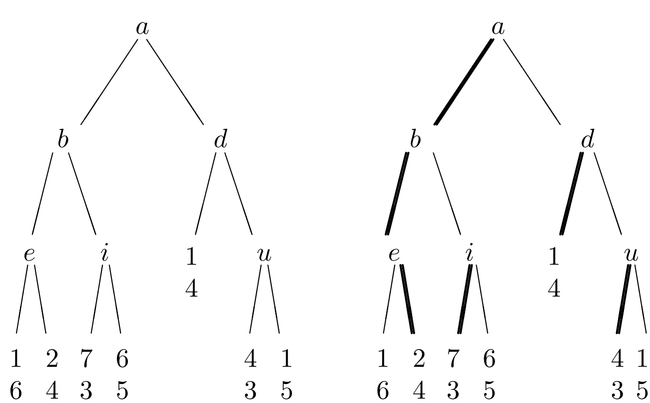

Figure 16. A Game in Extensive Form

The fact that epistemic notions are important in order to analyse certain solution

concepts in games, like common knowledge of rationality being crucial for backward induction, has been recognised for a long time, even though for certain game-theoretic solution concepts, the epistemic foundations are not always easy to determine. It seems most progress has been made in the case of strategic game forms.

8.1 Epistemic Foundations for Strategic Games

In ([18]) it is argued that a general form of epistemic characterisation results comes in a format in which one predicts the decision of each agent, given certain assumptions about each player's utility and rationality, and (iterated) knowledge thereof. The following provides an example, taken from [88]: we will mainly restrict ourselves to two player games in this section.

The proof of Theorem 7, and the backward induction algorithm applied above to recursively determine a subgame-perfect equilibrium in an extensive form game has its counterpart in strategic games. The left hand side of Table 6 represents a strategic game for two players r (choosing a row) and c (selecting a column). The entries x, y represent payoffs for player r and c, respectively. In this game, the (unique) Nash equilibrium can be achieved by iteratively removing strictly dominated strategies (see Section 2.1): since c's strategy c_3 is strictly dominated, by rationality he will not play it, so that we can remove its corresponding column from the game. Player r is rational and knows about c's rationality, and in the new game with only 2 columns that he needs to consider *he* has a dominated strategy r_3 that can be removed. Using $\mathsf{rat_i}$ to express that player i is rational, removal of r_3 is granted by the fact that $\mathsf{rat_r} \wedge \mathsf{K_r rat_c}$. Continuing in this matter, column c_2 and row r_2 can subsequently be removed, leaving us with the unique Nash equilibrium $\langle r_1, c_1 \rangle$. It seems that in our reasoning the last two steps are motivated by the fact that

$$\mathsf{rat_c} \wedge \mathsf{K_c rat_r} \wedge \mathsf{K_c K_r rat_c} \text{ and } \mathsf{rat_r} \wedge \mathsf{K_r rat_c} \wedge \mathsf{K_r K_c rat_r} \wedge \mathsf{K_r K_c K_r rat_c} \tag{19}$$

respectively. Before relating such a condition to [18]'s general format of characterisation results and his syntactic approach, we make a little detour.

$r \backslash c$	c_1	c_2	c_3
r_1	2,3	2,2	1,1
r_2	0,2	4,0	1,0
r_3	0,1	1,4	2,0

$r \backslash c$	c_1	c_2	c_3
r_1	$\mathsf{br}_r, \mathsf{br}_c$	–	–
r_2	br_c	br_r	–
r_3	–	br_c	br_r

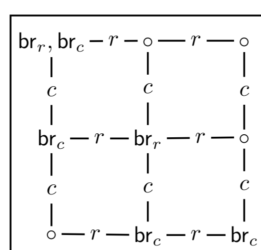

Table 6. A strategic game H for players r and c, distribution of best responses and the model M_H

A Semantic Approach

A semantic approach to clarify the nature of epistemic characterisation of solution concepts is given in [74], but here we follow a more recent approach ([88]). We do this since

the latter is closer to the Kripke models as used in this chapter, and it moreover gives a nice example of how dynamic epistemic logic (Section 7) can clarify the subtleties that are at stake here (for instance, is iterated knowledge as in (19) indeed *needed*?). Endowing finite two-player games in strategic form with an epistemic flavour uses the observation that each player knows his strategy, but not the other's. Hence, if we take the *strategy profiles* σ in a game G as the possible worlds, the epistemic indistinguishability relation that presents itself is then defined by $R_i\sigma\delta$ iff $\sigma_i = \delta_i$. This is in fact the definition that is used in the prominent *distributed* or *interpreted systems* approach to epistemic logic (see Section 5), in which global states in the overall system have a local component for each agent, each exactly knowing this local state. Thus, the *full model* over the game H of Table 6 is the left model in Figure 17; where the global states $\langle \sigma_r, \sigma_c \rangle$ are represented by their unique payoff for that profile.

As we have seen above, an algorithm to find a solution concept in a game G may transfer a model into a smaller one. Let us coin submodels of full models *general game models*. Doing so, we stay in the realm of $\mathbf{S5}_2$, since as [81] observes, every $\mathbf{S5}_2$-model is bisimular to a general game model. Now, is common knowledge of rationality *needed* to justify the elimination of dominated strategies algorithm? First of all, referring to common knowledge in full games seems to be some overkill: in every full model for two players, every pair of strategy profiles $\sigma = \langle \sigma_r, \sigma_c \rangle$ and $\tau = \langle \tau_r, \tau_c \rangle$ is connected through a third $\delta = \langle \sigma_r, \tau_c \rangle$ (and, indeed, a fourth $\gamma = \langle \tau_r, \sigma_c \rangle$), which immediately gives us $K_r K_c \varphi \rightarrow K_c K_r \varphi$ as a valid scheme on such models. This is reminiscent of the property that in interpreted systems, common knowledge in every run (roughly, every sequence of global states in the full model) is constant (see Section 5). In full models for two agents, we have $K_r K_c \varphi \rightarrow C\varphi$ (its contra-positive follows quickly from the semantic insight above: if $\neg C\varphi$ holds at σ then φ is false at some τ, which is in two steps connected through δ, giving $\hat{K}_r \hat{K}_c \neg\varphi$ —recall that $\hat{K}$ is the dual of K) so that there is a natural bound on the needed nesting of epistemic operators, and the notion of common knowledge is not really needed.

Secondly, we have to become a bit more precise of what rationality exactly amounts to in the current setting. The notion of a *best response* for agent i in a model M at state σ can be formalised as follows, where A_i is the set of actions available in the current game G to agent i. Let M be the (full or general) game model generated by G and, given a profile σ, $M, \sigma \models \pi(\cdot) \succeq_i \pi(i \mapsto a)$ means that the payoff, given profile σ is at least as big for i as for the profile that is like σ, but in which i plays a instead.

$$M, \sigma \models \mathsf{br}_i \text{ iff } M, \sigma \models \bigwedge_{a \in A_i} (\pi(i \mapsto a) \preceq_i \pi(\cdot)) \tag{20}$$

Note that a profile σ being in a Nash Equilibrium (NE) in a model M, can be described as follows: $M, \sigma \models \mathsf{NE} \leftrightarrow \bigwedge_{i \in N} \mathsf{br}_i$. In the general model M_H in the right hand side of Table 6, NE is true in the profile $\langle r_1, c_1 \rangle$. Note that we have $M_H \models (\neg K_r \mathsf{br}_r \wedge \neg K_c \mathsf{br}_c)$: neither player knows that he plays a best response, let alone that such a property is common knowledge.

Once a property br_i is true in σ in a full model M, it remains true in σ and any smaller general model M': this is because of the universal nature of br. One could alternatively define a relative notion of best response br_i^* as in (20), but with quantification restricted to all actions $A_i(M)$ in the model M. Doing so, a profile σ can *become* a best response for a player i, just because a better option for i has just been eliminated, when moving

to M'.

According to [88], a static analysis of strategic games using epistemics does not seem the right way to go: a general model for a game has players with common knowledge of rationality ($C\mathsf{Rat}$), iff Rat is true in all worlds, i.e., profiles, and such games seem not so interesting, under plausible notions of rationality. For instance, if we take rationality to mean that everybody plays a best response, then we would have that $C\mathsf{Rat}$ holds iff the model consists only of Nash equilibria. And, giving a modal logic argument, from the validity of $C(\mathsf{Rat} \rightarrow \mathsf{NE})$ one derives $C\mathsf{Rat} \rightarrow C\mathsf{NE}$, so that, assuming common knowledge of rationality, there is no need for an algorithm to eliminate worlds, since we already have $C\mathsf{NE}$: it is already common knowledge that a Nash equilibrium is played. Moreover, $C\mathsf{Rat}$ is not a plausible assumption as was illustrated in the game H of Table 6: not even any individual player knows that he is rational! The dynamic epistemic logic of Section 7 seems more appropriate to deal with assumptions about rationality.

Rationality should have an epistemic component. Rather than saying that all players play their best response, it should cover something like 'every player plays the best, given his knowledge'. We take the following notion of weak rationality wr from [88], using our notation $\hat{K}_i\varphi$ for $\exists\tau(R_i\sigma\tau \;\&\varphi$ is true at $\tau)$.

$$M, \sigma \models \mathsf{wr}_i \text{ iff } M, \sigma \models \bigwedge_{a \in Ac_i,\ a \neq \sigma_i} \hat{K}_i(\pi(\cdot) \succeq_i \pi(i \mapsto a)) \tag{21}$$

In words: a player i is weakly rational at σ, if for every alternative action for σ_i, he can imagine a profile σ', for which σ_i (which is, by the definition of the accessibility relation, σ'_i) would be at least as good for i as playing a. Alternatively: σ is a weakly rational profile for i, if for any alternative action, i does not know that σ_i is worse. It may be instructive to consider the dual reading of wr, which is $\neg \bigvee_{a \in Ac_i(M), a \neq \sigma_i} K_i(\pi(\cdot) < \pi(i \mapsto a)$: σ is weakly rational for i if there is no action a for i for which i knows that it would give him a better payoff. Yet phrased differently: σ is not weakly rational for a player, if it represents a dominated strategy. Going back to the model M_H of Figure 17, wr_c fails exactly in the third column, since there, player c *does* know to have a strictly better move than playing c_3.

THEOREM 35 ([88]). *Every finite general model has worlds where* wr_i *holds for both players* i.

Being defined as lack of knowledge, and given the fact that we are in the realm of $\mathbf{S}5_m$, we have $\mathsf{wr}_i \rightarrow K_i\mathsf{wr}_i$ as a validity, giving rationality its desired epistemic component. Moreover, we can expect players to announce that they are weakly rational, since they would know it. The next theorem uses the public announcements of Section 7.

THEOREM 36 ([88]). *Let* σ *be a strategy profile,* G *a game in strategic form, and* $M(G)$ *its associated full game model. Then the following are equivalent:*

(*i*) *Profile* σ *survives when doing iterated removal of dominated strategies;*

(*ii*) *Repeated announcement of* wr_i *stabilises at a substate* (N, σ), *for which the domain of* N *is exactly the set of states that survive when doing iterated removal of dominated strategies.*

In Figure 17, the left-most model is the model M_H from Table 6. The other models are obtained by public announcements of $\mathsf{wr}_c, \mathsf{wr}_r, \mathsf{wr}_c$ and wr_r, respectively. As a local

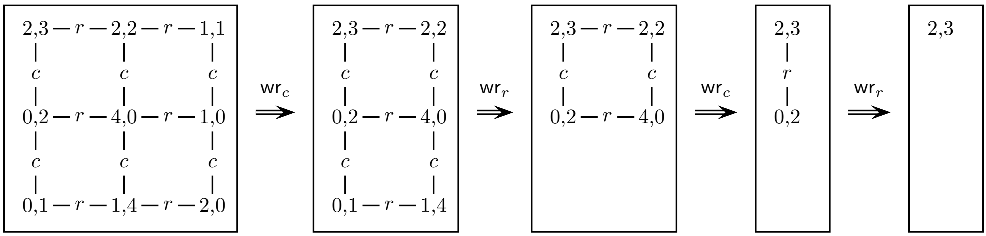

Figure 17. Epistemic model M_H for the game H (left), and after announcements of rationality.

update, this sequence can be executed in $\sigma = \langle r_1, c_1 \rangle$, but one can also conceive it as an operation on the whole model, cf. the interpretation of the learning operators in Section 7.2. Thus, in our model M_H, we have $M_H, \langle r_1, c_1 \rangle \models [\mathsf{wr}_c][\mathsf{wr}_r][\mathsf{wr}_c][\mathsf{wr}_r]C\mathit{Nash}$: if the players iteratively announce that they are weakly rational, the process of dominated strategy elimination leads them to a solution that is commonly known to be Nash.

One can give a similar analysis of *strong rationality*. A profile σ satisfies this property for a player i if i considers it possible that σ_i is as good as any other of i's actions.

$$M, \sigma \models \mathsf{sr}_i \text{ iff } M, \sigma \models \hat{K}_i \bigwedge_{a \in A_i,\ a \neq \sigma_i} (\pi(\cdot) \succeq_i \pi(i \mapsto a)) \tag{22}$$

If we abbreviate SR to be $\mathsf{sr}_r \wedge \mathsf{sr}_c$, we can again perform announcements of SR. In general, such announcements of wr, sr and SR give rise to different behaviour.

THEOREM 37 ([88]). *On full models, repeated announcements of* SR *lead to its common knowledge.*

We have assumed that games are finite. For infinite games, the reasoning put forward in this section would be naturally dealt with in some kind of fixed-point logic. We have for instance the following theorem:

THEOREM 38 ([88]). *The stable set of worlds for repeated announcement of* SR *is defined in the full game model by the greatest fixed point formula*

$$\nu p \cdot (\hat{K}_c(\mathsf{br}_c \wedge p) \wedge \hat{K}_r(\mathsf{br}_r \wedge p))$$

A Syntactic Approach

One of the main contributions of [18] is that it gives a unifying modal framework to present and relate several epistemic characterisation results of solution concepts. The claim is that such results, for a two-player strategic form game, are usually expressed in a form $\varphi(\mathsf{rat}_1, \mathsf{rat}_2, \mathsf{u}_1, \mathsf{u}_2) \rightarrow$ actions. This is demonstrated by (19), albeit that there the assumptions about the utilities (the u-propositions) are kept implicit in the model. It goes without saying that for instance player c can only apply his knowledge about r's rationality if he also knows r's utilities. A syntactic approach forces us to make such assumptions explicit.

Let us here briefly explain how [18] formalises a characterisation result for strategic form games. First of all, we need a language with knowledge operators K_i and probabilistic belief operators $\mathbf{P}_i$, where the intended interpretation of $\mathbf{P}_i(\varphi) = \mathsf{r}$ (with r a

rational number) is obvious. Basic propositions are $\mathsf{i}_1, \mathsf{i}_2, \ldots$ expressing that player i plays his first, second,... strategy. The expression $\mathsf{u}_i(k,l) = \mathsf{r}_{i,k,l}$ denotes that the utility for player i, when the strategy profile (k,l) is played, equals the number r.

The axioms needed are then $A1, A2$ and $A3$ for knowledge (see Table 2), axioms for dealing with inequalities of terms referring to probabilities of events, like $\mathsf{c} > 0 \Rightarrow (\sum_k \mathsf{q}_k \mathbf{P}_i(\varphi) \geq \mathsf{r} \Leftrightarrow \sum_k \mathsf{c}\mathsf{q}_k \mathbf{P}_i(\varphi)_k \geq \mathsf{c}\mathsf{r})$. Add the Kolmogorov axioms for $\mathbf{P}_i$, which say that $\mathbf{P}_i(\top) = 1$, $\mathbf{P}_i(\bot) = 0$, $\mathbf{P}_i(\varphi) \geq 0$, $\mathbf{P}_i(\varphi) = \mathbf{P}_i(\varphi \wedge \psi) + \mathbf{P}_i(\varphi \wedge \neg\psi)$ and $\mathbf{P}_i(\varphi) = \mathbf{P}_i(\psi)$ whenever $\varphi \leftrightarrow \psi$ is a propositional tautology. The connection axioms relate knowledge and probabilistic belief: $\mathbf{P}_i(\varphi) = 1$ is the same as $K_i\varphi$, and for every i-probability sentence φ (i.e., a Boolean combination of statements of the form $\mathbf{P}_i(\cdot) = \cdot$), we have $\varphi \rightarrow K_i\varphi$. The inference rules are $R1$ and $R2$ of Table 2.

Then there are axioms specifically for strategic game forms, called *axioms for game playing situations*. These are, respectively, that every player plays at least one strategy ($\bigwedge_i \bigvee_m \mathsf{i}_m$, where m ranges over the strategies available to player i), and not any other ($\bigwedge_i \bigwedge_{m \neq n} \neg(\mathsf{i}_m \wedge \mathsf{i}_n)$). Moreover, every player knows his chosen strategy ($\bigwedge_i \bigwedge_m K_i \mathsf{i}_m \leftrightarrow \mathsf{i}_m$), and likewise for his utilities ($\mathsf{u}_i(k,l) = \mathsf{r} \rightarrow K_i \mathsf{u}_i(k,l) = \mathsf{r}$). The scheme that captures rationality of player i is called meu_i, which is defined as the following implication:

$$K_i((\bigwedge_{k,l} \mathsf{u}_i(k,l) = \mathsf{r}_{i,k,l}) \wedge \bigwedge_l (\mathbf{P}_i(\mathsf{j}_l = \mathsf{p}_l)) \wedge \mathsf{i}_m) \rightarrow \bigwedge_k \sum_l \mathsf{p}_l \cdot \mathsf{r}_{i,m,l} \geq \sum_l \mathsf{p}_l \cdot \mathsf{r}_{i,k,l}$$

expressing that each player i aims at his Maximal Expected Utility: if i knows all his possible utilities in the game, and the probabilities with which his opponent j chooses his strategies, and i opts for his strategy m, then, for every alternative choice k for i, the expected utility for i, using i's expectations of j's behaviour, will never be bigger.

THEOREM 39 ([18]). *Let Γ be a 2-person normal form game. Assume that the following three conditions hold (where player 1 plays m and 2 plays n).*

(*i*)	*All players are rational*	$\bigwedge_i \mathsf{meu}_i$
(*ii*)	*All players know their own utility function*	$\bigwedge_i K_i \bigwedge_{k,l} \mathsf{u}_i(k,l) = \mathsf{r}_{i,k,l}$
(*iii*)	*All players know each player's actual choice*	$K_1 2_n \wedge K_2 1_m$

Then, the played action profile constitutes a Nash equilibrium, i.e., we have $\bigwedge_k \mathsf{r}_{1,m,n} \geq \mathsf{r}_{1,k,n} \wedge \bigwedge_l \mathsf{r}_{2,m,n} \geq \mathsf{r}_{2,m,l}$.

Note that the theorem above does not refer to common knowledge at all. As [18] points out, Theorem 39 is in fact well known in game theory (since 1995 [6], and even 1982, [73]). But once again, the added value of [18]'s analysis is that it can relate those approaches, and that framework for instance enables to point at weak spots in proofs of theorems similar to the one discussed here.

8.2 Epistemic Foundations for Extensive Games

The analysis in [18] is particularly interesting in the realm of extensive games, especially by pinpointing the difference between two interpretations of them: the *one-shot interpretation* on the one hand, and the *many-moment interpretation* on the other. The first interpretation is the one propagated by the key publication in game theory ([54]) and renders extensive games 'the same' as games in normal form: players act only once. Metaphorically speaking, under the one-shot interpretation, players can be thought of as making up their mind before the game really starts, and then all submit their chosen

strategy in a closed envelope to a referee. The outcome of the game is then completely determined, even without any player really 'performing' a move. In the many moment interpretation, a player only has to make a decision for the decision node he thinks he is at (and he thinks is his).

Let us briefly revisit the game on the left hand side of Figure 16. In the one-shot interpretation, as part of player 2's strategy, 2 makes a decision in node d, and rationality imposes him to choose 'left', and the decision $\langle d, left\rangle$ is part of the strategy that he will put in his envelop. (And the fact that 1 can predict this, makes the whole idea of backward induction work). In the many-moment interpretation however, if player 2 ever finds himself making a choice in node d, he obviously has to re-think his assumptions about the situation, and in particular, about player 1's rationality. It need not come as a surprise that this second interpretation has led several researchers to analyse this using *belief revision* or *counterfactuals* (see also Chapters 18 and 21 of this handbook), most notably by [75, 76].

Especially the analysis of common knowledge (or, for that matter, belief) is much harder under the second analysis, because "*... (i) at one single decision moment only the beliefs of one player are relevant ... and (ii) because we have to decide whether common beliefs involve past beliefs, or future beliefs, or both*" ([18, Chapter 4]). For a more philosophical view regarding the two interpretations, we refer to [18], here we indicate only how a formal analysis clarifies the difference.

For a proof system, we now take the axioms $A1, A2$ and $A6 - A10$ for K_i, E and C (note that since $A3$ is not assumed, we will call the attitude 'belief' but still write K_i), and the axioms for games from Section 8.1. On top of this, we add the following atoms to the language. Let i_k^x mean that player i chooses according to his k-th strategy in the subgame generated by node x, and $\mathsf{u}_i^x(k,l) = \mathsf{r}$ denotes that the utility for i, when the strategies k and l are played in the subgame generated by x, is r. An axiom KnUtSub says that these utilities are known by player i.

The principles of rationality now needed are nrat_i ("on-path rationality") and frat_i ("off-path rationality"), with the following axioms:

NRat$_{bas}$	$\mathsf{nrat}_i^x \to nsd_i(\mathcal{A}_i, \mathcal{A}_j)$
NRat$_{ind}$	$(\mathsf{nrat}_i^x \wedge K_i X_i \wedge K_i X_j) \to nsd_i(X_i, X_j)$
FRat	$\mathsf{frat}_i \leftrightarrow \bigwedge_{\rho \preceq x} \mathsf{nrat}_i^x$

The last axiom says that off-path rationality means on-path rationality at every subgame (generated by an arbitrary node x reachable form ρ, the root of the game). The statement $nsd_i(X_i, Y_j)$ means that i plays a strategy that is not strictly dominated in the game generated by i's strategies $X_i \subseteq \mathcal{A}_i$ (the latter being i's set of actions) and j's strategies $Y_j \subseteq \mathcal{A}_j$. On-path rationality is expected to model that "a player chooses a (full) strategy that given his beliefs prescribes optimal actions along the path that he expects will ensue" ([18, Chapter 4]). The base case for nrat_i then expresses that a full strategy that is optimal in a subgame, is not dominated. Similarly, the induction axiom says that a strategy that is optimal given the expectations of player i about how the game is played, is not strictly dominated in the game in which all other paths are eliminated.

THEOREM 40 ([18]). *Let Γ be a finite two-person extensive form game, with given utilities $\bigwedge_{i,k,l} \mathsf{u}_i(k,l) = \mathsf{r}_{i,k,l}$, for which the following hold*

(i)	*The players are rational*	$\bigwedge_i \mathsf{frat}_i$
(ii)	*(i) is common belief*	$C(\bigwedge_i \mathsf{frat}_i)$
(iii)	*the utilities are commonly believed*	$C(\bigwedge_{i,k,l} \mathsf{u}_i(k,l) = \mathsf{r}_{i,k,l})$

Then the players play the strategy profile that is generated using backward induction.

What about the many-moment interpretation? First of all, [18] adds some specific axioms, saying that every player knows always (that is, everywhere in the game) all payoffs, for any strategy profile, and that a player knows where he is in the game (KnWhere: $K_i^x \bigwedge_j \bigvee_{y \prec x, j_i \in D} \mathsf{j}_k^y$, where D collects all full strategies that are consistent with reaching x). The axiom KnStratM ($\mathsf{i}_k \leftrightarrow \bigwedge_{\rho \preceq x} K_i^x \mathsf{i}_k$) is rather pushing the limits of the many-moment interpretation: it says that player i, when playing strategy i_k, knows this wherever he ends up in the game.

The rationality principles *RRat* are a bit more involved, now:

$$\begin{aligned} \mathsf{rrat}_i^x \leftrightarrow \quad & ((K_i^x \textstyle\bigwedge_{k,l} \mathsf{u}_i^x(k,l) = \mathsf{r}_{i,k,l} \wedge \bigwedge_k \mathbf{P}_i^x(\mathsf{i}_k^x) = \mathsf{p}_k \wedge \bigwedge_l \mathbf{P}_j^x(\mathsf{j}_l^x) = \mathsf{p}_l \wedge \mathsf{i}_m(x)) \\ & \to \textstyle\bigwedge_k EU_i(m, x, \mathbf{P}_i^x) \geq EU_i(k, x, \mathbf{P}_i^x)) \end{aligned}$$

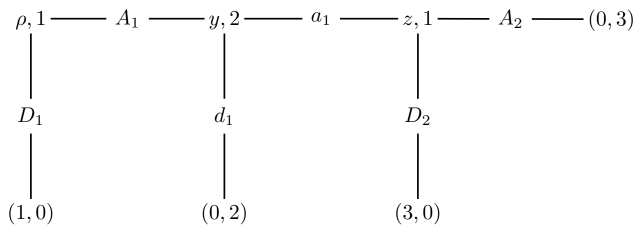
The property *RRat* above states that it holds for player i at node x iff the following implication holds. The antecedent states that i knows at x the utilities for every strategy profile, and he has some probabilistic beliefs about the strategies that both he and his opponent j will choose at x. Moreover, i in fact chooses the action prescribed by his m-th strategy at x. If this is fulfilled, then the chosen strategy m should give at least the utility obtained using any other option k. Here, $EU_i(m, x, \mathbf{P}_i^x)$ is the expected utility for i in the node y that he reaches immediately from x when using strategy m.

We now show how a negative result can be proven 'during progress in a game', using the two-player centepede example. In [70]'s variant of centepede, (see Figure 18), there are three decision nodes ρ, y and z. Of the two players, player 2 only moves in y. The payoffs for the players are represented as pairs (u_1, u_2) in the leaves of the tree, where u_i represents player i's payoff. We leave it to the reader to check that backward induction leads player 1 to play down D_1 at the root ρ. [18] formalises [70]'s claim about this game that says that in node y, there cannot be common knowledge of rationality.

To make the proof work, we need two persistence properties. The first applies to strategies, and says that i's prediction about j's choices should not change if nothing unexpected happens: if the nodes x, y and z appear in a path on the tree (in that order), then $\mathbf{P}_i^x(\mathsf{j}_j^z)$ and $\mathbf{P}_i^y(\mathsf{j}_j^z)$ should coincide. The other preservation property applies to rationality, and says that i will not change his rationality assumptions about j during a period that j did not make a move: $K_i^x \mathsf{rrat}_j^y \leftrightarrow K_i^x \mathsf{rrat}_j^z$ if x, y and z appear in a path on a tree (in that order, possibly $x = y$), and z is the first node from y where j moves.

The proof in [18] of the claim $C^y \mathsf{rrat}^y \to \perp$ runs as follows. First of all, we show $(a) C^y \mathsf{rrat}^y \to K_2^y K_1^\rho d_1$ (if the principle of rrat at y is common knowledge at y, then 2 knows at y that 1 knows at ρ that 2 plays d_1). To prove it, we prove $(i) C^y \mathsf{rrat}^y \to K_1^\rho d_1$ and then apply necessitation for K_2^y. Using the preservation of strategies principle, it is sufficient to prove $(ii) C^y \mathsf{rrat}^y \to K_1^y d_1$. Applying K_1^y-necessitation to the rationality axiom gives us $K_1^y \mathsf{rrat}_2^y \wedge K_1^y K_2^y D_2 \to K_1^y d_1$, so that, to prove (ii), we are done if we show $(iii) C^y \mathsf{rrat}^y \to (K_1^y \mathsf{rrat}_2^y \wedge K_1^y K_2^y D_2)$. The first conjunct is immediate, for the second, use the persistence of rationality (for K_2^y) and necessitation (for K_1^y) to show $K_1^y K_2^y \mathsf{rrat}_1^y \to K_1^y K_2^y \mathsf{rrat}_1^z$. Applying rationality to this gives the second conjunct.

Furthermore, from the persistence of rationality, it is easy to show $(b) C^y \mathsf{rrat}^y \to$



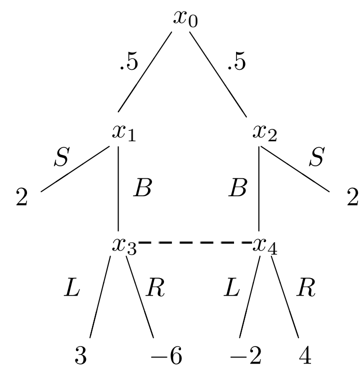


Figure 18. Centepede (left) and a one-person game with perfect recall (right)

$K_2^y \mathsf{rrat}_1^\rho$. Also, rationality and necessitation give $(c)(K_2^y K_1^\rho d_1 \wedge K_2^y \mathsf{rrat}_1^\rho) \rightarrow K_2^y \neg A_1$. Combining $(a), (b)$ and (c) immediately gives us $C^y \mathsf{rrat}^y \rightarrow K_2^y \neg A_1$. However, the D axiom $(\neg K_2^y \bot)$ together with the derivability of $K_2^y A_1$ from the KnWhere axiom (see above) then establishes our claim $C^y \mathsf{rrat}^y \rightarrow \bot$.

Which would again emphasise the intuition uttered by many game theorists that in the analysis with which we started this section, backward induction must be based on some form of counterfactual reasoning.

8.3 On the Representation of Games with Imperfect Information

The manuscript [28] gives a neat discussion on issues that arise when modelling a game with imperfect information. We already argued that the extensive form of a game gives a more natural account of the temporal aspects of a game than its strategic form. For imperfect information games, we can add equivalence relations to denote the player's information sets. However, such information sets can for instance not capture knowledge or beliefs that a player has over the strategies of the other players, or about their rationality. There are of course other ways of representing uncertainty in games, like for instance what [28] calls a *state space* representation, in which one for instance associates a strategy profile to every state (cf. the representation used in Section 8.1 and Figure 17). But in those representations, one loses the ability again to represent the temporal information. In fact, [28]'s main point is a plea to use *interpreted systems* (see Section 5) to model games of imperfect information, because they make explicit where the knowledge comes from.

Let us present [28]'s argument representing games as systems using the game that it borrows from [67], represented as the game on the right of Figure 18. In x_0, nature choses randomly either x_1 or x_2, and then the only player can chose either S or B. He cannot distinguish x_3 from x_4, where he has the option L or R. Using uniform strategies only, let the strategy $\sigma = \langle B, S, R \rangle$ denote that our player plays B in x_1, S in x_2 and R in the information set $\{x_3, x_4\}$. Similarly, let σ' be $\langle B, S, L \rangle$. One easily verifies that the payoff 3 when playing σ is the maximal expected utility: no other strategy is as good. One could easily implement such a strategy using an interpreted system where the local state ℓ of the player would indicate whether he is in $\{x_1\}$, in $\{x_2\}$ or in $\{x_3, x_4\}$.

Now [67] argues that if node x_1 is reached, the agent is better off by changing from strategy σ to σ'. And, as [28] argues, this is right, if the agent is able to remember that he switched strategies. Since the agent cannot distinguish x_3 from x_4, he should use a uniform strategy and do the same in both. However, if the agent would have perfect recall, he would distinguish the nodes, and by allowing him to remember that he switched strategies he can simulate perfect recall: if he ends up in $\{x_3, x_4\}$, he must realize that he came through x_1 and is now playing σ'. Under this assumption it is not clear anymore what it means to have a dotted line between x_3 and x_4, since the states become distinguishable. Using interpreted systems it is very natural to encode in the local state of the agent that he switched strategies, by recording the strategies he has been playing until now, for instance.

9 GAME LOGIC

Computer science has developed many different logics for reasoning about the behaviour of computer programs or algorithms. Propositional Dynamic Logic (PDL) (see [33, 34] and also Chapter 12 of this handbook) is a well-studied example which contains expressions $[\pi]\varphi$ stating that all terminating executions of program π will end in a state satisfying φ. What distinguishes PDL from simple multi-modal logic is that π can be a complex program such as $p_1; p_2$, the sequential execution of first p_1 and then p_2. PDL formalises properties of programs in its axioms such as $[p_1; p_2]\varphi \leftrightarrow [p_1][p_2]\varphi$ which completely characterises the sequential composition operator.

Nondeterministic programs may be viewed as particularly simple games, namely 1-player games. Examples of algorithms involving more than one player or agent are cake-cutting algorithms, voting procedures and auctions. Also structurally, games are very similar to programs. One game may be played after another, a player may choose to play a game repeatedly, and so on. Hence, one may expect reasoning about games to be similar to reasoning about programs, and consequently game logics should resemble program logics.

Game Logic (GL), introduced in [58, 59], is a generalisation of PDL for reasoning about determined 2-player games, allowing us to describe algorithms like the cake-cutting algorithm and to reason about their correctness. GL extends PDL by generalising its semantics and adding a new operator to the language. The meta-theoretic study of PDL has given us valuable insights, e.g., into the complexity of reasoning about programs and the expressive power of various programming constructs. By comparing GL to PDL, we can get an idea of how reasoning about games differs from reasoning about programs. In this section, we can only introduce the syntax and semantics of Game Logic (Subsection 9.1) and discuss some of its central meta-theoretic properties (Section 9.2). Further topics of research are briefly mentioned in Section 9.3. The interested reader is referred to a recent survey article on the subject [65] with more detailed references.

9.1 *Syntax and Semantics*

The games of Game Logic involve two players, player 1 (Angel) and player 2 (Demon). Just like PDL, the language of GL consists of two sorts, propositions and (in the case of GL) games. Given a set of atomic games Γ_0 and a set of atomic propositions Φ_0, games γ and propositions φ can have the following syntactic forms, yielding the set of GL-games

Γ and the set of GL-propositions/formulas Φ:

$$\begin{array}{ll} \gamma := & g \mid \varphi? \mid \gamma_1;\gamma_2 \mid \gamma_1 \cup \gamma_2 \mid \gamma^* \mid \gamma^d \\ \varphi := & \bot \mid p \mid \neg\varphi \mid \varphi_1 \vee \varphi_2 \mid \langle\gamma\rangle\varphi \end{array}$$

where $p \in \Phi_0$ and $g \in \Gamma_0$. As usual, we define $[\gamma]\varphi := \neg\langle\gamma\rangle\neg\varphi$. The formula $\langle\gamma\rangle\varphi$ expresses that Angel has a strategy in game γ which ensures that the game ends in a state satisfying φ. $[\gamma]\varphi$ expresses that Angel does not have a $\neg\varphi$-strategy, which by determinacy is equivalent to saying that Demon has a φ-strategy. To provide some first intuition regarding the game operations, $\gamma_1 \cup \gamma_2$ denotes the game where Angel chooses which of the two subgames to continue playing, and the sequential composition $\gamma_1;\gamma_2$ of two games consists of first playing γ_1 and then γ_2. In the iterated game γ^*, Angel can choose how often to play γ (possibly not at all); each time she has played γ, she can decide whether to play it again or not. Playing the dual game γ^d is the same as playing γ with the players' roles reversed, i.e., any choice made by Angel in γ will be made by Demon in γ^d and vice versa. The test game $\varphi?$ consists of checking whether a proposition φ holds at that position. This construction can be used to define conditional games such as $(p?;\gamma_1) \cup (\neg p?;\gamma_2)$: Suppose for instance that p holds at the present state of the game, then Angel will naturally choose the left side (if she chooses the right side, she loses at once), and γ_1 will be played. Otherwise Angel will choose right and γ_2 will be played.

Thanks to the dual operator, demonic analogues of these game operations can be defined. Demonic choice between γ_1 and γ_2 is denoted as $\gamma_1 \cap \gamma_2$ which abbreviates $(\gamma_1^d \cup \gamma_2^d)^d$. Demonic iteration of γ is denoted as $\gamma^\times$ which abbreviates $((\gamma^d)^*)^d$.

A further note on iteration: In γ^*, it is essential that Angel can decide as the game proceeds whether to continue playing another round of γ or not. The game where Angel has to decide up front how often to play γ is a different game and in general more difficult for Angel to win than γ^*. For programs (i.e., in PDL), these two notions of iteration coincide, but for games (i.e., in GL), they do not.

The formal semantics of Game Logic utilises the following game models which generalise the neighbourhood models or minimal models used in the semantics of non-normal modal logics [17]. A *game model* $\mathcal{M} = ((S, \{E_g | g \in \Gamma_0\}), V)$, consists of a set of states S, a valuation $V : \Phi_0 \to \mathcal{P}(S)$ for the propositional letters and a collection of *neighbourhood functions* $E_g : S \to \mathcal{P}(\mathcal{P}(S))$ which are monotonic, i.e. $X \in E_g(s)$ and $X \subseteq X'$ imply $X' \in E_g(s)$.

The intuitive idea is that $X \in E_g(s)$ (alternative notation: sE_gX) holds whenever Angel has a strategy in game g to achieve X. Intuitively, neighbourhood functions are reduced monotonic effectivity functions (see Section 2.3) in that they only represent the effectivity of a single player. Since we are dealing with determined games only, it is sufficient to represent Angel's effectivity. Then Demon is effective for X if and only if Angel is not effective for its complement $\overline{X}$. Furthermore, neighbourhood functions do not satisfy the two conditions we put on effectivity functions, i.e., due to the presence of the test operator ?, we allow that $\emptyset \in E_g(s)$ and $S \notin E_g(s)$. For Angel, these conditions correspond to heaven (a game where Angel can achieve anything at all) and hell (a game where Angel can achieve nothing whatsoever).

By simultaneous induction, we define truth in a game model on the one hand and the neighbourhood functions for non-atomic games on the other hand. The function $E_\gamma : S \to \mathcal{P}(\mathcal{P}(S))$ is defined inductively for non-atomic games γ (where $E_\gamma(Y) = \{s \in$

$S|sE_\gamma Y\}$), and the truth of a formula φ in a model $\mathcal{M} = ((S, \{E_g | g \in \Gamma_0\}), V)$ at a state s (denoted as $\mathcal{M}, s \models \varphi$) is defined by induction on φ. We define

$$\begin{array}{lll}
\mathcal{M}, s \not\models \bot & & \\
\mathcal{M}, s \models p & \text{iff} & p \in \Phi_0 \text{ and } s \in V(p) \\
\mathcal{M}, s \models \neg\varphi & \text{iff} & \mathcal{M}, s \not\models \varphi \\
\mathcal{M}, s \models \varphi \vee \psi & \text{iff} & \mathcal{M}, s \models \varphi \text{ or } \mathcal{M}, s \models \psi \\
\mathcal{M}, s \models \langle\gamma\rangle\varphi & \text{iff} & sE_\gamma\varphi^{\mathcal{M}}
\end{array}
\qquad
\begin{array}{rl}
E_{\alpha;\beta}(Y) & = E_\alpha(E_\beta(Y)) \\
E_{\alpha\cup\beta}(Y) & = E_\alpha(Y) \cup E_\beta(Y) \\
E_{\varphi?}(Y) & = \varphi^{\mathcal{M}} \cap Y \\
E_{\alpha^d}(Y) & = \overline{E_\alpha(\overline{Y})} \\
E_{\alpha^*}(Y) & = \bigcap\{X \subseteq S | Y \cup E_\alpha(X) \subseteq X\}
\end{array}$$

where $\varphi^{\mathcal{M}} = \{s \in S | \mathcal{M}, s \models \varphi\}$. For iteration, our definition yields a least fixpoint, i.e., the smallest set $X \subseteq S$ such that $Y \cup E_\alpha(X) = X$.

9.2 Metatheory

Axiomatisation and Expressiveness

PDL has a very natural complete axiomatisation, and given the similarity between programs and games, one can hope that adding an axiom for the dual operator is all that is needed to obtain a complete axiomatisation of GL. A small problem is presented by the induction principle

$$(\varphi \wedge [\gamma^*](\varphi \to [\gamma]\varphi)) \to [\gamma^*]\varphi$$

which is valid in PDL but invalid in GL. While this induction principle usually forms part of the axiomatic basis of PDL, alternative axiomatisations exist which instead of the induction axiom use a fixpoint inference rule (given below). It turns out that this rule is indeed sound, yielding the following axiomatic system.

Let **GL** be the smallest set of formulas which contains all propositional tautologies together with all instances of the axiom schemas of Figure 19, and which is closed under the rules of Modus Ponens, Monotonicity and Fixpoint, also presented in Figure 19.

Axioms:

$$\langle\alpha \cup \beta\rangle\varphi \leftrightarrow \langle\alpha\rangle\varphi \vee \langle\beta\rangle\varphi$$
$$\langle\alpha; \beta\rangle\varphi \leftrightarrow \langle\alpha\rangle\langle\beta\rangle\varphi$$
$$\langle\psi?\rangle\varphi \leftrightarrow (\psi \wedge \varphi)$$
$$(\varphi \vee \langle\gamma\rangle\langle\gamma^*\rangle\varphi) \to \langle\gamma^*\rangle\varphi$$
$$\langle\gamma^d\rangle\varphi \leftrightarrow \neg\langle\gamma\rangle\neg\varphi$$

Inference Rules:

$$\frac{\varphi \quad \varphi \to \psi}{\psi} \qquad \frac{\varphi \to \psi}{\langle\gamma\rangle\varphi \to \langle\gamma\rangle\psi} \qquad \frac{(\varphi \vee \langle\gamma\rangle\psi) \to \psi}{\langle\gamma^*\rangle\varphi \to \psi}$$

Figure 19. The axioms and inference rules (Modus Ponens, Monotonicity and Fixpoint Rule) of Game Logic.

Intuitively, the axiom for iteration (our fourth axiom) states that $\langle\gamma^*\rangle\varphi$ is a pre-fixpoint of the operation $\varphi \vee \langle\gamma\rangle X$. Conversely, the fixpoint rule states that $\langle\gamma^*\rangle\varphi$ is the *least* such pre-fixpoint.

THEOREM 41. **GL** *is sound with respect to the class of all game models.*

At the time of writing, completeness of **GL** is still open, but some weaker results exist. If x is an operator of Game Logic such as d or $*$, let $\mathbf{GL}^{-x}$ denote Game Logic without the operator x, i.e., restricted to formulas without the operator and without the axioms involving it.

THEOREM 42 ([59, 62]). *Dual-free Game Logic* $\mathbf{GL}^{-d}$ *and iteration-free Game Logic* $\mathbf{GL}^{-*}$ *are both sound and complete with respect to the class of all game models.*

Hence, we have axiomatic completeness for $\mathbf{GL}^{-d}$ as well as $\mathbf{GL}^{-*}$, but iteration together with duality remains a problem for axiomatisation. It may then not come as a surprise that it is precisely this combination which gives Game Logic its expressive power. This is most easily demonstrated when considering GL interpreted over Kripke models.

Kripke models can be viewed as special kinds of game models, namely game models where neighbourhood functions have a special property called *disjunctivity*: for every $g \in \Gamma_0$ and $V \subseteq \mathcal{P}(S)$ we have $\bigcup_{X \in V} E_g(X) = E_g(\bigcup_{X \in V} X)$. Hence, one may also investigate Game Logic when interpreted over Kripke models (i.e., disjunctive game models) only. Dual-free Game Logic over Kripke models is nothing but Propositional Dynamic Logic. Since the absence of infinite g-branches is not expressible in PDL but can be expressed by the GL-formula $\langle (g^d)^* \rangle \bot$, Game Logic over Kripke models is strictly more expressive than PDL.

Over Kripke models, full Game Logic can be embedded into the modal μ-calculus (see Chapter 12 and [41]). In fact, the 2-variable fragment of the μ-calculus suffices for the embedding, and since it has been shown that the variable hierarchy of the μ-calculus is strict [10], Game Logic is a proper fragment of the μ-calculus.

Complexity

The two central complexity measures associated with a logic are the complexity of model checking and the complexity of the satisfiability problem. For the latter, we are interested to know the difficulty of determining whether a formula φ is satisfiable, measured in the length of the formula $|\varphi|$.

Using a translation of Game Logic formulas into modal μ-calculus formulas, we can reduce Game Logic satisfiability to μ-calculus satisfiability. Since Game Logic and the standard modal μ-calculus are interpreted over different models, the models have to be translated as well. The result obtained via this procedure is the following:

THEOREM 43 ([59, 62]). *The complexity of the satisfiability problem for Game Logic is in EXPTIME.*

Turning now toward model checking, given a game model $\mathcal{M}$ and a Game Logic formula φ, we want to determine the set of states s for which $\mathcal{M}, s \models \varphi$ holds. The complexity of model checking is usually measured in terms of the size of the formula and the size of the model. Given a game model $\mathcal{M} = (S, \{E_g | g \in \Gamma_0\}, V)$, we define its size $|\mathcal{M}|$ as

$$|\mathcal{M}| = |S| + \sum_{\{s|s \in S\}} \sum_{\{g|g \in \Gamma_0\}} \sum_{\{X|sE_gX\}} |X|$$

Note that in practice one will want to represent game models more succinctly by only representing the non-monotonic core of E_g, i.e., we will disregard all those triples (s, g, X) for

which there is some $Y \subseteq X$ such that sE_gY. While in some cases (e.g., in case the game model corresponds to a Kripke model) such a representation can yield a dramatically more efficient representation, in general this is not the case, and hence the complexity result below cannot be essentially improved by disregarding supersets.

In the modal μ-calculus, the complexity of current model-checking algorithms depends on the alternation depth of a formula, i.e., on the nestings of least and greatest fixpoint operators in the formula. For GL, the situation is similar, since angelic iteration corresponds to a least fixpoint and demonic iteration to a greatest fixpoint. Hence, the maximal number of nested demonic and angelic iterations will determine the model-checking complexity of the formula. As an example, the alternation depth of a formula φ, denoted as $ad(\varphi)$ will be higher for $\langle (g^*)^\times \rangle p$ than for $\langle (g^*)^* \rangle p$.

THEOREM 44 ([62]). *Given a Game Logic formula φ and a finite game model $\mathcal{M}$, model checking can be done in time $O(|\mathcal{M}|^{ad(\varphi)+1} \times |\varphi|)$.*

9.3 Other Topics

The notion of bisimulation has been the central notion of process equivalence for modal and dynamic logic (see Chapter 1, 5 and [12]). As for modal logic, modal formulas are invariant for bisimulation, i.e., bisimular states satisfy the same modal formulas, and for finite models, the converse holds as well. Furthermore, it has been shown that the bisimular fragment of first-order logic is precisely modal logic [80].

Bisimulation can be generalised from Kripke models to game models. Two states s and s' are bisimular in case (i) they satisfy the same atomic properties, (ii) if player 1 has an X-strategy in game g from s, she also has an X'-strategy in g from s', where every state in X' must have a bisimular state in X, and (iii) analogously for strategies from s'. Intuitively, bisimular states cannot be distinguished by either their atomic properties or by playing atomic games. It can be shown that this notion of bisimulation generalises bisimulation as it is normally defined for Kripke models. Similarly, one can show that bisimular game models satisfy the same GL formulas, and one can even partially characterise the game operations of Game Logic in terms of bisimulation [61].

The operations of Game Logic have also been studied from an algebraic perspective [87]. We call two game expressions γ_1 and γ_2 *equivalent* provided that $E_{\gamma_1} = E_{\gamma_2}$ holds for all game models. Put differently, γ_1 and γ_2 are equivalent iff $\langle\gamma_1\rangle p \leftrightarrow \langle\gamma_2\rangle p$ is valid for a p which occurs neither in γ_1 nor in γ_2. When γ_1 and γ_2 are equivalent, we say that $\gamma_1 = \gamma_2$ is a *valid game identity.*

As an example, if a choice of a player between x and y is followed by game z in any case, then the player might as well choose between $x; z$ and $y; z$ directly. Hence, $(x \cup y); z = x; z \cup y; z$ is a valid game identity. The right-distributive law $x; (y \cup z) = x; y \cup x; z$ on the other hand is not valid. In the first game, player 1 can postpone her choice until after game x has been played. She may have a winning strategy which depends on how x is played, and hence such a strategy will not necessarily be winning in the second game, where she has to choose before x is played.

Game algebra further illustrates the link between games and processes that we already discussed in section 3.3. Basic game algebra studies the game operations of sequential composition, choice (demonic and angelic) and duality. The test-operator is excluded since it would take us out of the purely algebraic framework. The central result obtained for basic game algebra is a complete axiomatisation of the set of valid game identities

[25, 105]. So far, the complete axiomatisation has not been extended to a version of game algebra which includes iteration.

10 COALITION LOGIC

Modal logic describes transition systems at a very abstract level. The transition relation does not specify what or who is involved in making the transition, it only models all the possible evolutions of the system. Game forms on the other hand explicitly represent how different agents can contribute to the system's evolution by modeling the agents' strategic powers.

The semantic models of Coalition Logic [63, 64] make use of strategic games to describe the agents' abilities to influence system transitions. Using α-effectivity functions (see Section 2.3), we can formalise an agent's ability to bring about φ. More generally, the expression $[C]\varphi$ states that the coalition C, a subset of agents/players, can bring about φ. After presenting the syntax and semantics of Coalition Logic, Section 10.2 presents an axiomatisation of coalitional ability in extensive games of almost perfect information. Complexity results concerning the satisfiability problem will be discussed in Section 10.3.

10.1 Syntax and Semantics

Assuming a finite nonempty set of agents or players N, we define the syntax of Coalition Logic as follows. Given a set of atomic propositions Φ_0, a formula φ can have the following syntactic form:

$$\varphi := \quad \bot \mid p \mid \neg\varphi \mid \varphi_1 \vee \varphi_2 \mid [C]\varphi$$

where $p \in \Phi_0$ and $C \subseteq N$. We define $\top$, $\wedge$, $\rightarrow$ and $\leftrightarrow$ as usual. In case $C = \{i\}$, we write $[i]\varphi$ instead of $[\{i\}]\varphi$.

A *coalition frame* is a pair $\mathcal{F} = (S, G)$ where S is a nonempty set of states (the universe) and G assigns to every state $s \in S$ a strategic game form $G(s) = (N, (\Sigma_i)_{i\in N}, o, S)$. At state s, the game form $G(s)$ represents the possible transitions based on the strategic choices of the players. A *coalition model* is a pair $\mathcal{M} = (\mathcal{F}, V)$ where $\mathcal{F}$ is a coalition frame and $V : \Phi_0 \rightarrow \mathcal{P}(S)$ is the usual valuation function for the propositional letters. Given such a model, truth of a formula in a model at a state is defined as follows:

$$\begin{array}{ll}
\mathcal{M}, s \not\models \bot & \\
\mathcal{M}, s \models p & \text{iff } p \in \Phi_0 \text{ and } s \in V(p) \\
\mathcal{M}, s \models \neg\varphi & \text{iff } \mathcal{M}, s \not\models \varphi \\
\mathcal{M}, s \models \varphi \vee \psi & \text{iff } \mathcal{M}, s \models \varphi \text{ or } \mathcal{M}, s \models \psi \\
\mathcal{M}, s \models [C]\varphi & \text{iff } \varphi^{\mathcal{M}} \in E^{\alpha}_{G(s)}(C)
\end{array}$$

where $\varphi^{\mathcal{M}} = \{s \in S | \mathcal{M}, s \models \varphi\}$. Hence, a formula $[C]\varphi$ holds at a state s iff coalition C is α-effective for $\varphi^{\mathcal{M}}$ in $G(s)$.

Coalition frames are essentially extensive game forms of *almost perfect* information. The only source of imperfect information is that players make choices simultaneously. After the choices are made at state s, a new state t results and the choices become common knowledge, before new (and possibly different) choices can be made. Note that coalition frames are game graphs rather than trees (though they can be unravelled into trees), and they contain no terminal states since every state is associated to a game.

It is possible to isolate (semantically and axiomatically) the class of coalition frames corresponding to extensive game forms of *perfect* information, see [63] for details.

Note that by Theorem 12, we can equivalently view a coalition frame $\mathcal{F}$ as a pair(S, E), where

$$E : S \to (\mathcal{P}(N) \to \mathcal{P}(\mathcal{P}(S)))$$

assigns to every state $s \in S$ a monotonic, N-maximal and superadditive effectivity function $E(s)$ (see Section 2.3). Using this formulation, we can then simply define $\mathcal{M}, s \models [C]\varphi$ iff $\varphi^{\mathcal{M}} \in E(s)(C)$. From a logical point of view, this second formulation directly in terms of effectivity functions is preferable. It simplifies meta-theoretic reasoning, e.g. by immediately suggesting certain axioms of coalitional power, and it also demonstrates that coalition models are essentially neighbourhood models, providing a neighbourhood relation for every coalition of players. Neighbourhood models have been the standard semantic tool to investigate non-normal modal logics (see, e.g. [17]), and techniques used to provide complete axiomatisations for such logics can also be adapted to Coalition Logic.

The two extreme coalitions $\emptyset$ and N are of special interest. $[N]p$ expresses that some possible next state satisfies p, whereas $[\emptyset]p$ holds if no agent needs to do anything for p to hold in the next state. Hence, $[N]p$ corresponds to $\Diamond p$ in standard modal logic whereas $[\emptyset]p$ corresponds to $\Box p$. If $|N| = 1$, e.g. $N = \{1\}$, coalition models are just serial Kripke models, i.e., Kripke models where every state has at least one successor. In this case, $[\emptyset]\varphi$ coincides with $\Box\varphi$ and $[1]\varphi$ with $\Diamond\varphi$.

10.2 Axiomatics

Let $\mathbf{CL_N}$ denote the smallest set of formulas which contains all propositional tautologies together with all instances of the axiom schemas listed in Figure 20, and which is closed under the rules of Modus Ponens and Equivalence given below:

$$\frac{\varphi \quad \varphi \to \psi}{\psi} \qquad\qquad \frac{\varphi \leftrightarrow \psi}{[C]\varphi \leftrightarrow [C]\psi}$$

Note that axioms $(\bot)$ and $(\top)$ correspond to the two basic assumptions we made for effectivity functions in Definition 9. The remaining three axioms express the conditions of Theorem 12, N-maximality, monotonicity and superadditivity.

$(\bot)$	$\neg[C]\bot$
$(\top)$	$[C]\top$
(N)	$\neg[\emptyset]\neg\varphi \to [N]\varphi$
(M)	$[C](\varphi \wedge \psi) \to [C]\psi$
(S)	$([C_1]\varphi_1 \wedge [C_2]\varphi_2) \to [C_1 \cup C_2](\varphi_1 \wedge \varphi_2)$
	where $C_1 \cap C_2 = \emptyset$

Figure 20. The axiom schemas of Coalition Logic

THEOREM 45 ([63]). $\mathbf{CL_N}$ *is sound and complete with respect to the class of all coalition models.*

KD is the normal modal logic for reasoning about serial Kripke models. In the formulation closest to Coalition Logic, **KD** is the set of formulas containing all propositional tautologies, closed under the rules of Modus Ponens and Equivalence (for $\Box$ only), and containing the axioms of Figure 21.

$\Diamond\varphi \leftrightarrow \neg\Box\neg\varphi$	$\Box(\varphi \wedge \psi) \leftrightarrow (\Box\varphi \wedge \Box\psi)$
$\Box\top$	$\Diamond\top$

Figure 21. Axioms of **KD**

The following result states that **KD** is precisely single-agent Coalition Logic. The result is the axiomatic analogue to our earlier observation that if $|N| = 1$, coalition models are simply serial Kripke models.

THEOREM 46 ([63]). *Identifying* $[\emptyset]\varphi$ *with* $\Box\varphi$ *and* $[1]\varphi$ *with* $\Diamond\varphi$*, we have* $\mathbf{KD} = \mathbf{CL}_{\{\mathbf{1}\}}$.

The logic $\mathbf{CL_N}$ is the most general and hence weakest coalition logic which has been investigated. The only assumption made is that at every state, the coalitional power distribution arises from a situation which can be modeled as a strategic game. Additional axioms can be added for characterising special kinds of strategic interaction. For example, in order to characterise extensive game forms of perfect information, one adds the axiom

$$[N]\varphi \to \bigvee_{i\in N} [i]\varphi,$$

expressing that everything which can be achieved at all can be achieved already by some individual. This axiom will enforce that at every state there is a single agent who can determine the next state independent of the other agents. Note that the converse implication can be derived in $\mathbf{CL_N}$.

Nash-consistent Coalition Logic [32] is another example of a logic stronger than $\mathbf{CL_N}$. By adding a further axiom to $\mathbf{CL_N}$, one can characterise the class of Nash-consistent coalition models, i.e., coalition models where the strategic game form associated to every state must have a Nash equilibrium under every possible preference profile. Nash-consistent models can be viewed as stable systems, in the sense that no matter what the agents' preferences are, there is a stable strategy profile, a profile for which individual deviation is irrational.

10.3 Complexity

We assume in our discussion of complexity that $|N| > 1$. As was mentioned, the two extreme coalitions $\emptyset$ and N allow one to capture necessity and possibility. For this reason, the normal modal logic **KD** forms a fragment of Coalition Logic, thereby establishing a PSPACE lower bound for the basic Coalition Logic over general coalition models. As it turns out, this bound is tight, i.e., we have the following result.

THEOREM 47 ([63]). *The complexity of the satisfiability problem for Coalition Logic is PSPACE-complete.*

Via the satisfiability problem, we can compare the complexity of reasoning about games of various different kinds. For instance, it turns out that restricting the class

of coalition models to perfect information models, the satisfiability problem remains PSPACE-complete. Hence, given a coalitional specification, finding an extensive game (form) of almost perfect information satisfying the specification is not harder nor simpler than finding an extensive game of perfect information.

Besides comparing reasoning over different classes of games, we can compare reasoning about groups to reasoning about individuals. Let the *individual fragment of Coalition Logic* be the set of formulas of Coalition Logic where all modalities only involve singleton coalitions, i.e.

$$\varphi := \quad \bot \mid p \mid \neg\varphi \mid \varphi_1 \vee \varphi_2 \mid [i]\varphi$$

where $p \in \Phi_0$ and $i \in N$. The individual fragment is strictly less expressive than full Coalition Logic, since the formula $[C]p$ is in general not equivalent to any formula involving only singleton coalitions. More precisely, there is no formula φ of the individual fragment such that $\varphi^{\mathcal{M}} = [C]p^{\mathcal{M}}$ for every coalition model $\mathcal{M}$.

THEOREM 48 ([64]). *The complexity of the satisfiability problem for the individual fragment of Coalition Logic is NP-complete.*

Hence, reasoning about individuals is simpler than reasoning about coalitions if and only if NP $\neq$ PSPACE. For perfect information models, the complexity of the satisfiability problem for the individual fragment is not simpler, it remains PSPACE-complete.

11 ALTERNATING-TIME TEMPORAL LOGIC

Coalition Logic allows one to express strategic properties of multi-agent systems, where these systems are essentially modeled as extensive games of almost perfect information. The basic modal expression $[C]\varphi$ states that coalition C has a joint strategy for ensuring φ in the next state. What is lacking are more expressive temporal operators which allow us to describe, e.g., that coalition C has a strategy for achieving φ some time in the future. In other words, we are looking for the strategic coalitional analogue of a rich temporal logic like CTL (see Chapter 11 and [19]). Alternating-time temporal logic (ATL) [3] is precisely this temporal extension of Coalition Logic.

As usual, we start by presenting the syntax and semantics of ATL in Section 11.1. After discussing a modelling example in Subsection 11.2, we discuss axiomatisation and complexity (Subsection 11.3) and end with some extensions of ATL in Subsection 11.4.

11.1 Syntax and Semantics

Given a set of atomic propositions Π, an ATL formula φ can have the following syntactic form:

$$\varphi := \quad \bot \mid p \mid \neg\varphi \mid \varphi_1 \vee \varphi_2 \mid \langle\!\langle C \rangle\!\rangle \bigcirc \varphi \mid \langle\!\langle C \rangle\!\rangle \Box \varphi \mid \langle\!\langle C \rangle\!\rangle \varphi_1 \,\mathcal{U}\, \varphi_2$$

where $p \in \Pi$ and $C \subseteq N = \{1, \ldots, k\}$, the set of all agents. We define $\top$, $\wedge$, $\rightarrow$ and $\leftrightarrow$ as usual. The formula $\langle\!\langle C \rangle\!\rangle \bigcirc \varphi$ expresses that coalition C has a joint strategy for achieving φ at the next state. Thus, $\langle\!\langle C \rangle\!\rangle \bigcirc \varphi$ corresponds to $[C]\varphi$ in Coalition Logic. $\langle\!\langle C \rangle\!\rangle \Box \varphi$ expresses that coalition C can cooperate to maintain φ forever (always in the future), and $\langle\!\langle C \rangle\!\rangle \varphi_1 \,\mathcal{U}\, \varphi_2$ expresses that C can maintain φ_1 until φ_2 holds. In the standard way, we use $\Diamond\varphi$ to abbreviate $\top \,\mathcal{U}\, \varphi$.

In the same way in which CTL can be extended to CTL*, the language of ATL can be generalised to ATL*. We simultaneously define the set of ATL* *state formulas* φ and the set of ATL* *path formulas* ψ as follows:

$$\begin{array}{rl} \varphi := & \bot \mid p \mid \neg\varphi \mid \varphi_1 \vee \varphi_2 \mid \langle\!\langle C \rangle\!\rangle \psi \\ \psi := & \varphi \mid \neg\psi \mid \psi_1 \vee \psi_2 \mid \bigcirc \psi \mid \psi_1 \,\mathcal{U}\, \psi_2 \end{array}$$

where $p \in \Pi$ and $C \subseteq N$. Note that in ATL*, $\langle\!\langle C \rangle\!\rangle \Box \psi$ is expressible as $\langle\!\langle C \rangle\!\rangle \neg(\top \,\mathcal{U}\, \neg\psi)$ which is not an ATL formula. In general, ATL is a proper fragment of ATL*, containing only formulas where every temporal operator is immediately preceded by a cooperation modality. For $|N| = 1$, ATL=CTL and ATL*=CTL*. Given that CTL is less expressive than CTL*, it also follows that ATL is less expressive than ATL*.

The semantics of Alternating-time Temporal Logic uses concurrent game structures, essentially the coalition models we discussed for Coalition Logic. A *concurrent game structure* is a tuple $\mathcal{S} = (k, Q, \Pi, \pi, d, \delta)$, where k is the number of players ($N = \{1, \dots, k\}$),[2] Q is the set of states (usually assumed to be finite), Π is the set of atomic propositions, and $\pi : Q \to \mathcal{P}(\Pi)$ is the valuation function. For every agent $i \in N$ and every state $q \in Q$, $d_i(q) \geq 1$ gives the number of actions available to player i at state q. Hence, at state q, a *move vector* $(j_1, \dots, j_k) \in D(q) = \{1, \dots, d_1(q)\} \times \dots \times \{1, \dots, d_k(q)\}$ corresponds to a joint action at state q. Finally, for each such move vector, $\delta(q, j_1, \dots, j_k) \in Q$ is the transition function.

Like coalition models in Coalition Logic, different types of concurrent game structures correspond to natural classes of games. *Turn-based synchronous* game structures are extensive game forms of perfect information where only a single player can choose at each state. In *synchronous* game structures, the state space is the Cartesian product of the players' local state spaces. *Turn-based asynchronous* game structures involve a scheduler who determines the player who can choose the next state. Furthermore, fairness constraints can be added to these structures.

For two states $q, q' \in Q$ and an agent $i \in \Sigma$, we say that state q' is a *successor* of q if there exists a move vector $(j_1, \dots, j_k) \in D(q)$ such that $\delta(q, j_1, \dots, j_k) = q'$. A *computation* of $\mathcal{S}$ is an infinite sequence of states $\lambda = q_0, q_1, \dots$ such that for all $u > 0$, the state q_u is a successor of q_{u-1}. A computation λ starting in state q is referred to as a *q-computation*; if $u \geq 0$, then we denote by $\lambda[u]$ the u'th state in λ; similarly, we denote by $\lambda[0, u]$ and $\lambda[u, \infty]$ the finite prefix $q_0, \dots, q_u$ and the infinite suffix $q_u, q_{u+1}, \dots$ of λ respectively.

A *strategy* f_i for an agent $i \in N$ is a total function f_i mapping every finite nonempty sequence of states λ to a natural number such that if the last state of λ is q, $1 \leq f_i(\lambda) \leq d_i(q)$. Given a set $C \subseteq N$ of agents, and an indexed set of strategies $F_C = \{f_i | i \in C\}$, one for each agent $i \in C$, we define $out(q, F_C)$ to be the set of possible computations that may occur if every agent $a \in C$ follows the corresponding strategy f_a, starting when the system is in state $q \in Q$. Formally, $\lambda = q_0, q_1, \dots \in out(q, F_C)$ iff $q = q_0$ and for all $m \geq 0$, there exists a move vector $(j_1, \dots, j_k) \in D(q_m)$ such that $\delta(q_m, j_1, \dots, j_k) = q_{m+1}$ and for all $i \in C$, $j_i = f_i(\lambda[0, m])$. The semantics of ATL* can now be defined as follows.

[2]given $|N| = k$, we will sometimes use the equivalent representation $\mathcal{S} = (N, Q, \Pi, \pi, d, \delta)$

For state formulas we define

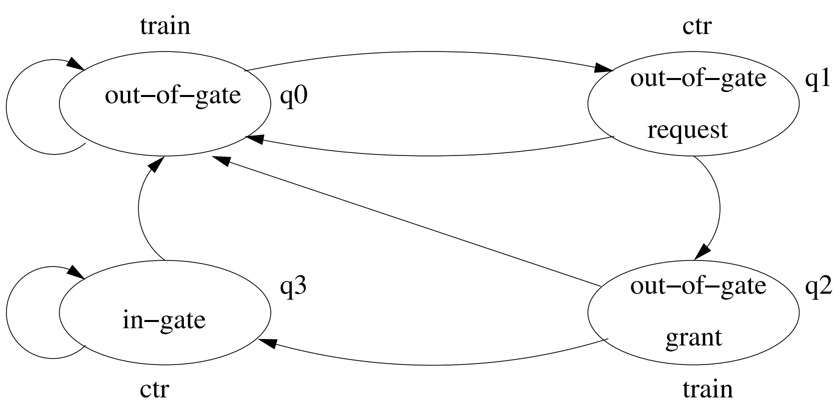
$$\begin{array}{ll}
\mathcal{S}, q \not\models \bot & \\
\mathcal{S}, q \models p & \text{iff } p \in \Pi \text{ and } p \in \pi(q) \\
\mathcal{S}, q \models \neg\varphi & \text{iff } \mathcal{S}, q \not\models \varphi \\
\mathcal{S}, q \models \varphi_1 \vee \varphi_2 & \text{iff } \mathcal{S}, q \models \varphi_1 \text{ or } \mathcal{S}, q \models \varphi_2 \\
\mathcal{S}, q \models \langle\langle C \rangle\rangle \psi & \text{iff } \exists F_C \forall \lambda \in out(q, F_C) : \mathcal{S}, \lambda \models \psi,
\end{array}$$

and for path formulas we define

$$\begin{array}{ll}
\mathcal{S}, \lambda \models \varphi & \text{iff } \mathcal{S}, \lambda[0] \models \varphi, \text{ where } \varphi \text{ is a state formula} \\
\mathcal{S}, \lambda \models \neg\psi & \text{iff } \mathcal{S}, \lambda \not\models \psi \\
\mathcal{S}, \lambda \models \psi_1 \vee \psi_2 & \text{iff } \mathcal{S}, \lambda \models \psi_1 \text{ or } \mathcal{S}, \lambda \models \psi_2 \\
\mathcal{S}, \lambda \models \bigcirc\psi & \text{iff } \mathcal{S}, \lambda[1, \infty] \models \psi \\
\mathcal{S}, \lambda \models \psi_1 \mathcal{U} \psi_2 & \text{iff } \exists m \geq 0 : (\mathcal{S}, \lambda[m, \infty] \models \psi_2 \text{ and } \forall l (0 \leq l < m \Rightarrow \mathcal{S}, \lambda[l, \infty] \models \psi_1))
\end{array}$$

11.2 An Example

The following example from [3] presents a turn-based synchronous game structure modeling a simple train system involving a train and a controller.



Formally, the concurrent game structure $\mathcal{S} = (k, Q, \Pi, \pi, d, \delta)$ consists of $\Pi = \{out{-}of{-}{-}gate, in{-}gate, request, grant\}$, $N = \{train, ctr\}$ and $Q = \{q_0, q_1, q_2, q_3\}$, with valuation function as given (e.g. $\pi(q_0) = \{out{-}of{-}gate\}$). The concurrent game structure is turn-based synchronous, so if we take the train as player 1 and the controller as player 2, we have, e.g., $d_1(q_0) = 2$ and $d_2(q_0) = 1$. The transition function at state q_0 is then described by $\delta(q_0, 1, 1) = q_0$ and $\delta(q_0, 2, 1) = q_1$.

ATL can be utilised to describe properties of this model. For instance, the formula $\langle\langle\emptyset\rangle\rangle \Box(in{-}gate \rightarrow \langle\langle ctr \rangle\rangle \bigcirc out{-}of{-}gate)$ expresses that whenever the train is in the gate, the controller can force it out immediately. Similarly, $\langle\langle\emptyset\rangle\rangle \Box(out{-}of{-}gate \rightarrow \langle\langle ctr, train \rangle\rangle \Diamond in{-}gate)$ states that whenever the train is out of the gate, it can cooperate with the controller to enter eventually. As a final example,

$$\langle\langle\emptyset\rangle\rangle \Box(out{-}of{-}gate \rightarrow \langle\langle train \rangle\rangle \Diamond(request \wedge \langle\langle ctr \rangle\rangle \Diamond grant \wedge \langle\langle ctr \rangle\rangle \Box \neg grant))$$

expresses that whenever the train is out of the gate, it can eventually send a request to enter, and the controller can then either grant it eventually or not. All these formulas are valid in the given game structure.

11.3 Axiomatics and Complexity

The axiomatisation of ATL given below is an extension of the axiomatisation given for Coalition Logic. The next-time $\bigcirc$ operator is characterised by the axioms of Coalition Logic, and the long-term temporal operators $\Box$ and $\mathcal{U}$ are captured using two fixpoint axioms each.

Formally, **ATL** is the smallest set of formulas which contains all propositional tautologies together with all instances of the axiom schemas listed in Figure 22, and which is closed under the inference rules of Modus Ponens, Monotonicity and Necessitation given below:

$$\frac{\varphi \quad \varphi \to \psi}{\psi} \qquad\qquad \frac{\varphi \to \psi}{\langle\langle C\rangle\rangle \bigcirc \varphi \to \langle\langle C\rangle\rangle \bigcirc \psi} \qquad\qquad \frac{\varphi}{\langle\langle \emptyset\rangle\rangle \Box \varphi}$$

For the case of $\Box$, $FP\Box$ states that $\langle\langle C\rangle\rangle \Box\varphi$ is a fixpoint of the operator $F(X) = \varphi \wedge \langle\langle C\rangle\rangle \bigcirc X$, and $GFP\Box$ states that it is the greatest fixpoint of $F(X)$. Analogously for the least fixpoint with $\mathcal{U}$.

$(\bot)$	$\neg\langle\langle C\rangle\rangle \bigcirc \bot$
$(\top)$	$\langle\langle C\rangle\rangle \bigcirc \top$
$(\mathtt{N})$	$(\neg\langle\langle \emptyset\rangle\rangle \bigcirc \neg\varphi \to \langle\langle N\rangle\rangle \bigcirc \varphi)$
$(\mathtt{S})$	$(\langle\langle C_1\rangle\rangle \bigcirc \varphi_1 \wedge \langle\langle C_2\rangle\rangle \bigcirc \varphi_2) \to \langle\langle C_1 \cup C_2\rangle\rangle \bigcirc (\varphi_1 \wedge \varphi_2)$ where $C_1 \cap C_2 = \emptyset$
$(FP\Box)$	$\langle\langle C\rangle\rangle \Box\varphi \leftrightarrow \varphi \wedge \langle\langle C\rangle\rangle \bigcirc \langle\langle C\rangle\rangle \Box\varphi$
$(GFP\Box)$	$\langle\langle \emptyset\rangle\rangle \Box(\psi \to (\varphi \wedge \langle\langle C\rangle\rangle \bigcirc \psi)) \to \langle\langle \emptyset\rangle\rangle \Box(\psi \to \langle\langle C\rangle\rangle \Box\varphi)$
$(FP\mathcal{U})$	$\langle\langle C\rangle\rangle \varphi_1 \mathcal{U} \varphi_2 \leftrightarrow \varphi_2 \vee (\varphi_1 \wedge \langle\langle C\rangle\rangle \bigcirc \langle\langle C\rangle\rangle \varphi_1 \mathcal{U} \varphi_2)$
$(LFP\mathcal{U})$	$\langle\langle \emptyset\rangle\rangle \Box((\varphi_2 \vee (\varphi_1 \wedge \langle\langle C\rangle\rangle \bigcirc \psi)) \to \psi) \to \langle\langle \emptyset\rangle\rangle \Box(\langle\langle C\rangle\rangle \varphi_1 \mathcal{U} \varphi_2 \to \psi)$

Figure 22. The axiom schemas of ATL

THEOREM 49 ([26]). **ATL** *is sound and complete with respect to the class of all concurrent game structures.*

The complexity of model checking ATL formulas has been investigated in [3]. As with Game Logic, given a formula φ and a finite model $\mathcal{S}$, we are interested in the complexity of determining the states of $\mathcal{S}$ where φ holds. The results are for general concurrent game structures.

THEOREM 50 ([3]). *Given an ATL formula φ and a concurrent game structure $\mathcal{S}$ with m transitions, model checking can be done in time $O(m \times |\varphi|)$. For ATL* formulas, model checking is 2EXPTIME-complete.*

The complexity of the satisfiability problem has been investigated only more recently. At the time of writing, only the complexity of ATL has been determined. Let us say that an ATL-formula φ is over a set of agents N if all coalitions mentioned in φ are subsets of N. Moreover, we say that a concurrent game structure $\mathcal{S} = (M, Q, \Pi, \pi, d, \delta)$ is over N if $M = N$ (see Footnote 2)

THEOREM 51 ([103, 26]). *Let N be a finite set of players. Then, the complexity of the satisfiability problem for ATL-formulas over N with respect to concurrent game structures over N is EXPTIME-complete.*

To demonstrate that Theorem 51 marks ongoing work in a lively research area, note that the decision procedure of [103, 26] is 2EXPTIME if the set of agents N in not fixed in advance. This gives rise to the following two related questions:

1. Is the following problem in EXPTIME: Given an ATL-formula φ, is φ satisfiable in an ATL-model over a set of agents containing at least the agents occurring in φ?

2. Is the following problem in EXPTIME: Given a set of agents N and an ATL-formula φ over N, is φ satisfiable in an ATL-model over N?

Positive answers to both questions are given in [106].

11.4 Extensions: μ-calculus and imperfect information

CTL and CTL* are both subsumed by the very expressive μ-calculus. Similarly for ATL and ATL*, one can develop an analogous *alternating μ-calculus* with general fixpoint expressions. Formally, we have a set of propositional variables V, and formulas

$$\varphi := \quad \bot \mid p \mid \neg\varphi \mid \varphi_1 \vee \varphi_2 \mid X \mid \langle\!\langle C \rangle\!\rangle \bigcirc \varphi \mid \mu X.\varphi$$

where $X \in V$ and in $\mu X.\varphi$, X occurs free only under an even number of negations in φ. The semantics of the fixpoint operator is defined as $(\mu X.\varphi)^{\mathcal{S}} = \bigcap\{Q_0 \subseteq Q | \varphi[X := Q_0]^{\mathcal{S}} \subseteq Q_0\}$. Corresponding to the least fixpoint μX there is also a greatest fixpoint νX defined as $\nu X.\varphi = \neg\mu X.\neg\varphi$. The alternating μ-calculus subsumes both ATL and ATL*. For ATL, note that $\langle\!\langle C \rangle\!\rangle \Box\varphi = \nu X.\varphi \wedge \langle\!\langle C \rangle\!\rangle \bigcirc X$ and $\langle\!\langle C \rangle\!\rangle \varphi \,\mathcal{U}\, \psi = \mu X.\psi \vee (\varphi \wedge \langle\!\langle C \rangle\!\rangle \bigcirc X)$. In fact, it can be shown that the alternating μ-calculus is strictly more expressive than ATL*. As in the standard modal μ-calculus and in Game Logic, the complexity of model checking depends on the alternation depth of a formula, i.e., the nesting depth of alternating least and greatest fixpoints.

Various attempts have been made to introduce imperfect information into concurrent game structures. Since at the time of writing this problem is still under discussion, we restrict ourselves here to a rough sketch of some of the difficulties. In [3], a set of observable propositions is associated with every player. This extension of ATL introduces quite a few new complexities, syntactically as well as semantically, and this is witnessed by the result that model-checking becomes undecidable. Syntactically, not all ATL expressions make sense anymore, since, e.g., $\langle\!\langle C \rangle\!\rangle \Box p$ presupposes that the cooperative goal p is actually observable by the members of C. Semantically, a player's strategy has to be restricted in such a way that it can only influence propositions observable by that player. The difficulties which arise when trying to extend ATL to incomplete information also become visible in an alternative approach explored in [92]. Here, concurrent game structures are augmented with an epistemic accessibility relation $\sim_i$ for each player i. In contrast to the previous approach, the language of ATL is also extended with an epistemic K_i knowledge operator with its standard definition. The resulting *Alternating-time Temporal Epistemic Logic* (ATEL) can express properties from a variety of domains, e.g. confidentiality properties like $\langle\!\langle \{1,2\} \rangle\!\rangle(\neg K_3 p \,\mathcal{U}\, K_2 p)$. The semantics of ATL, however,

cannot simply be left unchanged. At a state q, player 1 may have some strategy s_1 to eventually achieve φ. But if he cannot distinguish q from q' where only a different strategy s_2 achieves φ, player 1 does *not* have a strategy at q (as defined for imperfect information games) for achieving φ. More precisely, player 1 has a strategy only *de dicto*, but not *de re*, and it is the de re strategies which game theory is interested in [39]. A further approached is presented in [72].

12 CONCLUSION

What can modal logic contribute to the study of strategic interaction? Four answers, not mutually exclusive, suggest themselves to us. First, logic contributes a more abstract and hence more general perspective on games. As we have seen in Sections 3 and 6, games can essentially be viewed as special kinds of Kripke models, with move relations and possibly epistemic uncertainty relations to model players' knowledge. In this way, certain game-theoretic notions such as perfect recall turn out to be special cases of general logical axioms (cf. 6.1) which have been investigated in more generality in modal logic. Similarly, game logic (Section 9) presents games as generalisations of programs, providing a semantics which is general enough to study the difference between 2-player games and 1-player games (i.e., programs). This more general perspective provided by logic also raises new questions. In the case of game logic, for instance, we may ask what operations on games suffice to build all games in a particular class of games. More generally, to the best of our knowledge, operations on games are rarely investigated in game theory, while a computational logic perspective naturally suggests such an investigation.

Second, there is the analysis of players' knowledge and beliefs in games. While much of the game-theoretic analysis of interactive epistemics has been independent of developments in epistemic logic (Section 4), the models employed are essentially the same (information partitions or Kripke models satisfying the S5 axioms), as is the notion of common knowledge. Developments in update logics (Section 7) and belief revision (see Chapter 21 of this handbook) have shifted the logical focus from an analysis of static epistemic situations to epistemic dynamics, without a doubt important in the analysis of games of imperfect information. Furthermore, the epistemic foundation of solution concepts (Section 8) translates solution concepts into the language of the epistemic logician, while the language itself remains hidden from view. More precisely, while epistemic logic rests on the link between the semantic model of knowledge and the formal language used to describe it, game theory has mainly focused on the semantic model exclusively. Only more recently have syntactic approaches to the epistemic foundations of solution concepts been advanced.

The issue of syntax or formal language is, in fact, a third way in which logic can raise new issues in strategic interaction. While many game theorists may find the logician's insistence on syntax cumbersome and unnecessary, it is precisely the interplay between syntax and semantics that the logician is interested in. In general, decision makers use a certain language and conceptual apparatus to reason about the situation at hand. As a consequence, one would suspect that game theoretic models and solution concepts would be language dependent (see also [71]). More specifically, we may be interested whether a particular logical language is rich enough to define a particular solution concept such as the Nash equilibrium (see, e.g., Theorem 15 in Section 3). As mentioned above, we may wonder whether a certain set of game operations suffices to construct all games of a

particular class. Or we may be interested in the computational complexity of reasoning about information update in games. For all these questions, a syntactic approach may help.

Fourth, due to its formal language, logic becomes important when it comes to the specification and verification of multi-agent systems. Logics like Alternating-time Temporal Logic (Section 11) have been devised as a way to specify properties of systems of interacting agents. By analysing the complexity of model checking, we find out how complex certain game-theoretic properties are to verify for a given game or game form. Hence, logic is also useful when applying game theory to complex games played by artificial agents, and hence modal logic can serve as a tool of computation for difficult real or artificial life games.

While we hope to have given some insights into how modal logic may enrich game theory, we should point out again that there are many cases where game theory can be useful for modal logic. Maybe the most interesting example is Independence-Friendly Modal Logic (IFML) [78]. In IFML, we consider formulas like $\Box\Diamond^* p$, where the modal diamond $\Diamond^*$ is independent of the box. Such a formula will be true just in case the diamond successor satisfying p can be chosen independently from the earlier box successor, in other words, there needs to be a uniform diamond successor satisfying p for all earlier box successors. As this example suggests, the semantics of IFML can be formulated in terms of imperfect information games. IFML is interesting from a logical point of view since it is more expressive than standard modal logic, due to its ability to express certain weak confluence properties.

The area of modal logic and games is active and in full development. Due to upcoming technologies like on-line auctions and e-voting, researchers apply a new range of tools and techniques to ask and settle 'standard' questions of logicians and computer scientists regarding the specification, verification and synthesis of interactive systems or mechanisms. In the 'classical' areas of game theory and social choice theory, this logical work generates both interesting results regarding formalisation and computational complexity, and at the same time new and sometimes even philosophical questions about the nature of games, or more generally, interaction.

ACKNOWLEDGEMENTS

We are thankful to Johan van Benthem, Giacomo Bonanno, Govert van Drimmelen, Valentin Goranko and Michael Wooldridge, who gave valuable suggestions on earlier drafts of this chapter.

Modal logic is one of philosophy's many children. As a mature adult it has moved out of the parental home and is nowadays straying far from its parent. But the ties are still there: philosophy is important for modal logic, modal logic is important for philosophy. Or, at least, this is a thesis we try to defend in this chapter. Limitations of space have ruled out any attempt at writing a survey of all the work going on in our field — a book would be needed for that. Instead, we have tried to select material that is of interest in its own right or exemplifies noteworthy features in interesting ways. Here are some themes which have guided us throughout the writing:

- *The back-and-forth between philosophy and modal logic.* There has been a good deal of give-and-take in the past. Carnap tried to use his modal logic to throw light on old philosophical questions, thereby inspiring others to continue his work and still others to criticise it. He certainly provoked Quine, who in his turn provided — and continues to provide — a healthy challenge to modal logicians. And Kripke's and David Lewis's philosophies are connected, in interesting ways, with their modal logic. Analytic philosophy would have been a lot different without modal logic!

- *The interpretation problem.* The problem of providing a certain modal logic with an intuitive interpretation should not be conflated with the problem of providing a formal system with a model-theoretic semantics. An intuitively appealing model-theoretic semantics may be an important step towards solving the interpretation problem, but only a step. One may compare this situation with that in probability theory, where definitions of concepts like 'outcome space' and 'random variable' are orthogonal to questions about "interpretations" of the concept of probability.

- *The value of formalisation.* Modal logic sets standards of precision, which are a challenge to — and sometimes a model for — philosophy. Classical philosophical questions can be sharpened and seen from a new perspective when formulated in a framework of modal logic. On the other hand, representing old questions in a formal garb has its dangers, such as simplification and distortion.

- *Why modal logic rather than classical (first or higher order) logic?* The idioms of modal logic — today there are many! — seem better to correspond to human ways of thinking than ordinary extensional logic. (Cf. Chomsky's conjecture that the NP + VP pattern is wired into the human brain.)

In his *An Essay in Modal Logic* [107] von Wright distinguished between four kinds of modalities: *alethic* (modes of truth: necessity, possibility and impossibility), *epistemic* (modes of being known: known to be true, known to be false, undecided), *deontic* (modes of obligation: obligatory, permitted, forbidden) and *existential* (modes of existence: universality, existence, emptiness). The existential modalities are not usually counted as modalities, but the other three categories are exemplified in three sections into which this chapter is divided. Section 1 is devoted to alethic modal logic and reviews some main themes at the heart of philosophical modal logic. Sections 2 and 3 deal with topics in epistemic logic and deontic logic, respectively, and are meant to illustrate two different uses that modal logic or indeed any logic can have: it may be applied to already existing (non-logical) theory, or it can be used to develop new theory.

1 ALETHIC MODAL LOGIC

In this part we consider the challenge that Quine posed in 1947 to the advocates of modal logic to provide an account of modal notions that is intuitively clear, allows "quantifying in", and does not presuppose intensional entities. The modal notions that Quine and his contemporaries were primarily concerned with in the 1940's were, broadly speaking, the logical modalities rather than the metaphysical ones that have since come to prevail. In the 1950's modal logicians responded to Quine's challenge by providing quantified modal logic with model-theoretic semantics of various types. In doing so they also, explicitly or implicitly, addressed Quine's interpretation problem. Here we shall consider the approaches developed by Carnap in the late 1940's, and by Kanger, Hintikka, Montague, and Kripke in the 1950's and early 1960's, and discuss to what extent these approaches were successful in meeting Quine's doubts about the intelligibility of quantified modal logic.

It is useful to divide the reactions to Quine's challenge into two periods. During the first period modal logicians provided modal logic with formal semantics as just mentioned. In the second period philosophers — inspired by the success of possible worlds

semantics — came to take the notion of a possible world seriously as a tool for philosophical analysis. Philosophical analyses in terms of possible worlds were provided for many concepts of central philosophical importance: propositional attitudes [42, 43, 45], metaphysical necessity, identity, and naming [69, 70], "intensional entities" like propositions, properties and events [84, 61, 102, 103], counterfactual conditionals and causality [77, 78], supervenience [62]. At the same time the notion of a possible world itself came in for philosophical analysis. The problems of giving a satisfactory analysis of this notion indicates that Quine's interpretational challenge is still alive. The basic philosophical questions surrounding the notions of alethic necessity and possibility are as puzzling as ever! We end this section by discussing the relationship between the logical and metaphysical interpretation of the alethic modalities.

1.1 The search for the intended interpretation

Starting with the work of C. I. Lewis, an immense number of formal systems of modal logic have been constructed based on classical propositional or predicate logic. The originators of modern modal logic, however, were not very clear about the intuitive meaning of the symbols $\Box$ and $\Diamond$, except to say that these should stand for some kind of necessity and possibility, respectively. For instance, in *Symbolic Logic* [72], Lewis and Langford write:

> It should be noted that the words "possible", "impossible" and "necessary" are highly ambiguous in ordinary discourse. The meaning here assigned to $\Diamond p$ is a *wide* meaning of "possibility" — namely, logical conceivability or the absence of self-contradiction. (160–61)

This situation led to a search for more rigorous interpretations of modal notions. Gödel [35] suggested interpreting the necessity operator $\Box$ as standing for provability (*informal provability* or, alternatively, *formal provability* in a fixed formal system), a suggestion that subsequently led to the modern *provability interpretations* of Solovay, Boolos and others.[1]

After Tarski [105, 106] had developed rigorous notions of satisfaction, truth and logical consequence for classical extensional languages, the question arose whether the same methods could be applied to the languages of modal logic and related systems. One natural idea, that occurred to Carnap in the 1940's, was to let $\Box\varphi$ be true of precisely those formulæ φ that are *logically valid* (or logically true) according to the standard semantic definition of logical validity. This idea led him to the following semantic clause for the operator of logical necessity:

> $\Box\varphi$ is true in an interpretation $\mathcal{I}$ iff φ is true in every interpretation $\mathcal{I}'$.

This kind of approach, which we may call the *validity interpretation*, was pursued by Carnap, using so-called state descriptions, and subsequently also by Kanger [53, 54] and Montague [83], using Tarski-style model-theoretic interpretations rather than state descriptions. In Hintikka's and Kanger's early work on modal semantics other interpretations of $\Box$ were also considered, especially, epistemic ('It is known that φ') and deontic ones ('It ought to be the case that φ'). In order to study these and other non-logical modalities, the introduction by Hintikka and Kanger of *accessibility relations* between

[1] Cf. [101] and [13].

possible worlds (models, domains) was crucial. Finally, Kripke [66, 67, 68] introduced the kind of model structures that are nowadays the standard formal tool for the model-theoretic study of modal and related non-classical logics: Kripke models. Thus Kripke gave possible worlds semantics its modern and mature form.

In Carnap's, Kanger's and Montague's early theories, the space of possibilities (the "possible worlds") is represented by one comprehensive collection containing *all* state descriptions, domains, or models, respectively. Hence, every state description, domain, or model is thought of as representing a genuine possibility. Hintikka, Kripke and modern possible worlds semantics are instead working with semantic interpretations in which the space of possibilities is represented by an arbitrary non-empty set **K** of model sets (in the case of Hintikka) or "possible worlds" (Kripke). Following Hintikka's [46, 47] terminology, one may say that the early theories of Carnap, Kanger, and Montague were considering *standard interpretations* only, where one quantifies over what is, in some formal sense, *all* the possibilities. In the possible worlds approach, one also considers *non-standard* interpretations, where arbitrary non-empty sets of possibilities are considered.[2] The consideration of interpretations (model structures) that are non-standard in this sense — in combination with the use of accessibility relations between worlds in each interpretation — made it possible for Kripke [64, 67, 68] to prove completeness theorems for various systems of propositional and quantified modal logic (**T**, **B**, **S4**, etc.).

1.2 Carnap's formal semantics for quantified modal logic

The proof theoretic study of quantified modal logic was pioneered by Ruth Barcan Marcus [5, 6, 7] and Rudolf Carnap [16, 17] who were the first to formulate axiomatic systems that combined quantification theory with (**S4**- and **S5**-type) modal logic. The attempts to interpret quantified modal logic by means of formal semantic methods also began with Carnap.

Carnap's project was not only to develop a semantics (in the sense of Tarski) for intensional languages, but also to use metalinguistic notions from formal semantics to throw light on the modal ones. In 'Modalities and quantification' from 1946 he writes:

> It seems to me ... that it is not possible to construct a satisfactory system before the meaning of the modalities are sufficiently clarified. I further believe that this clarification can best be achieved by correlating each of the modal concepts with a corresponding semantical concept (for example, necessity with **L**-truth).

In [16, 17] Carnap presented a formal semantics for logical necessity based on Leibniz's old idea that a proposition is necessarily true if and only if it is true in all possible worlds. Suppose that we are considering a first-order predicate language $\mathcal{L}$ with predicate symbols and individual constants, but no function symbols. In addition to Boolean connectives, quantifiers and the identity symbol $=$ (considered as a logical symbol), the language $\mathcal{L}$ also contains the modal operator $\Box$ for logical necessity. We assume that $\mathcal{L}$ comes with a *domain of individuals* D and that there is a one-to-one correspondence between the individual constants of $\mathcal{L}$ and the individuals in D. Intuitively speaking, each individual in D has exactly one individual constant as its (canonical) name. A *state description* S for $\mathcal{L}$ is simply a set of (closed) atomic sentences of the form $P(a_1, \ldots, a_n)$, where P is

[2]For the standard/non-standard distinction, see also [23].

an n-ary predicate in $\mathcal{L}$ and $a_1, \ldots, a_n$ are individual constants in $\mathcal{L}$.[3] Carnap [17, p. 9] writes "...the state descriptions represent Leibniz's possible worlds or Wittgenstein's possible states of affairs".

In order to interpret quantification, Carnap introduced the notion of an *individual concept* (relative to $\mathcal{L}$): An individual concept is simply a function f that assigns to every state description S an individual constant $f(S)$ (representing an individual in D). Intuitively speaking, individual concepts are functions from possible worlds to individuals. According to Carnap's semantics, individual variables are assigned values *relative to* state descriptions. An *assignment* is a function g that to every state description S and every individual variable x assigns an individual constant $g(x, S)$. Intuitively, $g(x, S)$ represents the individual that is the value of x under the assignment g in the possible world represented by S. We may speak of $g(x, S)$ as the *value extension* of x in S relative to g. Analogously, the individual concept $(\lambda S)g(x, S)$ that assigns to every state description S the value extension of x in S relative to g, we call the *value intension* of x relative to g. Thus, according to Carnap's semantics a variable is assigned both a *value intension* and a *value extension* [17, p. 45]. The value extension assigned to a variable in a state description S is simply the value intension assigned to the variable applied to S.

With these notions in place, we can define what it means for a formula φ of $\mathcal{L}$ to be *true* in a state description relative to an assignment g (in symbols, $S\varphi[g]$).

For atomic formulæ of the form $P(t_1, \ldots, t_n)$, where $t_1, \ldots, t_n$ are individual terms, i.e., variables or individual constants, we have:

(1) $S \models P(t_1, \ldots, t_n)[g]$ iff $P(S(t_1, g), \ldots, S(t_n, g)) \in S$.

Here, $S(t_i,\ g)$ is the extension of the term t_i in the state description S relative to the assignment g. Thus, if t_i is an individual constant, then $S(t_i, g)$ is t_i itself; and if t_i is a variable, then $S(t_i, g) = g(t_i, S)$.

The semantic clause for the identity symbol is:

(2) $S \models (t_1 = t_2)[g]$ iff $S(t_1, g) = S(t_2, g)$.

That is, the identity statement $t_1 = t_2$ is true in a state description S relative to an assignment g if and only if the terms t_1 and t_2 have the same extension in S relative to g.

The clauses for the Boolean connectives are the usual ones. Carnap's clause for the universal quantifier is:

(3) $S \models \forall x\varphi[g]$ iff for every assignment g' such that $g =_x g', S \models \varphi[g']$,

where $g =_x g'$ means that the assignments g and g' assign the same value intensions to all the variables that are distinct from x and possibly assign different value intensions to x. Intuitively, then $\forall x\varphi(x)$ may be read: "for every assignment of an individual concept to $x, \varphi(x)$".

Finally, the semantic clause for the necessity operator is the expected one:

(4) $S \models \Box\varphi[g]$ iff, for every state description $S', S' \models \varphi[g]$.

[3] Actually Carnap's state descriptions are sets of literals (i.e., either atomic sentences or negated atomic sentences) that contain for each atomic sentence either it or its negation. However, for our purposes we may identify a state description with the set of atomic sentences that it contains.

That is, the modal formula 'it is (logically) necessary that φ' is true in a state description S (relative to an assignment g) if and only if φ is true in every state description S' (relative to g).

A formula φ is *true in a state description* S (in symbols, $S \vDash \varphi$) if it is true in S relative to every assignment. *Logical truth* (logical validity) is defined as truth in all state descriptions. We write $\vDash \varphi$ for φ being logically true.

Carnap's semantics satisfies the following principles:

(5) All truth-functional tautologies are logically true.

(6) The set of logical truths is closed under modus ponens.

(7) The standard principles of quantification theory (without identity) are valid. In particular,

(US) $\forall x\varphi(x) \to \varphi(x)$ (*Universal Specification*)
(EG) $\varphi(t/x) \to \exists x\varphi$ *(Existential Generalisation)*
(where t is substitutable for x in φ)

hold without restrictions.

It is easy to verify that $\Box$ satisfies the usual laws of the system **S5**, together with the so-called Barcan formula and its converse, and the rule of necessitation:

(K)	$\vDash \Box(\varphi \to \psi) \to (\Box\varphi \to \Box\psi)$.	
(T)	$\vDash \Box\varphi \to \varphi$	
(S4)	$\vDash \Box\varphi \to \Box\Box\varphi$.	
(S5)	$\vDash \neg\Box\varphi \to \Box\neg\Box\varphi$	
(BF)	$\vDash \forall x\Box\varphi(x) \to \Box\forall x\varphi(x)$.	(*The Barcan formula*)
(CBF)	$\vDash \Box\forall x\varphi(x) \to \forall x\Box\varphi(x)$.	(*The Converse Barcan formula*)
(Nec)	If $\vDash \varphi$, then $\vDash \Box\varphi$.	

Notice that the Barcan formula (BF) and its converse (CBF) are schemata rather than single formulæ.

The following schemata are also valid in Carnap's semantics:

(8) $\vDash \Box\varphi$ iff $\vDash \varphi$.

(9) $\vDash \neg\Box\varphi$ iff $\nvDash \varphi$.

(10) Either $\vDash \Box\varphi$ or $\vDash \neg\Box\varphi$.

For identity, we have:

(LI) $\vDash t = t$. (*Law of Identity*)

However, the unrestricted principle of *indiscernibility of identicals* is not valid in Carnap's semantics. In other words, the following principle does not hold for all formulæ φ:

$(I =)$ $\vDash \forall x\forall y(x = y \to (\varphi(x/z) \to \varphi(y/z)))$.

Instead, we have a restricted version of $(I =)$:

$(I =_{\text{restr}})$ $\vDash \forall x\forall y(x = y \to (\varphi(x/z) \to \varphi(y/z)))$, provided that φ does not contain any occurrences of $\Box$.

For the unrestricted case, we only have:

$(I\Box =) \vDash \forall x \forall y(\Box(x = y) \to (\varphi(x/z) \to \varphi(y/z)))$.

The following principle is of course not valid according to Carnap's semantics:

$(\Box =) \quad \forall x \forall y(x = y \to \Box(x = y))$. (*Necessity of Identity*)

In the presence of the other principles, it is equivalent to the unrestricted principle of indiscernibility of identicals. Nor do we have:

$(\Box \neq) \quad \forall x \forall y(x \neq y \to \Box(x \neq y))$. (*Necessity of Non-Identity*)

In view of Church's undecidablity theorem for the predicate calculus, it is easy to prove that Carnap's quantified modal logic is not axiomatizable. For every sentence φ of predicate logic φ, either $\Box\varphi$ or $\neg\Box\varphi$ is true in every state description. So, if Carnap's logic were axiomatizable, then we could decide effectively whether φ is provable in predicate logic. But this is contrary to Church's theorem.

THEOREM 1. *The set of all logically true sentences according to Carnap's semantics is not recursively enumerable, so there is no formal axiomatic system with this set as its theorems.*

Carnap introduced the notion of a *meaning postulate* to account for analytic connections between the non-logical symbols of a predicate language. Thus, suppose that *MP* is the set of all the meaning postulates of a given language $\mathcal{L}$. *MP* is then a set of sentences in the non-modal fragment of $\mathcal{L}$. We say that a state description S is *admissible* if *MP* $\cup S$ is consistent. Then, we can interpret $\Box$ as 'analytic necessity' by modifying clause (4) above to:

(4′) $S \vDash \Box\varphi$ iff, for every admissible state description $S', S' \vDash \varphi$.

We also say that φ is *analytically true* iff φ is true in all admissible state descriptions. In the modified semantics, we have:

$S \vDash \Box\varphi$ iff φ is analytically true.
$S \vDash \neg\Box\varphi$ iff φ is not analytically true.

Carnap's semantics for the quantifiers can be understood in two ways. The most straightforward interpretation is to say that the quantifiers simply range over individual concepts. Sometimes Carnap himself characterises his interpretation of the quantifiers in this way, and this is how Quine describes it. There is, however, another more subtle interpretation according to which every individual term, including the (free) variables, has a double semantic role given by its extension and its intension, respectively. Each variable has a value extension as well as a value intension. According to this interpretation — which presumably is the one that Carnap really had in mind — it is simply wrong to ask for *the* range of the individual variables. In ordinary extensional contexts the variables can be thought of as ranging over ordinary individuals. However, in intensional contexts the intensions associated with the variables come into play. This is what explains why the principle $(\Box =)$ fails.

Carnap's interpretation of the quantifiers can still be criticised for being unintuitive. The problem is that he lacks a way of discriminating between those individual concepts that, intuitively speaking, pick out one and the same individual in all possible worlds and those that don't. Suppose that we have assigned to the variable x as its value intension the individual concept: *the number of planets.* Relative to this assignment it is true that:

(1) $x = 9 \wedge \neg\Box(x = 9)$.

However, there is no *object* that has the property of being identical with 9 but doesn't have this property necessarily. So from (1) it should not follow that:

(2) $\exists x(x = 9 \wedge \neg\Box(x = 9))$.

But of, course, on Carnap's interpretation of the quantifiers, (2) is a logical consequence of (1). Intuitively, one should be able to make the inference from (1) to (2) only if the concept assigned to x in (1) is, what might be called, a *logically rigid concept*, i.e. a concept that picks out the same individual relative to every state description.[4]

1.3 Quine's interpretational challenge

Quine's criticism of quantified modal logic comes in different strands. First, there is the simple observation that classical quantification theory with identity cannot be applied to a language in which substitutivity of identicals for singular terms fails. It seems, from the so-called Morning Star Paradox, that either universal specification (US) (and its mirror image: existential generalisation (EG)) or indiscernibility of identicals, (I=), has to be given up. This observation gives rise to the following weak, and apparently uncontroversial, Quinean claim: Classical quantification theory (with identity and individual constants) cannot be combined with non-extensional operators (i.e., operators for which substitutivity of identicals for singular terms fail) without being modified in some way. This weak claim already gives rise to the challenge of extending quantification theory in a consistent way to languages with non-extensional operators.

In addition to the weak claim, there is the much stronger claim that one sometimes can find in Quine's early works, that objectual quantification into non-extensional (so called "opaque") constructions simply does not make sense [91, 93, 94]. The argument for this claim is based on the idea that occurrences of variables inside of opaque constructions do not have purely referential occurrences, i.e., they do not serve simply to refer to their objects, and cannot therefore be bound by quantifiers outside of the opaque construction. Thus quantifying into contexts governed by non-extensional operators would be like trying to quantify into quotations. This claim is hardly credible in the face of the multitude of quantified intensional logics that have been developed since it was first made, and we take it to be refuted by the work of among others, David Kaplan [59, 61] and Kit Fine [26, 27].[5]

Then, there is Quine's claim that quantified modal logic is committed to *Aristotelian essentialism*, i.e., the view that it makes sense to say of an object, quite independently of how it is described, that it has certain of its traits necessarily, and others only contingently. Aristotelian essentialism, however, comes in stronger and weaker forms. Kripke's "metaphysical necessity" of *Naming and Necessity* represents a strong form of essentialism, while there are weaker forms according to which only logical properties that are shared by all individuals are essential. A quantified modal logic needs only be committed to this weak relatively benign form of essentialism.

---

[4]The notion of a logically rigid concept is closely related Carnap's [17, Part II] notion of an L-determinate intension. Intuitively, an L-determinate intension picks out the same extension in every state description. Thus, Carnap's notion of L-determinacy may be viewed as a precursor of Kripke's notion of rigidity.

[5]See also Burgess [14] and Neale [86] for recent evaluations of Quine's criticism of quantified modal logic.

Here we shall only consider the specific criticism that Quine directed in 1947 toward quantification into contexts of logical or analytical necessity. In his paper 'The problem of interpreting modal logic' from 1947, Quine formulates what one might call *Quine's challenge* to the advocates of quantified modal logic:

> There are logicians, myself among them, to whom the ideas of modal logic (e. g. Lewis's) are not intuitively clear until explained in non-modal terms. But so long as modal logic stops short of quantification theory, it is possible ... to provide somewhat the type of explanation required. When modal logic is extended (as by Miss Barcan) to include quantification theory, on the other hand, serious obstacles to interpretation are encountered — particularly if one cares to avoid a curiously idealistic ontology which repudiates material objects.

What Quine demands of the modal logicians is nothing less than an explanation of the notions of quantified modal logic in non-modal terms. Such an explanation should satisfy the following requirements:

(i) It should be expressed in an extensional language. Hence, it cannot use any non-extensional constructions.

(ii) The explanation should be allowed to use concepts from the 'theory of meaning' like analyticity and synonymy applied to expressions of the metalanguage. Quine is, of course, quite sceptical about the intelligibility of these notions as well. But he considers it to be progress of a kind, if modal notions could be explained in these terms.

(iii) The explanation should make sense of sentences like:

$$\exists x(x \text{ is red } \wedge \Diamond(x \text{ is round})),$$

in which a quantifier outside a modal operator binds a variable within the scope of the operator and the quantifier ranges over ordinary physical objects (in distinction from Frege's "Sinne" or Carnap's "individual concepts"). In other words, the explanation should make sense of 'quantifying in' in modal contexts.

Quine [92] — like Carnap before him — starts out from a metalinguistic interpretation of the necessity operator $\Box$ in terms of the predicate '... is analytically true'. Disregarding possible complications in connection with the interpretation of iterated modalities, we have for sentences φ of the object language:

$$\text{`}\Box\varphi\text{' is true iff } \varphi \text{ is analytically true.}$$

Now Quine argues for the thesis that it is impossible to combine analytical necessity with a standard theory of quantification (over physical objects). The argument (a variation of "the Morning Star Paradox") is based on the premises:

(1) $\Box$(Hesperus = Hesperus)

(2) Phosphorus = Hesperus

(3) $\neg\Box$(Phosphorus = Hesperus),

where 'Phosphorus' and 'Hesperus' are two proper names (individual constants) and $\Box$ is to be read 'It is analytically necessary that'. We assume that 'Phosphorus' is used by the language community as a name for a certain bright heavenly object sometimes visible in the morning and that 'Hesperus' is used for some bright heavenly object sometimes visible in the evening. Unbeknownst to the community, however, these objects are one and the same, namely, the planet Venus. 'Hesperus = Hesperus' being an instance of the Law of Identity is clearly an analytic truth. It follows that the premise (1) is true. (2) is true, as a matter of fact. 'Phosphorus = Hesperus' is obviously not an analytic truth, 'Phosphorus' and 'Hesperus' being two different names with quite distinct uses. So, (3) is true.

From (1), (2), (3) and the Law of Identity, we infer by sentential logic:

(4) Phosphorus = Hesperus $\wedge \neg\Box$(Phosphorus = Hesperus),

(5) Hesperus = Hesperus $\wedge \Box$(Hesperus = Hesperus).

Applying (EG) to (4) and (5), we get:

(6) $\exists x(x =$ Hesperus $\wedge\neg\Box(x =$ Hesperus$))$,

(7) $\exists x(x =$ Hesperus $\wedge \Box(x =$ Hesperus$))$.

As Quine [92] points out, however, (6) and (7) are incompatible with interpreting $\forall x$ and $\exists x$ as objectual quantifiers meaning "for all objects x (in the domain D)" and "for at least one object x (in D)" and letting the identity sign stand for genuine identity between objects (in D). Because, under this interpretation, (6) and (7) imply that one and the same object, Hesperus, both is and is not necessarily identical with Hesperus, which seems absurd.

The following are classical proposals for solving Quine's interpretational challenge:

(i) *Russell–Smullyan* (Smullyan [99]). According to this proposal, all singular terms except variables are treated as *Russellian terms*, i.e., as "abbreviations" of definite descriptions that are eliminated from the language by means of contextual definition à la Russell. If we let 'Hesperus' and 'Phosphorus' be Russellian terms having minimal scope everywhere — which clearly corresponds to the intended reading — then the inference will not go through (i.e., once the Russell terms have been contextually eliminated): the (EG)-steps above will not correspond to valid steps in primitive notation. With this treatment of singular terms, the paradox is avoided. One has the feeling, however, that the problem has been circumvented rather than solved.

(ii) *Carnap* (at least the way Quine reads him): The individual variables are not taken to range over physical objects, but instead over individual concepts. According to this reading, the names 'Phosphorus' and 'Hesperus' stand for different but coextensive individual concepts. The identity sign is interpreted not as a genuine identity between physical objects but as coextensionality between individual concepts. That is, an identity statement '$u = v$' is true if and only if the terms 'u' and 'v' stand for coextensive individual concepts. According to this interpretation, (6) and (7) mean:

(6′) There is an individual concept x which actually coincides with the individual concept Hesperus but does not do so by analytical necessity.

(7′) There is an individual concept x which not only happens to coincide with the individual concept Hesperus but does so by analytic necessity.

No contradiction ensues from these two statements. The price for this interpretation, however, seems to be as Quine expresses it: "a curiously idealistic ontology which repudiates material objects".

1.4 The advent of possible worlds semantics

1.4.1 Semantics for quantified modal logic in 1957: Hintikka and Kanger

1957 was a pivotal year in the history of modal logic.[6] In that year Stig Kanger published his dissertation *Provability in Logic* and a number of other papers where he outlined a new model-theoretic semantics for quantified modal logic. In the same year, Jaakko Hintikka published two papers on the semantics of quantified modal logic: 'Modality as referential multiplicity' and 'Quantifiers in deontic logic' (Hintikka [39, 40]). There are some striking parallels between these works by Hintikka and Kanger, but there are also notable differences.

Hintikka and Kanger had both done important and closely similar work in non-modal predicate logic. Using so-called model sets (nowadays often called "Hintikka sets" or "downward saturated sets") for predicate logic, Hintikka [38] had developed a new complete and effective proof procedure for predicate logic.

Let $\mathcal{L}$ be a language of predicate logic with identity and let U be a non-empty set of individual constants that do not belong to $\mathcal{L}$. A *model set* (over U) is a set m of sentences of the expanded language $\mathcal{L}_U$ satisfying the following conditions:[7]

$(C.\neg)$	if $\neg\varphi \in m$, then $\varphi \notin m$,
$(C.\neg\neg)$	if $\neg\neg\varphi \in m$, then $\varphi \in m$,
$(C.\wedge)$	if $\varphi \wedge \psi \in m$, then $\varphi \in m$ and $\psi \in m$,
$(C.\neg\wedge)$	if $\neg(\varphi \wedge \psi) \in m$, then $\neg\varphi \in m$ or $\neg\psi \in m$,
$(C.\forall)$	if $\forall x\varphi \in m$, then for every constant a in U, $\varphi(a/x) \in m$,
$(C.\neg\forall)$	if $\neg\forall x\varphi \in m$, then for some constant a in U, $\neg\varphi(a/x) \in m$,
$(C.=)$	for no individual constant a in $\mathcal{L}_U, a \neq a \in m$,
$(C.\mathrm{Ind})$	if $\varphi(a/x) \in m$, where φ is atomic, and $a = b \in m$, then $\varphi(b/x) \in m$.

Hintikka showed, what nowadays goes under the name *Hintikka's lemma*, namely, that a set Γ of sentences is satisfiable (true in some Tarski-style model) iff it can be imbedded in a model set over some non-empty set U of (new) individual constants. Furthermore, he provided an effective proof procedure for classical predicate logic. The method is very similar to the nowadays more familiar semantic tableaux method of Beth [11].

Hintikka [38, p. 47] points out that there is a close connection between his proof procedure and proofs in Gentzen's sequent calculus. The systematic search for a counterexample of a formula φ corresponds to the backward application of the rules of Gentzen's

[6] See [24] for a comprehensive historical account of the development of possible worlds semantics. For a mathematical exposition of the development of modal logic, see [36]).

[7] Here we have assumed that $\neg$, $\wedge$ and $\forall$ are primitive and that $\vee$, $\rightarrow$ and $\exists$ are introduced as abbreviations in the usual way. For other choices of primitive logical constants, the definition of a model set has to be adjusted accordingly.

cut-free calculus for predicate logic. As a matter of fact, Kanger in *Provability in Logic* [53] provided an elegant effective proof procedure for classical predicate logic based on a sequent calculus that is equivalent to Hintikka's.

Hintikka's formal semantics for modal logic. When studying classical predicate logic, Hintikka and Kanger used strikingly similar techniques and obtained similar results. However, their approaches to modal logic were different. Kanger started out from the work of Tarski and set himself the task of extending the method of Tarski-style truth-definitions to predicate languages with modal operators. Hintikka, on the other hand, generalised his method of model sets to the case of modal logic. In doing so he invented the notion of a *model system*. Roughly speaking, a model system consists of a set Ω of model sets and a binary relation R defined between the members of Ω. Different versions of Hintikka's semantics impose different conditions on model sets, but in order simplify the exposition, we can say that a model system is an ordered pair $\mathcal{S} = \langle \Omega, R \rangle$, such that:

(a) Ω is a non-empty set of model sets for $\mathcal{L}$,

(b) R is a binary relation between the members of Ω (the alternativeness relation),

(c) for all $m \in \Omega$, if $\Box\varphi \in m$, then for all $n \in \Omega$ such that $mRn, \varphi \in n$,

(d) for all $m \in \Omega$, if $\neg\Box\varphi \in m$, then $\neg\varphi \in n$, for some $n \in \Omega$ such that mRn.

Hintikka thought of the members of Ω as partial descriptions of possible worlds. A set Γ of sentences is *satisfiable* (in the sense of Hintikka) iff there exists a model system $\mathcal{S} = \langle \Omega, R \rangle$ and a model set $m \in \Omega$ such that $\Gamma \subseteq m$. A sentence φ is valid iff the set $\{\neg\varphi\}$ is not satisfiable.

Hintikka [40] sketched a tableaux-style method of proving completeness theorems in modal logic. The idea is a generalisation of his proof procedure for first order logic. Hintikka [41] states (without formal proofs) that the systems **T**, **B**, **S4**, **S5** for sentential logic are sound and complete with respect to the Hintikka-style semantics where R is assumed to be reflexive, symmetric, reflexive and transitive and an equivalence relation, respectively. Rigorous completeness proofs using the tableaux method were published by Kripke, [64], for the case of quantified S5, and for numerous systems of propositional modal logic in [67, 68].[8]

An important difference between Hintikka's semantics for modal logic, on the one hand, and the ones developed by Carnap, Kanger and Montague [83], on the other, is that Hintikka allows the space of possibilities Ω to vary from one system to another. The only requirement is that Ω is a non-empty set satisfying the constraints (b), (c) and (d) above. In the formal semantics of Carnap, Kanger and Montague, on the other hand, the space of possibilities is fixed once and for all to be the set of all state descriptions (Carnap), the class of all systems (or alternatively, domains) (Kanger), or all first-order models over a given domain (Montague). One could say that Carnap, Kanger and Montague only allow interpretations of modalities that are in a sense *standard* and disallow *non-standard interpretations*. Thus, the relationship between Hintikka's semantics (and the one later developed by Kripke) and the ones developed by Carnap, Kanger and Montague is analogous to that between *standard* and *non-standard* semantics for higher-order

[8]In [65], Kripke announces a great number of completeness results in modal propositional logic. He also notes "For systems based on **S4**, **S5**, and **M**, similar work has been done independently and at an earlier date by K. J. J. Hintikka".

predicate logic. This distinction between the various approaches has been emphasised by Cocchiarella [23] and Hintikka [46]. Allowing non-standard interpretations for modal logics, of course, facilitated the proofs of completeness results, since the logics for logical or analytical necessity corresponding to the standard semantics are in general not recursively enumerable.

Kanger's Tarski-style semantics for quantified modal logic. Kanger's ambition was to provide a language of quantified modal logic with a model-theoretic semantics à la Tarski.[9]

A Tarski-style interpretation for a first-order predicate language $\mathcal{L}$ consists of a non-empty domain D and an assignment of appropriate extensions in D to every non-logical symbol and variable of $\mathcal{L}$. Kanger's basic idea was to relativise the notion of extension to various possible domains. In other words, he thought of an interpretation for a given language $\mathcal{L}$ as a *function* that *simultaneously* assigns extensions to the non-logical symbols and variables of $\mathcal{L}$ for *every* possible domain. Such a function Kanger called a (*primary*) *valuation*. Formally, a valuation for a language L of quantified modal logic is a function v which for *every* non-empty domain D assigns an appropriate extension in D to every individual constant, individual variable, and predicate constant in $\mathcal{L}$. Kanger also introduced the notion of a *system* $\mathcal{S} = \langle D, v\rangle$ consisting of a designated domain D and a valuation v. Notice that v does not only assign extensions to symbols relative to the designated domain D, but relative to *all* domains simultaneously.

Kanger then defined the notion of a formula φ being *true in a system* $\mathcal{S} = \langle D, v\rangle$ (in symbols, $\mathcal{S} \vDash \varphi$):

(1) $\mathcal{S} \vDash (t_1 = t_2)$ iff $v(D, t_1) = v(D, t_2)$,

(2) $\mathcal{S} \vDash P(t_1, \ldots, t_n)$ iff $\langle v(D, t_1), \ldots, v(D, t_n)\rangle \in v(D, P)$,

(3) $\mathcal{S} \nvDash \bot$,

(4) $\mathcal{S} \vDash (\varphi \to \psi)$ iff $\mathcal{S} \nvDash \varphi$ or $\mathcal{S} \vDash \psi$

(5) $\langle D, v\rangle \vDash \forall x\varphi$ iff $\langle D, v'\rangle \vDash \varphi$, for each v' such that $v' =_x v$,

(6) for every operator $\Box, \mathcal{S} \vDash \Box\varphi$ iff $\forall \mathcal{S}'$, if $\mathcal{S} R_\Box \mathcal{S}'$, then $\mathcal{S}' \vDash \varphi$.

Explanation: v' is like v except possibly at x (also written, $v' =_x v$) if and only if, for every domain U and every variable y other than $x, v'(U, y) = v(U, y)$. In the above definition, $R_\Box$ is a binary relation between systems that is associated with the modal operator $\Box$. $R_\Box$ is what is nowadays called the *accessibility relation* associated with the operator $\Box$. Kanger points out that by imposing certain formal requirements on the accessibility relation, like reflexivity, symmetry, transitivity, etc., one can make the operator satisfy corresponding well-known axioms of modal logic.

One source of inspiration for Kanger's use of accessibility relations in modal logic was no doubt the work of Jónsson and Tarski [52] on representation theorems for Boolean algebras with operators.[10] Jónsson and Tarski define operators $\Diamond$ on arbitrary subsets X of a set U in terms of binary relations $R \subseteq U \times U$ in the following way:

$$\Diamond X = \{x \in U : \exists y \in X(yRx)\},$$

[9] Cf. Kanger [53, 54, 55, 56, 57]). See also Lindström [81] for a more extensive discussion of Kanger's approach to quantified modal logic.

[10] On [53, p. 39] Kanger makes an explicit reference to Jónsson and Tarski [52].

that is $\Diamond X$ is the image of X under R. They also point to correspondences between properties of $\Diamond$ and properties of R. Among other things, they prove a representation theorem for so-called closure algebras that, via the Tarski-Lindenbaum construction, yields the completeness theorem for propositional **S4** with respect to Kripke models with a reflexive and transitive accessibility relation. However, Jónsson and Tarski do not say anything about the relevance of their work to modal logic.

Among the modal operators in $\mathcal{L}$, Kanger introduced two designated ones, **N** ("analytic necessity") and **L** ("logical necessity"), with the following semantic clauses:

$$\langle D, v\rangle \models \mathbf{N}\varphi \text{ iff for every domain } D', \langle D', v\rangle \models \varphi$$
$$\langle D, v\rangle \models \mathbf{L}\varphi \text{ iff for every system } \mathcal{S}, \mathcal{S} \models \varphi.$$

A formula φ is *true* in a system $\langle D, v\rangle$ iff $\langle D, v\rangle \models \varphi$. A formula φ is said to be *valid (logically true)* if it is true in every system $\langle D, v\rangle$. A formula φ is a *logical consequence* of a set Γ of formulæ (in symbols, $\Gamma \models \varphi$) if φ is true in every system in which all the formulæ in Γ are true.

In order to get a clearer understanding of Kanger's treatment of quantification, we shall speak of selection functions that pick out from each domain an element of that domain as *individual concepts*. We can think of a system $\mathcal{S} = \langle D, v\rangle$ as assigning to each individual constant c the individual concept $\{\langle D, v(D, c)\rangle : D \text{ is a domain}\}$ and to each variable x the individual concept $\{\langle D, v(D, x)\rangle : D \text{ is a domain}\}$. The formula $P(t_1, \ldots, t_n)$ is true in $\mathcal{S} = \langle D, v\rangle$ if and only if the individual concepts designated by $t_1, \ldots, t_n$ pick out objects in the domain D that stand in the relation $v(D, P)$ to each other. The identity symbol designates the relation of *coincidence* between individual concepts (at the "actual" domain D). That is, $t_1 = t_2$ is true in a system $\mathcal{S} = \langle D, v\rangle$ if and only if the individual concepts designated by t_1 and t_2, respectively, pick out one and the same object in the domain D of $\mathcal{S}$.

The universal quantifier $\forall x$ can now be thought of as an objectual quantifier that ranges not over the "individuals" in the "actual" domain D, but over the (constant) domain of all individual concepts. That is, $\forall x\varphi$ is true in a system $\langle D, v\rangle$ if and only if φ is true in every system that is exactly like $\langle D, v\rangle$ except, possibly, for the individual concept that it assigns to the variable x.

Kanger's solution to Quine's paradox of identity is essentially the same as Carnap's. Quine's objection to Kanger would therefore be the same as to Carnap: Kanger's quantifiers do not range over ordinary individuals but over individual concepts instead. Moreover, Kanger's treatment of quantification in modal contexts does not provide any means of *identifying* individuals from one domain to another. Hence there is no way of saying in Kanger's modal language that *one and the same* individual has a property P and possibly could have lacked P. That is, neither Carnap's nor Kanger's semantics can account for modality *de re*.

1.4.2 Hintikka's response to Quine's challenge

Quine's interpretational challenge seemed to place the advocates of quantified modal logic in a dilemma. They would either have to accept standard quantification theory (with the usual laws of universal instantiation, existential generalisation and indiscernibility of identicals) and reject quantified modal logic, or accept a quantified modal logic, where the quantifiers were interpreted in a non-standard way à la Carnap as ranging over

intensional entities (individual concepts), rather than over robust extensional entities as Quine would demand.

Hintikka [39, 40], however, rejected the terms in which Quine's interpretational challenge was stated. First of all he broadened the discussion by not only considering the logical modalities and Quine's metalinguistic interpretation of these, but also epistemic modalities ('It is known that φ') and deontic ones ('It is obligatory that φ'). He then introduced the idea of *referential multiplicity*. In answer to Quine's question whether a certain occurrence of a singular term in a modal context is purely referential, and thus open to substitution and existential generalisation, or non-referential, in which case substitution and existential generalisation would fail according to Quine, Hintikka [39] pointed to a third possibility. According to the classical Fregean approach [32] singular terms would in non-extensional contexts not have their standard reference but instead refer to intensional entities, their ordinary senses. Hintikka saw no need to postulate special intensional entities for the singular terms to refer to in non-extensional contexts. The failure of substitutivity was instead explained by the referential multiplicity of the singular terms and by the fact that in intensional contexts the reference of the terms in various alternative courses of events ("possible worlds") is considered simultaneously.

Informally Hintikka [39] expressed the basic ideas behind the possible worlds interpretation of modal logic in the following words:

> ...we often find it extremely useful to try to chart the different courses the events may take even if we don't know which one of the different charts we are ultimately going to make use of. ...This analogy is worth elaborating. The concern of a general staff is not limited to what there will actually be. Its business is not just to predict the course of a planned campaign, but rather to be prepared for all the contingencies that may crop up during it. ...Most of the maps prepared by the general staff represent situations that will never take place. ...There are for the most parts some actual units for which the marks on the map stand, and the mutual positions of the units are such that the situation could conceivably arise. ...But the location of the units on the maps may be different from the locations the units have or ever will have. Some of the marks may stand for units which have not yet been formed; other maps may be prepared for situations in which some of the existing units have been destroyed. All these features have their analogues in modal logic.

In this example Hintikka informally speaks of the same units as occurring in different situations ("cross-world identification of individuals") and of individuals coming into existence or disappearing as one goes from one situation to another ("varying domains").

Hintikka goes on to explain the bearing of the above example on referential opacity.

> We may perhaps say that when we are doing modal logic, we are doing more than one thing at one and the same time. We use certain symbols — constants and variables — to refer to the actually existing objects of our domain of discourse. But we are also using them to refer to the elements of certain other states of affairs that need not be realized. Or, which amounts to the same, we are employing these symbols to build up 'maps' or models for the purpose of sketching certain situations that will perhaps never take place. If we could confine our attention to one of these possible states of affairs at a time, the occurrences of our symbols would be purely referential. The

> interconnections between the different models interfere with this. But since the symbols are purely referential within each particular model, the deviation from pure referentiality is not strong enough to destroy the possibility of employing quantifiers with pretty much the same rules as in the ordinary quantification theory. If I had to characterize the situation briefly, I should say that the occurrences of our terms in modal contexts are not usually *purely referential*, but rather that they are *multiply referential*.

This idea of referential multiplicity is perhaps the basic intuitive idea behind the possible worlds interpretation of modal notions and of indexical semantics in general. It seems that Hintikka here gives one of the earliest, or perhaps the earliest, clear expression of the idea.

Hintikka's semantics for quantified modal logic is informally interpreted in such a way that the quantifiers range over genuine individuals. Thus, Hintikka has a notion of cross-world identification: one and the same individual may occur in different worlds. However, the semantics allows individuals to *split* from one world to another, i.e., the individuals a and b may be identical in one world w_0 but they may fail to be identical in some alternative world to w_0. Thus, the principle:

$$(\Box =) \quad \forall x \forall y(x = y \to \Box(x = y)), \quad (\textit{Necessity of Identity})$$

is not valid in Hintikka's semantics. As a consequence, the unrestricted principle of indiscernibility of identicals does not hold in modal contexts according to Hintikka (cf., Hintikka [41] and later writings).

Hintikka's solution to Quine's paradox of identity. There are two cases to consider:

(1) One or the other of the singular terms under consideration ('Hesperus' or 'Phosphorus') is not a "rigid designator", that is it does not designate the same individual in every possible world (or "scenario") under consideration. Then, existential generalisation fails and Quine's paradoxical argument does not go through.

(2) Each of the two names picks out "the same" individual in every world under consideration. However, some scenario w under consideration is such that the individual Hesperus in w is distinct from the individual Phosphorus in w. In this case, Quine's argument goes through, but Hintikka has to argue that the conclusion:

(6) $\exists x(x = \text{Hesperus} \land \neg\Box(x = \text{Hesperus}))$

(7) $\exists x(x = \text{Hesperus} \land \Box(x = \text{Hesperus}))$,

contrary to appearance, is not absurd, since an individual can "split" when we go from one possible scenario to one of its alternatives. Consider for example:

> Superman and Clark Kent are in fact identical, but Lois Lane doesn't believe that they are identical.

Hintikka may explain the apparent truth (according to the story) of this sentence by the fact that some scenarios (possible worlds) in which Superman and Clark Kent are different individuals are among Lois Lane's doxastic alternatives in the actual world (where they are identical).

1.4.3 Montague's early semantics for quantified modal logic

A semantic approach to first-order modal predicate logic that has a certain resemblance to Kanger's was developed by Montague [83].[11] Like Kanger, Montague starts out from the standard model-theoretic semantics for non-modal first-order languages and extends it to languages with modal operators. He defines an *interpretation* for an ordinary first-order predicate language $\mathcal{L}$ to be a triple $\mathcal{I} = \langle D, I, g\rangle$, where (i) D is a non-empty set (the *domain*); (ii) I is a function that assigns appropriate denotations in D to the non-logical constants (predicate symbols and individual constants) of $\mathcal{L}$; and (iii) a function g (an *assignment* in D) that assigns values in D to the individual variables of $\mathcal{L}$. For each non-logical constant or variable X, let $\mathcal{I}(X)$ be the *semantic value* (i.e., *denotation* for non-logical constants and *value* for variables) of X in the interpretation $\mathcal{I}$. Then the notion of *truth* relative $\mathcal{I}$ is defined as follows:

(1) $\mathcal{I} \vDash P(t_1, \ldots, t_n)$ iff $\langle \mathcal{I}(t_1), \ldots, \mathcal{I}(t_n)\rangle \in \mathcal{I}(P)$,

(2) $\mathcal{I} \vDash (t_1 = t_2)$ iff $I(t_1) = I(t_2)$,

(3) $\mathcal{I} \vDash \neg\varphi$ iff $\mathcal{I} \nvDash \varphi$,

(4) $\mathcal{I} \vDash (\varphi \to \psi)$ iff $\mathcal{I} \nvDash \varphi$ or $\mathcal{I} \vDash \psi$,

(5) $\mathcal{I} \vDash \forall x\varphi$ iff for every object $a \in D, \mathcal{I}(a/x) \vDash \varphi$.

Here, $\mathcal{I}(a/x)$ is the interpretation that is exactly like $\mathcal{I}$, except for assigning the object a to the variable x as its value.

Montague now asks the same question as Kanger: How can this definition of the truth-relation be generalised to first-order languages with modal operators? As we recall, Kanger solved the problem by modifying the notion of an interpretation: a Kanger-type interpretation (what he called 'a system') assigns denotations to the non-logical constants and values to the variables not only for one single domain (the 'actual' one) but for all domains in one fell swoop. Montague's approach is simpler than Kanger's: he keeps the notion of an interpretation $\mathcal{I}$ of first-order logic intact, and just adds semantic evaluation clauses for the modal operators. As in the Kanger semantics, each modal operator $\Box$ is associated with an accessibility relation $R_\Box$. Now, however accessibility relations are relations between interpretations $\mathcal{I} = \langle D, I, g\rangle$ of the underlying non-modal first-order language. The semantic clause corresponding to the operator $\Box$, with associated accessibility relation $R_\Box$, is:

(6) $\mathcal{I} \vDash \Box\varphi$ iff for every interpretation $\mathcal{I}'$ such that $\mathcal{I}R_\Box\mathcal{I}', \mathcal{I}' \vDash \varphi$.

Montague associates with the operator **L** of *logical necessity* the accessibility relation R_L defined by:

$$\langle D, I, g\rangle R_L \langle D', I', g'\rangle \text{ iff } D = D' \text{ and } g = g'.$$

Thus, his semantic clause for **L** becomes:

[11] Montague [83] writes: "The present paper was delivered before the Annual Spring Conference in Philosophy at the University of California, Los Angeles, in May, 1955. It contains no results of any great technical interest; I therefore did not initially plan to publish it. But some closely analogous, though not identical, ideas have recently been announced by Kanger [54, 55] and by Kripke in [64]. In view of this fact, together with the possibility of stimulating further research, it now seems not wholly inappropriate to publish my early contribution."

(7) $\langle D, I, g\rangle \vDash \mathbf{L}\varphi$ iff for every I' defined over D, $\langle D, I', g\rangle \vDash \varphi$.

That is, $\mathbf{L}\varphi$ is true in an interpretation $\mathcal{I}$ iff φ is true in every interpretation $\mathcal{I}'$ that is like $\mathcal{I}$ except for, possibly, assigning different semantic values to the non-logical constants of $\mathcal{L}$.

Stated in contemporary terms, Montague's semantic clause for the logical necessity operator becomes:

(8) $\mathbf{L}\varphi$ is true in a model $\mathcal{M} = \langle D, I\rangle$ relative to an assignment g iff for every model $\mathcal{M}'$ with domain D, φ is true in $\mathcal{M}'$ relative to g.

Let us say that a formula φ of $\mathcal{L}$ is *D-valid relative to g* iff for every model $\mathcal{M}$ with domain D, φ is true in $\mathcal{M}$ relative to g. We say that φ is *D-valid* iff it is D-valid relative to every assignment g in D. Then, from Montague's semantic clause for $\mathbf{L}$, we can conclude:

(9) $\mathbf{L}\varphi$ is true in $\mathcal{M} = \langle D, I\rangle$ relative to g iff φ is D-valid relative to g.

and

(10) $\mathbf{L}\varphi$ is true in $\mathcal{M} = \langle D, I\rangle$ iff φ is D-valid.

We say that a formula φ of $\mathcal{L}$ is *logically true* iff it is D-valid in every non-empty domain D.

Montague's [83] semantics for $\mathbf{L}$ is exactly what Cocchiarella [23] refers to as the "primary semantics" for logical necessity. Hence, we can reformulate Cocchiarella's [23] *incompleteness theorem* for that semantics as follows:

THEOREM 2. *Suppose that $\mathcal{L}$ contains at least one binary predicate symbol. Then, the set of logically true sentences in Montague's [83] semantics for logical necessity is not recursively enumerable. Thus, Montague's [83] logic for logical necessity is not axiomatizable.*

Montague's solution to Quine's paradox of identity. According to Montague's interpretation, $\mathbf{L}\varphi$ is logically equivalent with a *formula of second-order predicate logic* $()\varphi$, where $()$ stands for a string of universal quantifiers that bind all non-logical symbols in φ. In other words, Montague's semantics induces a translation from first-order modal logic to extensional second-order predicate logic. According to Montague's semantics from [83], the quantifier $\forall x$ is interpreted as a genuine quantifier over individuals. Free variables are "directly referential", i.e., a free variable is interpreted uniformly inside a formula as standing for one and the same individual regardless of where in the formula it occurs. Individual constants, on the other hand, are reinterpreted freely from one interpretation to another.

Montague's semantics validates the following principles without restrictions:

(LI) $\forall x(x = x)$, *(Law of Identity)*
(I=) $\forall x\forall y(x = y \rightarrow (\varphi(x/z) \rightarrow \varphi(y/z)))$. *(Indiscernibility of Identicals)*

In addition, we have: $\forall x\mathbf{L}(x = x)$. Therefore, the following principle is valid:

($\Box$I) $\forall x\forall y(x = y \rightarrow \mathbf{L}(x = y))$. *(Necessity of Identity)*

But the following is not valid:

$$\text{Phosphorus} = \text{Hesperus} \rightarrow \mathbf{L}(\text{Phosphorus} = \text{Hesperus}).$$

It follows that the principles of *Universal Specification* (US) and *Existential Generalisation* (EG) are not valid. Thus, Quine's paradoxical argument (Section 1.3, (1)–(7)) cannot be carried through within Montague's logic. Although (US) and (EG) cannot be applied to individual constants, they do hold for variables.

It appears that Montague's semantical interpretation satisfies all requirements imposed by Quine [92] on an interpretation of quantified modal logic for the logical modalities. However, Montague's semantics still has counterintuitive consequences. Consider, for instance, the following proof of the thesis that *everything there is exists necessarily*:

(1) $\forall x \exists y(x = y)$ predicate logic

(2) $\mathbf{L}\forall x \exists y(x = y)$ from (1) by necessitation

(3) $\forall x \exists y(x = y) \rightarrow \exists y(x = y)$ universal specification (US) (for variables)

(4) $\mathbf{L}(\forall x \exists y(x = y) \rightarrow \exists y(x = y))$ from (3) by necessitation

(5) $\mathbf{L}\exists y(x = y)$ from (2) and (4) by modal logic

(6) $\forall x \mathbf{L}\exists y(x = y)$ from (5) by universal generalization (UG)

This proof is valid according to Montague's semantics: line (1) is logically true and the steps in the proof preserve logical truth. It is also easy to see directly that the conclusion (6) of the argument is logically true according to Montague's definition. This conclusion, however, is extremely counterintuitive (provided we read the quantifiers in the normal way as ranging over ordinary objects). Intuitively, it is simply false that everything there is exists necessarily. Hence, there are still problems with Montague's semantics. We shall return to the above problematic argument in connection with Kripke's [66] possible worlds semantics.

It should also be noted that Montague's semantics validates the schema:

(I) $\exists x \mathbf{L}\varphi(x) \leftrightarrow \forall x \mathbf{L}\varphi(x)$.

i.e., φ holds necessarily of one thing just in case φ holds necessarily of everything. Moreover, the semantics validates the Barcan schema and its converse:

(BF) $\forall x \mathbf{L}\varphi(x) \rightarrow \mathbf{L}\forall x \varphi(x)$
(CBF) $\mathbf{L}\forall x \varphi(x) \rightarrow \forall x \mathbf{L}\varphi(x)$.

From (1), (BF) and (CBF) we infer:

(II) $\exists x \mathbf{L}\varphi(x) \leftrightarrow \mathbf{L}\forall x \varphi(x)$.

That is, a property holds necessarily of one thing just in case it is necessary that it holds of everything.

According to Montague's semantics the logically necessary properties are the same for everything; namely, just those properties that by logical necessity hold of everything. That is, Montague's semantics is *essentialist* in the weak Quinean sense of distinguishing between properties that hold necessarily of a thing and properties that hold only contingently of it. But it rejects the *strong essentialist thesis* that there are properties that some objects have necessarily and others do not have at all, or have only contingently

(cf. [8, 89]).[12] Hence, condition (I) seems to be correct, as long as we speak of logical necessity. Logic does not discriminate between individuals, so if F is a logically necessary property of one thing, it is a logically necessary property of everything there is.[13]

The Barcan formula and its converse, however, are dubious. Consider first (BF). Suppose that a is the only thing that exists. Then, $\forall x\mathbf{L}(x = a)$. However, it does not seem intuitively correct to infer: $\mathbf{L}\forall x(x = a)$. Next, consider (CBF). Clearly, $\mathbf{L}\forall x\exists y(x = y)$. If (CBF) were valid, we could infer $\forall x\mathbf{L}\exists y(x = y)$, which — as we have already pointed out — is counterintuitive. We will return to the semantic significance of (BF) and (CBF) in Section 1.4.4. Finally, condition (II) is clearly counterintuitive. Burgess [14] says of (II) that it "could silence any critic who claimed the notion of *de re* modality to be more obscure than that of *de dicto* modality, but would do so only at the cost of making *de re* notation pointless".

1.4.4 Kripke's semantics for quantified modal logic

Kripke 1959. The possible worlds semantics introduced by Kripke [64] may be cast in the following form (which differs from Kripke's original formulation in terminology as well as in some minor details). We consider a language $\mathcal{L}$ of modal predicate logic with identity containing for each $n \geq 1$, a denumerably infinite list of n-ary predicate symbols, but no function symbols or individual constants. Let D be a non-empty set. We define a *valuation* for $\mathcal{L}$ over D to be a function V which to every n-ary predicate symbol $P(n \geq 1)$ in $\mathcal{L}$ assigns a value $V(P) \subseteq D^n$. An *assignment* in D is a function g which to every individual variable x assigns a value $g(x) \in D$. A model over D is an ordered pair $\mathcal{M} = \langle \mathbf{K}, V_0 \rangle$ such that (i) $\mathbf{K}$ is a set of valuations for $\mathcal{L}$ over D, and (ii) $V_0 \in \mathbf{K}$.

Given a model $\mathcal{M} = \langle \mathbf{K}, V_0 \rangle$ over D, an evaluation V in $\mathbf{K}$, assignment g in D, and formula φ we define recursively what it means for φ to be *true in V relative to $\mathcal{M}$ and g* (in symbols: $V \vDash_M \varphi[g]$):

(1) $V \vDash_{\mathcal{M}} P(x_1, \ldots, x_n)[g]$ iff $\langle g(x_1), \ldots, g(x_n) \rangle \in V(P)$,

(2) $V \vDash_{\mathcal{M}} (x = y)[g]$ iff $g(x) = g(y)$,

(3) $V \vDash_{\mathcal{M}} \neg\varphi[g]$ iff $V \nvDash_{\mathcal{M}} \varphi[g]$,

(4) $V \vDash_{\mathcal{M}} (\varphi \to \psi)[g]$ iff $V \nvDash_{\mathcal{M}} \varphi[g]$ or $V \vDash_{\mathcal{M}} \psi[g]$,

(5) $V \vDash_{\mathcal{M}} \forall x\varphi[g]$ iff for every object $a \in D, V \vDash_{\mathcal{M}} \varphi[g(a/x)]$,

(6) $V \vDash_M \Box\varphi$ iff for every valuation V' in $\mathbf{K}$, $V' \vDash_{\mathcal{M}} \varphi$.

As usual, $g(a/x)$ is the assignment that is exactly like g except for assigning a to the variable x.

[12]See also Kaplan's [61] penetrating analysis of the distinction between logical and metaphysical necessity. According to Kaplan, logical necessity is committed to a *benign* form of Aristotelian essentialism that "makes a specification of an individual essential only if it is logically true of that individual". Metaphysical necessity, on the other hand, is *invidious*, since it allows for distinct individuals to have different essential properties.

[13]On the other hand, (I) is clearly counterintuitive for metaphysical necessity. Let, for example, $\varphi(x)$ be the formula '$(\exists y(y = x) \to x \in \{\text{Socrates}\})$' and let $\Box$ stand for metaphysical necessity. Then, $\Box\varphi(\text{Socrates})$ is true. Socrates is a member of {Socrates}, in every possible world where Socrates exists. But, of course, $\Box\varphi(\text{Plato})$ is false. Thus (I) fails for metaphysical necessity.

We say that φ is *true in $\mathcal{M}$ relative to g* if $V_0 \vDash_{\mathcal{M}} \varphi[g]$. φ is *true in $\mathcal{M}$* if $V_0 \vDash_M \varphi[g]$ for every assignment g in D. φ is *valid in the domain D* if φ is true in all models $\mathcal{M}$ over D. φ is *universally valid* if φ is valid in every non-empty domain D (i.e., just in case φ is true in every model $\mathcal{M}$).

Kripke gives the following intuitive motivation for this semantics: The valuations in **K** are thought of as representing the set of all "possible" (or "conceivable" or "imaginable") worlds. The valuation V_0 represents the "real" world. It is assumed that the set D of individuals is the same for all possible worlds. Necessity is defined as truth in all possible worlds.

Kripke's [64] semantics validates all the classically valid schemata of first-order predicate logic with identity, the characteristic axioms of **S5**, as well as the Barcan formula (BF) and its converse (CBF). The set of valid sentences is closed under modus ponens, uniform substitution, necessitation, and universal generalization. In [64], Kripke defines a formal system $\mathbf{S5}^{*=}$ for quantified modal logic and proves using semantic tableaux methods that it is sound and complete for the given semantics.

Let us now compare Kripke's [64] semantics with Montague's semantics [83] for logical necessity. Let us say that a Kripke [64] model $\mathcal{M} = \langle \mathbf{K}, V_0 \rangle$ over a non-empty domain D is *maximal* if **K** contains all valuations for $\mathcal{L}$ over D.[14]

Montague's semantics for logical necessity differs from Kripke's [64] semantics in considering maximal models only. We obtain Montague's semantics for logical necessity by imposing the requirement on Kripke's [64] models that the set **K** should contain all valuations V for $\mathcal{L}$ over D. Hence, a sentence φ of $\mathcal{L}$ is logically true in Montague's [83] semantics for logical necessity iff it is true in all maximal Kripke [64] models. By restricting our attention to maximal models, we get what Cocchiarella [23] calls the "primary semantics" for logical necessity.

At this point it is natural to ask what intended interpretation Kripke had in mind for the necessity operator in 1959. Was it logical necessity, analytical necessity, or perhaps some kind of metaphysical necessity? One reason for thinking that Kripke's notion of necessity in 1959 was not logical necessity is his use of models that are non-maximal (or "non-standard" in the terminology of Hintikka [46]). Instead of working with all models or valuations over D, like Montague, or with all possible systems as Kanger, Kripke is considering an arbitrary non-empty subset of all possible valuations. This feature of his models may suggest that Kripke's intended interpretation of the necessity operator is not strict logical necessity, but perhaps instead some kind of metaphysical necessity. This conclusion is however, not unavoidable: Kripke's intended interpretation of the necessity operator could still have been logical necessity and his *intended interpretations* could still be some or all of the *maximal models*. Kripke's reason for allowing non-maximal models, in addition to maximal ones, when defining validity, could have been logical rather then philosophical.[15] If Kripke, like Kanger and Montague, had chosen to work only with maximal models, the set of valid sentences would not have been recursively enumerable and there would be no completeness theorem to be proved. Kripke's intended model could, for instance, be a maximal model over some infinite set. A modal sentence of an interpreted language of modal predicate logic would then be *true* if it was true in the

[14] The term "maximal model" was introduced by Parsons [89] in connection with Kripke's [66] semantics for quantified logic. It is less tendentious than Hintikka's term "standard model".

[15] Ballarin [4] argues that Kripke's development of his possible worlds semantics was driven entirely "by formal considerations, not interpretive concerns".

intended model. Interpreted in this way, Kripke's 1959 approach would be very close to Montague's of 1960. The only essential difference would be Kripke's use of non-standard models in addition to the standard ones for the purpose of defining a notion of universal validity that is recursively enumerable.

On the other hand, in [64, p. 3], Kripke speaks of **K** as representing the set of all "conceivable" worlds. He writes "... a proposition $\Box B$ is evaluated as true when and only when B holds in all conceivable worlds". This seems to indicate that Kripke's operator $\Box$ of [1959] should not be interpreted as strict logical necessity. It is very likely that the set of valuations representing all "conceivable" worlds is a proper subset of the set of absolutely all valuations. Thus Kripke may have had philosophical reasons, in addition to formal ones, for favouring a "non-standard" semantics allowing non-maximal models to a "standard" one.[16]

Kripke 1963. We present a version of Kripke's [66] semantics for modal predicate logic with identity, where the notion of a possible world is an explicit ingredient of the semantic theory. We differ from Kripke [66] in letting the language $\mathcal{L}$ contain individual constants.

A (*Kripke*) *frame* (or to use Kripke's own terminology, a *model structure*) for a language $\mathcal{L}$ of first-order modal predicate logic (with identity and individual constants, but no function symbols) is a quintuple $\mathcal{F} = \langle W, D, R, E, w_0\rangle$ where, (i) W is a non-empty set; (ii) D is a non-empty set; (iii) $R \subseteq W \times W$; (iv) E is a function which to each $w \in W$ assigns a subset E_w of D; and (v) w_0 is a designated element of W. Intuitively we think of matters thus: W is the set of all (*possible*) *worlds* (possible states of affairs, possible ways the world could have been), D is the set of all (*possible*) *individuals*, R is the *accessibility relation* between worlds, for each world w, E_w is the set of *individuals that exist in* w; and w_0 is the *actual world*. It is required that $D = \bigcup_{w\in W} E_w$, i. e., that every possible individual exists in at least one world.

Next, let us say that I is an *interpretation* (in D with respect to W) if it is a family of functions I_w, where w ranges over W, such that I_w assigns a subset $I_w(P)$ of D^n to each n-ary predicate constant P of $\mathcal{L}$ and an element $I_w(c) \in D$ to each individual constant c of $\mathcal{L}$. A *Kripke model* (for $\mathcal{L}$) is an ordered pair $\mathcal{M} = \langle \mathcal{F}, I\rangle$, where $\mathcal{F} = \langle W, D, R, E, w_0\rangle$ is a frame and I is an interpretation in D with respect to W. A model $\mathcal{M}$ of the form $\langle \mathcal{F}, I\rangle$ is said to be *based on* the frame $\mathcal{F}$.

Observe that $I_w(P)$ is not necessarily a subset of $(E_w)^n$, i. e., the extension of P in w may contain individuals that do not exist in w. Nor do we require that $I_w(c) \in E_w$. An *assignment* in $\mathcal{M}$ is a function g which assigns to each variable x an element $g(x)$ in D. For any term t in $\mathcal{L}$, we define $\mathcal{M}_w(t, g)$ to be $g(t)$ if t is a variable; and $I_w(t)$ if t is an individual constant. We speak of $\mathcal{M}_w(t, g)$ as the *denotation of the term t at the world w relative to the model $\mathcal{M}$ and the assignment g.*

With these notions in place, we can define what it means for a formula φ to be *true at a world w with respect to the model $\mathcal{M}$ and the assignment g* (in symbols, $w \vDash_{\mathcal{M}} \varphi[g]$):

(1) $w \vDash_{\mathcal{M}} P(t_1, \ldots, t_n)[g]$ iff $\langle \mathcal{M}_w(t_1, g), \ldots, \mathcal{M}_w(t_n, g)\rangle \in I_w(P)$.

(2) $w \vDash_{\mathcal{M}} (t_1 = t_2)[g]$ iff $\mathcal{M}_w(t_1, g) = \mathcal{M}_w(t_2, g)$.

(3) $w \vDash_{\mathcal{M}} \neg\varphi[g]$ iff $w \nvDash_{\mathcal{M}} \varphi[g]$.

[16] Cf., however, Almog [1, p. 217], who writes about Kripke [64]: "... Kripke had at the time nothing more than "complete assignments," and the modality he worked with was definitely *logical* possibility".

(4) $w \vDash_{\mathcal{M}} (\varphi \rightarrow \psi)[g]$ iff $w \nvDash_{\mathcal{M}} \varphi[g]$ or $w \vDash_{\mathcal{M}} \psi[g]$.

(5) $w \vDash_{\mathcal{M}} \forall x\varphi[g]$ iff, for every $a \in E_w$, $w \vDash_{\mathcal{M}} \varphi[g(a/x)]$.

(6) $w \vDash_{\mathcal{M}} \Box\varphi[g]$ iff, for every $u \in W$ such that $wRu, u \vDash_{\mathcal{M}} \varphi[g]$.

We say that φ is *true with respect to the model $\mathcal{M}$ and the assignment g* (in symbols $\vDash_{\mathcal{M}} \varphi[g]$), iff φ is true at the actual world w_0 with respect to $\mathcal{M}$ and g. φ is *true in the model $\mathcal{M}$* (in symbols, $\vDash_{\mathcal{M}} \varphi$), if for every assignment $g, \vDash_{\mathcal{M}} \varphi[g]$. φ is *true in a frame $\mathcal{F}$* (in symbols, $\vDash_{\mathcal{F}} \varphi$) if φ is true in every model based on $\mathcal{F}$. Let $\mathbf{K}$ be a class of frames. We say that φ is $\mathbf{K}$*-valid* if φ is true in every $\mathcal{F} \in \mathbf{K}$.

Observe that there are two notions of validity that are naturally defined on classes of Kripke frames. With respect to the notion that we have just defined — we may call it *real-world validity* — the actual world plays a special role: a sentence φ is real-world valid in a class $\mathbf{K}$ of frames if it is true at the actual world in every frame in $\mathbf{K}$. Then, there is another notion of validity that we may call *general validity*: A sentence φ is generally valid in a class $\mathbf{K}$ just in case it is true at each world w in each frame in $\mathbf{K}$.[17] In the definition of general validity, the designated point of a Kripke model does not play any role. Thus, if we are only interested in general validity, there is no need to provide Kripke frames with designated worlds. Let us write $\vDash_{\mathbf{K}}$ and $\vDash^*_{\mathbf{K}}$ for real-world validity in $\mathbf{K}$ and general validity in $\mathbf{K}$, respectively. Then we have, for any sentence φ of $\mathcal{L}$

(1) $\vDash^*_{\mathbf{K}} \varphi$ iff $\vDash_{\mathbf{K}} \Box\varphi$

Let us say that a class $\mathbf{K}$ of Kripke frames is *normal* iff it satisfies the condition:

> Whenever $\mathcal{F}$ is in $\mathbf{K}$ and $\mathcal{F}'$ is a frame that differs from $\mathcal{F}$ only with respect to which world is the actual one, then $\mathcal{F}'$ is also in $\mathbf{K}$.

For normal classes of frames, real-world validity coincides with the general validity. Thus, for any sentence φ of $\mathcal{L}$,

(1) if $\mathbf{K}$ is normal, then $\vDash_{\mathbf{K}} \varphi$ iff $\vDash^*_{\mathbf{K}} \varphi$

The semantic import of the Barcan formula and its converse. Notice that Kripke frames in general have *varying domains*, i.e., the domains of quantification E_w are allowed to vary from one possible world to another. We say that a frame $\mathcal{F} = \langle W, D, R, E, w_0 \rangle$ has *increasing domains* iff for all $u, v \in W$, if uRv, then $E_u \subseteq E_v$. $\mathcal{F}$ has *decreasing domains* iff for all $u, v \in W$, if uRv, then $E_v \subseteq E_u$. $\mathcal{F}$ has *locally constant domains* iff for all $u, v \in W$, if uRv, then $E_u = E_v$. $\mathcal{F}$ has *globally constant domains* iff for all $u \in W, E_u = D$. We also say that F is a *constant domain frame* iff $\mathcal{F}$ has globally constant domains.

Consider now the following conditions on frames $\mathcal{F}$:

(ID) $\mathcal{F}$ has increasing domains.

(DD) $\mathcal{F}$ has decreasing domains.

(LCD) $\mathcal{F}$ has locally constant domains.

[17] Cf. [51, 22–24], for a comparison between the two concepts of logical truth (validity) and for the history of the distinction between the two.

(CBF) Every instance of the converse Barcan formula: $\Box\forall x\varphi(x) \to \forall x\Box\varphi(x)$, is generally valid in every model based on $\mathcal{F}$.

(BF) Every instance of the Barcan formula: $\forall x\Box\varphi(x) \to \Box\forall x\varphi(x)$, is generally valid in every model based on $\mathcal{F}$.

(CBF + BF) Every instance of the Barcan formula and its converse is generally valid in every model based on $\mathcal{F}$.

There is an exact correspondence between the conditions (ID), (DD), (LCD) and (CBF), (BF) and (CBF + BF), respectively (cf. [30]). That is:

(i) $\mathcal{F}$ has increasing domains iff it satisfies (CBF).

(ii) $\mathcal{F}$ has decreasing domains iff it satisfies (BF).

(iii) $\mathcal{F}$ has locally constant domains iff it satisfies (CBF + BF).

Moreover,

(iv) A sentence is generally valid in the class of all constant domain frames iff it is generally valid in all locally constant domain frames.

We may introduce an *existence predicate* **E** as a new logical constant and give it the semantic clause:

$$w \vDash_{\mathcal{M}} \mathbf{E}(t)[g] \text{ iff } \mathcal{M}_w(t,g) \in E_w.$$

However, this is unnecessary as long as we have identity in the language, since the predicate **E** is definable in terms of the existential quantifier and identity:

$$w \vDash_{\mathcal{M}} \mathbf{E}(t)[g] \text{ iff } w \vDash_{\mathcal{M}} \exists y(y = t)[g], \text{ where } y \text{ is a variable that is distinct from } t.$$

Hence, we may take $\mathbf{E}(t)$ as an abbreviation of $\exists y(y = t)$.

In terms of **E** we can express the requirements of increasing and decreasing domains in a simple way:

(v) $\mathcal{F}$ has increasing domains iff the sentence $\Box\forall x\Box\mathbf{E}(x)$ is valid in $\mathcal{F}$.

(vi) $\mathcal{F}$ has decreasing domains iff the formula $\Box(\Diamond\mathbf{E}(x) \to \mathbf{E}(x))$ is valid in $\mathcal{F}$.

We are especially interested in frames where R is the *universal relation* in W, i.e., in which:

$$w \vDash_{\mathcal{M}} \Box\varphi[g] \text{ iff, for every } u \in W, u \vDash_{\mathcal{M}} \varphi[g].$$

Let **QS5=** be the class of all such frames. It follows from what we have stated above, that neither the Barcan formula nor its converse is (**QS5=**)-valid.

In order to illustrate the difference between Kripke's [66] semantics and his earlier semantics from 1959, consider again the purported proof that *everything there is exists necessarily* (Section 1.4.3). The proof is valid in the semantics of Montague [83] as well as in Kripke [64]. However, according to Kripke [66], the argument fails. It is easy to see that the conclusion is not valid according to Kripke [66]. When we look at the purported proof, we see that it is line (3) that fails:

(3) $\forall x \exists y(x = y) \rightarrow \exists y(x = y)$ universal specification (US) (for variables)

That is, (US) is not valid according to Kripke [66] (not even for variables): The universal quantifier in the antecedent of (3) ranges over the domain of actually existing objects, while the free variable x in the succedent may take possible objects as values that lie outside the domain of actually existing objects. The failure of this intuitively invalid argument in Kripke's [66] semantics speaks in favour of this semantics in comparison with Montague [83] and Kripke [64].

Rigid designators. Kripke's [66] semantics validates the *Law of Identity*,

(L=) $\forall x(x = x)$,

as well as the principle of *Indiscernibility of Identicals*,

(I=) $\forall x \forall y[x = y \rightarrow (\varphi(x/z) \rightarrow \varphi(y/z))]$,

applicable without restrictions also to modal contexts $\varphi(z)$. From these principles, together with the rule of Necessitation it is easy to infer:

($\Box =$) $\forall x \forall y(x = y \rightarrow \Box(x = y))$ *(Necessity of Identity)*

($\Box \neq$) $\forall x \forall y(x \neq y \rightarrow \Box(x \neq y))$. *(Necessity of Distinctness)*

However, neither

(1) $c = d \rightarrow \Box(c = d)$

nor

(2) $c \neq d \rightarrow \Box(c \neq d)$,

is valid, for arbitrary individual constants c, d. This reflects an important difference between how individual variables and individual constants are treated in our modelling: in spite of their name, the denotation of individual constants may vary from one possible world to another, whereas the denotation of variables — in spite of their name — remains fixed throughout the universe of possible worlds. Here is obviously a niche to be filled! Suppose we introduce a new syntactic category of *names* and require that the interpretation of a name $\mathbf{n}$ be constant over the set of all possible worlds in any model $\mathcal{M}$; formally,

$$I_u(\mathbf{n}) = I_v(\mathbf{n}),$$

for all $u, v \in W$. Then, if $\mathbf{n}$ and $\mathbf{m}$ are any names, then:

(3) $\mathbf{n} = \mathbf{m} \rightarrow \Box(\mathbf{n} = \mathbf{m})$

(4) $\mathbf{n} \neq \mathbf{m} \rightarrow \Box(\mathbf{n} \neq \mathbf{m})$.

are both valid. The proposed modification amounts to treating the elements of the new category of names as what is now known, after Kripke [71], as *rigid* designators. In [71] Kripke made the claim that ordinary "proper names" in natural language are rigid designators.

Maximal models and maximal validity. Next, we introduce a special kind of Kripke models that we refer to as *maximal models*. We say that an ordered triple $\langle D, A, V \rangle$ is a

first-order model for $\mathcal{L}$ with *outer domain* D and *inner domain* A iff (i) $D \neq \varnothing, A \subseteq D$; and (ii) for each n-ary predicate constant $P, V(P) \subseteq D^n$; (iii) for each individual constant $c, V(c) \in D$.

A Kripke model $\mathcal{M} = \langle W, D, R, E, w_0, I\rangle$ is *maximal* if (i) $R = W \times W$; (ii) for every subset A of D and every first-order model $\langle D, A, V\rangle$ with outer domain D and inner domain A, there exists a $w \in W$ such that $E_w = A$ and $I_w = V$; and (iii) if $u, v \in W$ and $E_u = E_v$ and $I_u = I_v$, then $u = v$. Thus, in a maximal Kripke model with individual domain D, the possible worlds can be identified with all first-order models with outer domain D. Thus, for each non-empty set D, there is a unique maximal Kripke model with individual domain D.

The notion a maximal Kripke model is due to Terence Parsons [89]. Montague's [83] models correspond to the maximal Kripke models with a constant domain, i.e. where each $E_w = D$. If $\mathcal{M}$ is the maximal Kripke model with domain D, then for every formula φ of $\mathcal{L}$:

> $\Box\varphi$ is true at a world w in $\mathcal{M}$ relative an assignment g iff φ is true in every first-order model with outer domain D relative to g.

Thus, it is natural to interpret $\Box$ as a kind of logical (or combinatorial) necessity with respect to maximal Kripke models: $\Box\varphi$ is true in a maximal model with domain D iff φ is true in every first-order model with outer domain D.

Let us say that a formula φ is *maximally valid* iff for every maximal Kripke model $\mathcal{M}$ and every assignment g in $\mathcal{M}, \vDash_M \varphi[g]$. Observe that the set of maximally valid sentences is not closed under uniform substitution of arbitrary sentences for atomic sentences: for an atomic formula $Pc, \Diamond Pc$ is maximally valid, but, of course, $\Diamond\varphi$ is not in general maximally valid. Moreover, if φ is a formula that does not contain $\Box$ or $\Diamond$ which is not a theorem of first-order logic, then $\neg\Box\varphi$ is maximally valid. Of course, neither the Barcan schema nor its converse is maximally valid.

Suppose now that the intended model of $\mathcal{L}$ is some maximal Kripke model $\mathcal{M}_0$ with an infinite domain D_0. Then, all sentences of the form:

$$(n)\ \ \Diamond\exists x_1 \ldots \exists x_n(x_1 \neq x_2 \wedge \ldots \wedge x_1 \neq x_n \wedge x_2 \neq x_3 \wedge \ldots \wedge x_2 \neq x_n \wedge \ldots \wedge x_{n-1} \neq x_n),$$

where $x_1, \ldots, x_n$ are $n (n > 1)$ distinct variables, are *true* in (the intended model for) $\mathcal{L}$. This appears to be as it should be, given the interpretation of $\Diamond$ as (a kind of) logical possibility. With this notion of truth in $\mathcal{L}$, we can associate various notions of *logical truth*. One alternative is to say that a sentence in $\mathcal{L}$ is logically true iff it is true in every maximal model with the given outer domain D. With this notion all the sentences (n) come out as logically true. Another alternative is to say that a sentence is logically true if it is maximally valid, i.e., true in all maximal Kripke models. Then the sentences (n) are no longer logically true. Finally, we may identify logical truth in $\mathcal{L}$ with truth in all **QS5=**-Kripke models. Of these choices, only the last one satisfies the standard requirement on a logic of being closed under uniform substitution. Thus, if we insist that a logic should be closed under uniform substitution, it is reasonable to identify logical truth in $\mathcal{L}$ with Kripke's notion of universal validity. Hence, regardless of whether the intended model is a maximal model or not, we may reasonably conclude that the logic of alethic necessity is the set of all **QS5**=-valid sentences. By this line of reasoning, we come to the conclusion that regardless of whether we interpret $\Box$ as standing for logical

or metaphysical necessity, the *logic* of $\Box$ will be the same.[18]

Kripke versus Quine. In 1959 Kripke wrote:

> It is noteworthy that the theorems of this paper can be formalized in a metalanguage (such as Zermelo set theory) which is "extensional," both in the sense of possessing set-theoretic axioms of extensionality *and* in the sense of postulating no sentential connectives other than the truth-functions. Thus it is seen that at least a certain non-trivial portion of the semantics of modality is available to an extensionalist logician.

Perhaps, Kripke meant that he had refuted Quine's scepticism about quantified modal logic. Had he not after all done for quantified modal logic what Tarski and others had done for non-modal predicate logic: provided it with an extensional set-theoretic semantics? In addition he had axiomatised the logic and proved it complete for the given semantics. What else could one require of the interpretation of a logic?

Quine, however, was not satisfied. In 1972 he writes in a review of Kripke's paper 'Identity and Necessity' [96]:

> The notion of possible world did indeed contribute to the semantics of modal logic, and it behoves us to recognize the nature of its contribution: it led to Kripke's precocious and significant theory of models of modal logic. Models afford consistency proofs; also they have heuristic value; but they do not constitute explication. Models, however clear in themselves, may leave us still at a loss for the primary, intended interpretation.

Whatever was his aim in 1959 or 1963, in his later work Kripke's project is not to give an explanation of modal concepts in non-modal terms. In the Preface to *Naming and Necessity*, 1980 he writes:

> I do not think of 'possible worlds' as providing a *reductive* analysis in any philosophically significant sense, that is, as uncovering the ultimate nature, from either an epistemological or a metaphysical point of view, of modal operators, propositions, etc., or as 'explicating' them.

Clearly, Kripke's essentialist concept of necessity ("metaphysical necessity") simply cannot be reductively explained in non-modal terms.

Among other modellings for predicate modal logic, David Lewis's counterpart theory should be mentioned.[19] According to the Kripke paradigm, an individual may exist in more than one possible world (with respect to our formal modelling, it is possible that E_u and E_v should overlap, even if $u \neq v$). For Lewis, however, each individual inhabits only its own possible world; but it may have counterparts in other possible worlds. This approach has also been influential, both in philosophical and in mathematical quarters.

1.5 General intensional logic

1.5.1 Carnap-Montague's Intensional Logic

Frege's theory of *Sinn* (*sense*) and *Bedeutung* (*denotation*, *reference*), which was outlined in the article 'Über Sinn und Bedeutung' [32] has great intuitive appeal. In particular,

[18] Cf. [15].
[19] Cf. [75, 37].

it seems to provide elegant and intuitively appealing solutions to the familiar difficulties concerning:

(i) the cognitive significance of identity statements: how can '$a = b$' if true, be an informative statement differing in cognitive significance from '$a = a$'?

(ii) the problem of oblique or non-extensional contexts: how can two meaningful expressions with the same denotation (extension) ever fail to be interchangeable *salva veritate*?

(iii) the problem of providing an adequate truth-conditional semantics for propositional attitude reports.

Fregean solutions to these problems essentially involve the distinction between sense and denotation. The appearance of oblique contexts in natural languages was interpreted by Frege as indicating a certain kind of systematic ambiguity rather than a failure of extensionality. According to Frege's doctrine of indirect denotation, expressions denote in (unembedded) oblique contexts what is ordinarily their sense. Frege's extensional point of view has been advocated and developed in the 20th century by Alonzo Church [19, 20, 21] in his *Logic of Sense and Denotation*.[20]

Carnap [17], although still working within the Fregean tradition, saw the occurrence of oblique contexts in natural languages as genuine counterexamples to the *principle of extensionality*, according to which the denotation of a meaningful expression is always a function of the denotations of its semantically relevant parts.

According to Carnap [17], each well-formed expression of a language has both an *extension* (corresponding to Frege's denotation) and an *intension* (roughly corresponding to Frege's sense). Intuitively, the intension of a sentence is the proposition that the sentence expresses and the extension is the truth-value (true or false) of the sentence. A proposition partitions the set of all possible worlds in two cells: (i) the set of all worlds in which the proposition is true; and (ii) the set of all worlds in which the proposition is false. Carnap, therefore, proposed to identify a proposition p with the function f_p from the set W of all possible worlds to truth-values which for every possible world w has the value $f_p(w) =$ the truth-value of p in the world w. Thus, propositions are identified with functions from possible worlds (or in Carnap's case, from state descriptions, or set-theoretical models, that are taken to represent possible worlds) to truth-values. The *intension* of a sentence is the proposition it expresses and its *extension* in a possible world w is the truth-value in w of the proposition it expresses.

The intension of a predicate expression is intuitively the property (or relation-in-intension) that the predicate expresses. A property of individuals determines for every possible world w, the set of individuals that has the property in that world. Hence, a *property* P, can according to Carnap and Montague be identified with a function f_P from the set W of all possible worlds to sets of individuals, which for every possible world w

[20]As emphasised by Church [22] and Kaplan [60], the Fregean tradition in intensional logic should be distinguished from the quite different tradition stemming from Russell where the sense/denotation distinction is avoided. Russellian semantics, in contrast to Fregean semantics, assigns only one kind of semantic value, most naturally thought of as a kind of denotation, to the well-formed expressions of a language. In Russellian semantics, (logically) proper names refer (directly) to objects, sentences designate Russellian propositions, i.e. complexes of properties and objects, and predicates stand for propositional functions. Modern so-called theories of direct reference belong to the Russellian tradition (cf., for instance, [98]).

has the value $f_P(w)$ = the set of all entities that in the world w has the property P. For instance, the property of being red, is identified with the function form possible worlds to individuals that associates with every possible world the set of red objects in that world. Similarly, an n-ary *relation-in-intension* R is identified with a function from possible worlds to sets of ordered n-tuples. The intension of a predicate expression is the property or relation-in-intension it expresses and its extension in a possible world w is the set or relation-in-extension that is the value of that intension in the world w.

Finally, singular terms have individuals as their extensions and their intensions are what Carnap calls *individual concepts*, i.e., functions from possible worlds to individuals. The singular term 'the Greek philosopher that taught Alexander the Great' has in the actual world Aristotle as its extension. In another possible world, the extension may be Plato. In possible worlds where there is no unique Greek philosopher that taught Alexander, the singular term might be assigned an arbitrary conventional extension, the *null extension.* Since proper names, presumably, are *rigid designators* (cf. [71]) they have the same extension in every possible world (or at least in every possible world where the bearer of the name exists). Hence, the intension of a proper name is a constant function picking out the same object in every possible world (or at least this is the case for rigid designators of objects that exist necessarily, for instance, the numerals designating the natural numbers). On Kripke's view, co-referring proper names have the same intension. As a result, if a and b are co-referring proper names, then '$a = a$' and '$a = b$' have the same intension. Thus, it seems that difference in cognitive significance cannot be explained by difference in intension.

Kripke's [66, 67, 68] major innovation was his use — within each model structure — of a set of abstract points (indices, "possible worlds") to represent the space of possibilities. This innovation made it possible for Montague [84] — building on ideas from Carnap [17] — to represent intensional entities (senses, intensions) by set-theoretic functions from points (representing possible worlds) to extensions. Every kind of meaningful expression has according to Carnap-Montague semantics a suitable *intension*, i.e., a function from possible worlds to appropriate extensions. If E is an expression with intension $Int(E)$, and w is a possible world, then $Int(E)(w)$, i.e., the result of applying the intension of E to the possible world w, is the *extension of E in the world w* (in symbols $Ext_w(E)$). The *extension of E*, $Ext(E)$, is the extension of E in the actual world.

Following Carnap [17] we distinguish between different kind of constructions (or contexts) Φ:

(i) Φ is *extensional* iff there exists a function f_Φ such that for every possible world w, and all (appropriate) expressions $E_1, \dots, E_n$, $Ext_w(\Phi(E_1, \dots, E_n)) = f_\Phi(Ext_w(E_1), \dots, Ext_w(E_n))$. An *extensional language* is a language where every grammatical construction is extensional. An extensional language satisfies the *principle of extensionality*, i.e., the principle that the extension of a complex expression is always a function of the extensions of its semantically meaningful constituents.

(ii) Φ is *intensional* iff there exists a function F_Φ such that for all (appropriate) expressions $E_1, \dots, E_n$, $Int(\Phi(E_1, \dots, E_n)) = F_\Phi(Int(E_1), \dots, Int(E_n))$. An intensional language is a language in which every grammatical construction is intensional. Intensional languages satisfy the *principle if intensionality*, i.e., the principle that the intension of a complex expression is always a function of the intensions of its semantically meaningful constituents.

The principles of extensionality and intensionality are special cases of the *principle of compositionality*, i.e., the principle that the meaning of a complex expression is determined by its structure and the meaning of its constituents (cf., [104]).

The classical Boolean connectives are, of course, paradigm examples of extensional constructions. By modifying the above definitions slightly, in order to take variable binding operators into account, the classical quantifiers $\forall$ and $\exists$ are naturally construed as extensional operators as well. The modal operators $\Box$ and $\Diamond$, on the other hand, are examples of constructions that are intensional but not extensional. Carnap also considered propositional attitude constructions like 'John believes that ... ', that in his opinion were not even intensional. Such constructions for which the principle of intensionality fails, may be called *ultraintensional*.

In order to give a semantic analysis of belief contexts, Carnap introduced the notion of *intensional isomorphism* [17, §14]. Roughly speaking, two expressions are intensionally isomorphic iff they are built up from atomic expressions with the same intensions in the same way. Intensionally isomorphic expressions were said to have the same *intensional structure*. The intensional structure of an expression can thus be identified with the equivalence class of all expressions of the given language that are intensionally isomorphic with it. Intensional isomorphism and intensional structure was Carnap's explications of the intuitive notions of synonymy and meaning, respectively.[21] The intensional structures that correspond to sentences may be viewed as *structured propositions* in contrast to Carnapian propositions (functions from possible worlds to truth-values) that lack syntactical structure.[22] Carnap suggested that belief and other propositional attitudes be operators on such structured propositions rather than on intensions. If so, then intensionally isomorphic expressions are substitutable *salva veritate* in propositional attitude contexts. This seems fairly reasonable since one might argue that synonymous expressions are substitutable in such contexts.

Montague's intensional logic **IL** is a typed λ-calculus.[23] There are two basic types e and t of (possible) *individuals* and *truth-values* (true and false), respectively. Then, there is for every two types α and β, a type $(\alpha\beta)$ of *functions* from entities of type α to entities of type β. Finally, for every type α, there is a type $(s\alpha)$ of *senses* appropriate for entities of type α. Montague identifies the senses with Carnapian intensions, i.e., the members of $(s\alpha)$ are functions from possible worlds to entities of type α. All the domains of the various types are constant from one world to another. In particular, there is one domain of individuals that is common to all possible worlds. Thus, the domain of individuals is best thought of as the domain of all *possible* individuals.

For every type α, the language of **IL** contains variables and non-logical constants of type α. It also contains the logical constants: $=$ (identity), λ (lambda-abstraction), $\hat{}$ (intensional abstraction), $\check{}$ (intensional application), and brackets [,]. The sentential connectives, quantifiers $\forall$, $\exists$, and modal operators $\Box, \Diamond$, are definable in terms of $=, \lambda$, $\hat{}$, and $\check{}$ (Gallin [33, 15-16]). For each type α, one can quantify in IL over all the entities of type α. In particular, one can quantify over the collection of all *possible individuals.*

---

[21] This theme is developed further in Lewis [76].

[22] See King [63] for an overview of more recent work on structured propositions and references to the relevant literature (including work by David Kaplan, Nathan Salmon, Scott Soames, Jeff King, and others within the "direct reference"-tradition on so-called "Russellian propositions").

[23] See Montague [84], and especially Gallin [33] for a thorough model-theoretic study of Montague's intensional logic. In particular, Gallin presents an axiomatisation of Montague's intensional logic and proves that it is strongly complete with respect to general Henkin-type models.

In other words, **IL** is committed to an ontology of possible individuals.

Complex terms of **IL** are built up from atomic terms (variables and constants as follows): (i) If A is a term of type $(\alpha\beta)$ and B is a term of type α, then $[AB]$ is a term of type β; (ii) If A is a term of type β and x is a variable of type α then λxA is a term of type $(\alpha\beta)$: (iii) If A, B are terms of the same type, then $[A = B]$ is a term of type t; (iv) If A is a term of type α, then $\hat{}A$ is a term of type (sα); (v) If A is a term of type (sα), then $\check{}A$ is a term of type α. Terms of type t are called *formulæ*.

In the semantics, every (closed) term A of type α is assigned an extension $Ext_w(A)$ of type α relative to w, for each possible world w. The intension $Int(A)$ of A is then the function from worlds to extensions such that for each w, $Int(A)(w) = Ext_w(A)$. For each term A, $\hat{}A$ is a name of the intension of A. And, for each term A denoting an intension F, $\check{}A$ is a term which at every world w, refers to the value of F at w. Hence, $(A = \check{}\,\hat{}A)$ will always hold. The semantics of **IL** satisfies the principle of intensionality and $\hat{}$ is the only primitive non-extensional construction of **IL**. The modal operator $\Box$ is defined in **IL** as follows:

$$\Box\varphi =_{df.} [\hat{}\varphi = \hat{}T],$$

that is, φ is necessarily true iff the intension of φ equals the intension of any tautology T. $\Box$ is an **S5**-operator and the Barcan formulæ and their converses are valid in the semantics.

Montague's intensional logic admits quantifying into intensional constructions. According to Montague's intended interpretation, the individual quantifiers range over *possible* individuals. Quantification over actual individuals can be analysed by means of the introduction of an existence predicate. However, Montague's use of quantifiers ranging over possibilia is of course an abomination in the eyes of Quine and likeminded philosophers who favour an actualist metaphysics.

1.5.2 Church's logic of sense and denotation

The expressions of natural language are according to the Fregean view *systematically ambiguous*: both the sense and the denotation of an expression vary with the linguistic context in which it occurs. This systematic ambiguity is the basis for Church's program [19, 20, 21] of representing natural language discourse involving oblique contexts within a formal language the logic of which is completely *extensional*, that is, in which the ordinary principles of substitutivity of classical logic are valid. His fundamental idea is to let each expression A of the natural language be represented by different expressions $A_0, A_1, A_2, \ldots$ of the formal language depending on the context in which A occurs. Suppose, for instance, that the sentence "Tom is married", when it occurs in a non-oblique context, is translated as **Married(Tom)**. Then, the sentence (1), where the verb phrase "suspects that" gives rise to an oblique context, may be represented as:

(2) **Suspects**(**Mary**, **Married**$_1$(**Tom**$_1$)),

where **Married**$_1$ and **Tom**$_1$ are atomic expressions that denote the (ordinary) senses of **Married** and **Tom**, respectively. Analogously,

(3) George knows that Mary suspects that Tom is married

may be represented as

(4) **Knows**(**George**, $\mathbf{Suspects}_1(\mathbf{Mary}_1, \mathbf{Married}_2(\mathbf{Tom}_2))$).

Using Church's terminology, we may say that $\mathbf{Tom}_1$ and $\mathbf{Tom}_2$ denote *the concept of being Tom* and *the concept of being the concept of being Tom,* respectively. In this way ambiguity is avoided in the representing language and the classical principles of substitutivity as well as all other principles of classical logic are preserved.

Church's logic of sense and denotation is a simple type theory that has much in common with Montague's intensional logic **IL** but which differs from **IL** in not violating the principle of extensionality. In Montague's language there is, as we recall, only one non-extensional operator $\hat{}$ which transforms a term A into a term $\hat{}A$ that denotes the intension of A. Since A occurs in $\hat{}A$, $\hat{}$ is non-extensional. Church's logic of sense and denotation, on the other hand, is fully extensional. For each denoting expression A, there is in Church's language another expression $\langle A \rangle$, denoting the sense of A. Since $\langle A \rangle$ does not contain A as a syntactic part, the occurrence of A in the language does not violate extensionality. $\langle A \rangle$ replaces A in oblique contexts. For instance, the indirect discourse construction: 'John believes that φ' is replaced by the direct discourse version: 'John believes $\langle \varphi \rangle$', where $\langle \varphi \rangle$ is a name of the proposition expressed by the sentence φ. The construction 'John believes $\langle \varphi \rangle$' differs from 'John believes $\hat{}\varphi$' in being fully extensional.

In Church [18] and [19], three alternative principles of individuation for senses were proposed referred to as Alternatives (0), (1) and (2). The alternative that individuates senses most coarsely is Alternative (2), according to which two expressions have the same sense iff they are logically equivalent. Roughly speaking, Alternative (2) amounts to identifying Fregean senses with Carnapian intensions, i.e., with functions from possible worlds (or models or state descriptions representing possible worlds) to denotations (or extensions). Thus, Alternative (2) is the alternative which is closest to modern possible worlds semantics.

The alternative that is closest to Frege's own conception of sense is probably Alternative (0), according to which two terms A and B have the same sense, if and only if they are *intensionally isomorphic* in the sense of Carnap [17]. In addition to alternatives (0) and (2), Church also considered an intermediate alternative called Alternative (1), which is fairly close to Alternative (0) but seems to have less intuitive motivation. According to Alternative (1) expressions that are lambda-convertible to each other have the same sense.

Church's logic of sense and denotation is not directly concerned with linguistic expressions and their senses and denotations, but rather with the language-independent so-called *concept relation* that holds between senses and the entities that they are senses of. As Church points out in [21], the more finely senses are individuated, the more closely will the abstract theory of senses and their objects resemble the more concrete theory of names and their denotations, with the concept relation playing a role similar to the one played by the *denotation predicate* of semantics. Consequently, antinomies analogous to the semantic antinomies may arise for formulations of the logic of sense and denotation along the lines of Alternative (0) or (1). Indeed, Myhill [85] points out that Church's Alternative (0) is threatened by the antinomy described by Russell in *The Principles of Mathematics*, Appendix B, p. 527, the so-called *Russell-Myhill paradox* (cf. Anderson [2]).

The development of a logic of sense and denotation along the lines of Alternative (0) — taking Carnap's intensional isomorphism, Church's synonymous isomorphism, or some related notion as a criterion for two expressions having the same sense — is of great

theoretical interest. First of all, the fundamental principle of Alternative (0):

$$sense(FA) = sense(FB) \rightarrow sense(A) = sense(B),$$

seems to be involved whenever a difference in sense between FA and FB is *explained* in terms of a difference in sense between A and B. Secondly, any principle of individuation for senses that is substantially less strict than Alternative (0) seems to be inadequate for a Fregean treatment of the logic of propositional attitudes.

Unfortunately, however, the attempts so far to develop a logic of sense and denotation along the lines of Alternative (0) have led either to inconsistency or to great complications, for instance, in the form of an infinite hierarchy of concept relations of different orders. Furthermore, no entirely satisfactory explanation has so far been given of the notion of sense involved in Alternative (0). Related to this is the lack of an intuitive semantic theory for Alternative (0) and a corresponding notion of logical validity.

However, the pursuit of Church's Alternative (2) has made considerable progress. Thus, David Kaplan [58, 60] and Charles Parsons [88] have provided versions of Church's logic of sense and denotation with a possible worlds semantics of Carnap-Montague type. Parsons [88] even shows that his version of Church's logic of sense and denotation is exactly equivalent to (intertranslatable with) Montague's intensional logic. Moreover he provides an axiomatisation of Church's Alternative 2 that is equivalent to Gallin's axiomatisation of Montague's intensional logic.

1.6 Logical and metaphysical necessity

We make a rough distinction between two types of intuitive interpretations of the operators $\Diamond$ and $\Box$ of alethic modal logic. First there is the *metaphysical* or *counterfactual* interpretation:

$\Diamond\varphi$: either φ, or it could have been the case that φ.
$\Box\varphi$: φ, and it could not have been the case that $\neg\varphi$.

Then, there is the *logical* or *metalogical* interpretation:

$\Diamond\varphi$: it is not self-contradictory to assume that φ is the case.
$\Box\varphi$: it is self-contradictory to assume that $\neg\varphi$ is the case.

From now on, we shall use $\mathbf{L}\varphi$ and $\mathbf{M}\varphi$ for the logical modalities and reserve $\Box$ and $\Diamond$ for the metaphysical ones.

According to the *possible worlds analysis* of metaphysical necessity:

$\Box\varphi$ is true at a possible world w iff φ is true at every possible world.

There is an extensive and fast growing philosophical literature on the proper analysis of the notion of a possible world (cf. [25, 87]). Roughly speaking, we are distinguishing between *the world* as the (concrete) totality of everything there is and *possible worlds* as total alternative ways the world could have been (cf. [71, pp. 15–20]). Characterised in this way, possible worlds are abstract entities: *total possible states of the world.* This notion of possible world should be contrasted with David Lewis's notion of a possible world as a concrete alternative universe (cf. [80]). Regardless of our ultimate understanding of possible worlds, to say that a statement φ is *true at* a possible world w means, intuitively, that φ, with its actual meaning, would have been true (simpliciter) had w obtained.

A delicate question that now arises is how metaphysical necessity relates to logical necessity. The answer, of course, depends on how precisely we characterise the notion of logical necessity. Different semantic characterisations give rise to different answers. Suppose that we define logical necessity in terms of a class K of (admissible) models (or interpretations). Each model $\mathcal{M}$ is associated with a set $U_{\mathcal{M}}$ of points (representing "possible worlds") of which one is the designated point $@_{\mathcal{M}}$ (representing "the actual world"). We write $u \vDash_{\mathcal{M}} \varphi$ for the sentence φ being *true at the point u in the model $\mathcal{M}$*. *Truth in a model $\mathcal{M}$* is defined as truth at the designated point $@_{\mathcal{M}}$ of the model $\mathcal{M}$. *Logical truth*, or *validity*, is defined as truth in every model in K. We assume that:

(i) $u \vDash_{\mathcal{M}} \neg\varphi$ iff not: $u \vDash_{\mathcal{M}} \varphi$

(ii) $u \vDash_{\mathcal{M}} (\varphi \rightarrow \psi)$ iff either $u \nvDash_{\mathcal{M}} \varphi$ or $u \vDash_{\mathcal{M}} \psi$.

(iii) $u \vDash_{\mathcal{M}} \mathbf{L}\varphi$ iff for every model $\mathcal{N}$ in $K, @_{\mathcal{N}} \vDash_{\mathcal{N}} \varphi$.

(iv) $u \vDash_{\mathcal{M}} \Box\varphi$ iff for every point $v \in U_{\mathcal{M}}, v \vDash_{\mathcal{M}} \varphi$.

Given this type of semantics, there is no guarantee that logical necessity implies metaphysical necessity. Suppose, for example, that the language contains a logical constant **actually** with the semantic clause:

(v) $u \vDash_{\mathcal{M}}$ **actually** (φ) iff $@_{\mathcal{M}} \vDash_{\mathcal{M}} \varphi$,

i.e., **actually** (φ) is true at a point in a model iff φ is true at the designated point in the model. Then, every instance of the following schema is valid:

(1) $\mathbf{L}(\varphi \leftrightarrow$ **actually** $(\varphi))$,

although, the following schema fails (in both directions):

(2) $\Box(\varphi \leftrightarrow$ **actually** $(\varphi))$.

We can easily construct models $\mathcal{M}$ for a sentential language of the indicated kind for which (2) fails.

Thus it appears, as Zalta [108] has argued, that logical necessity does not imply metaphysical necessity. There are logical truths that are metaphysically contingent. However, this claim is highly counterintuitive. There are various ways of avoiding the conclusion that logical truth does not imply metaphysical necessity. One may, for one reason or another, refuse constructions like **actually**, that make reference to special worlds, the status of logical constants.

Another option is to modify the notion of logical truth. The notion of logical truth that we have employed is the one we have called *real-world validity*. It is the notion according to which a statement φ is logically true (valid) iff it is true at the actual world in each model. As we have seen, however, there is an alternative notion, *general validity*, according to which a statement is logically true iff it is true at each world in each model.

Let us write $\vDash$ and $\vDash^*$ for real-world validity and general validity, respectively. The two notions are related as follows: For any statement φ,

(1) $\vDash \varphi$ iff $\vDash^*$ **actually** (φ).

(2) $\vDash^* \varphi$ iff $\vDash \Box\varphi$.

The operator **L** was introduced by "reflecting" the meta-linguistic notion of real-world validity into the object language. We can also introduce an operator $\mathbf{L}^*$ corresponding to the notion of general validity. The semantic clauses for **L** (*real-world logical necessity*) and $\mathbf{L}^*$ (*general logical necessity*) are:

(vi) $u \vDash_{\mathcal{M}} \mathbf{L}\varphi$ iff for every model $\mathcal{N}$ in $K, @_{\mathcal{N}} \vDash_{\mathcal{N}} \varphi$.

(vii) $u \vDash_{\mathcal{M}} \mathbf{L}^*\varphi$ iff for every model $\mathcal{N}$ in K and every point v in $\mathcal{N}, v \vDash_{\mathcal{N}} \varphi$.

That is, **L** corresponds to truth at the actual world in each model and $\mathbf{L}^*$ corresponds to truth at every world in each model. The two notions of logical necessity are interdefinable:

(1) $\vDash^* \mathbf{L}\varphi \leftrightarrow \mathbf{L}^*\mathbf{actually}(\varphi)$.

(2) $\vDash^* \mathbf{L}^*\varphi \leftrightarrow \mathbf{L}\Box\varphi$.

Moreover, we have:

(3) $\vDash^* \mathbf{L}^*\varphi \rightarrow \Box\varphi$,

although, as we have seen, the corresponding implication does not hold for real-world logical necessity, i.e., for **L**.

Metaphysical necessity does not imply logical necessity. It does not appear self-contradictory to think, as the Greeks did, that water is an element. But since water, as it turned out, is a compound of oxygen and hydrogen, it could not have been an element. There is, so to speak, no counterfactual situation, or possible world, where *water* is not a compound. So even if it is not logically necessary, it is metaphysically necessary that water is a compound. Hence, the statement:

(1) Water is a compound

is metaphysically necessary (assuming that "water", is a rigid designator), but it is not logically necessary. In conclusion, we can say that real-world logical necessity (**L**) neither implies nor is implied by metaphysical necessity ($\Box$). General logical necessity ($\mathbf{L}^*$) on the other hand, implies metaphysical necessity, but is not implied by it.

The (epistemological) distinction between *a priori* and *a posteriori* also comes in here. In Kripke's theory, (1) exemplifies a statement that, although metaphysically necessary, is nevertheless *a posteriori*. On the other hand, given certain assumptions, "The Paris meter is one meter long" may be an example of a statement that is true *a priori* but is not metaphysically necessary [71].

2 THE MODAL LOGIC OF BELIEF CHANGE

In this section, modal logic is brought to bear on an area which has already reached a degree of maturity (although still in need of further development) and which has been formulated with little or no regard to modal logic. By re-formulating the theory in terms of modal logic, a degree of systematisation is gained, and — it is hoped! — the theoretical understanding of the theory is enhanced.

2.1 Introduction

2.1.1 Two paradigms

The theory of belief change is a fairly sprawling phenomenon. In the tradition examined here, one is interested in how new information is handled by a "rational" agent. By assumption, the agent is situated in an environment, often referred to as "the world". The world is always in some world state or other, and the agent is always in some belief state or other. From time to time, the agent is presented with new information about the world. The problem is to describe how the new information affects the current belief state. In the two cases studied here, two further assumptions are made: that the new information is always accepted, and that acceptance always leads to a uniquely defined (usually, but not necessarily, different) belief state.

We distinguish between two cases: the case when the world is static (the world does not change) and the case when the world is dynamic (the world might change); belief change is called *belief revision* in the former case, *belief update* in the latter. We also distinguish between two attitudes which an agent may have and which are called *conditionalisation* and *imaging*, respectively; these terms, which have an origin in probability theory, will not be explained (see Lewis [128], Gärdenfors [112]). The two paradigms selected for study here, AGM and KM, exemplify those two attitudes: AGM is a conditionalising and KM is an imaging theory. It is commonly accepted that a conditionalising attitude is appropriate for belief revision and an imaging attitude for update. Thus AGM is said to be a theory of belief revision and KM a theory of update.

In this section we shall offer explications within modal logic of both the AGM paradigm and the KM paradigm. They are not meant to be exact counterparts of AGM and KM as they were historically defined; they are rather meant to bring out what we take to be essential to those conceptions. (Our use of the terms "AGM" and "KM" is ambiguous: they stand both for certain people (Alchourrón, Gärdenfors and Makinson in the former case, Katsuno and Mendelzon in the latter) and for the theories developed by those authors.)

2.1.2 Revision

There is a strong connection between the theory of belief change and the logic of conditionals. That this should be so is not so surprising if it is remembered that the following much quoted passage in a paper of Frank Ramsey, published posthumously, inspired both fields:

> If two people are arguing 'If p will q?' and are both in doubt as to p, they are adding p hypothetically to their stock of knowledge and arguing on that basis about q; so that in a sense 'If p, q' and 'If $p, {\sim}q$' are contradictories. We can say that they are fixing their degrees of belief in q given p. If p turns out false, these degrees of belief are rendered *void*. If either party believes p for certain, the question ceases to mean anything for him except as a question about what follows from certain laws or hypothesis. [133, p. 149].

Both Robert Stalnaker and David Lewis cite this passage as a point of departure for their respective theories of conditional logic (Stalnaker [140], Lewis [127]). But it was read also by Peter Gärdenfors, who was looking for a different kind of theory of conditionals, one

with a semantics not formulated in terms of possible worlds. Given a formal language of some familiar sort, what an agent believes on a certain occasion may be represented by what Gärdenfors called a *belief set*, namely, the set of propositions believed by the agent. It is assumed that belief sets are theories in Tarski's sense, that is, that they contains all tautologies and are closed under modus ponens. Fundamental for Gärdenfors's theory of belief change is the existence of an operation $*$ such that, for any T, if T is an agent's belief set on a certain occasion and φ is a proposition, then $T * \varphi$ is the agent's belief set if and after he has revised his beliefs by φ. Given $*$, Ramsey may be read as suggesting that two people, who share a belief set T and argue 'If φ will ψ?', can be represented as arguing whether ψ is an element of $T * \varphi$. In this way Gärdenfors was led to look for *assertability conditions* for conditionals rather than *truth conditions*. In particular, he had hoped to find a conditional $\Rrightarrow$ satisfying the following form of the so-called Ramsey Test:

$$(RT) \qquad \varphi \Rrightarrow \psi \in T \text{ iff } \psi \in T * \varphi.$$

Everything now hangs on the properties of the revision operation $*$. Proceeding in the same way as C. I. Lewis when the latter was trying to characterise his modal operators, Gärdenfors laid down a number of postulates in order to characterise $*$. Let K be a certain *background theory*, that is, a special belief set that is taken for granted and not subject to revision. A *K-theory* is a theory that includes K. We say that a formula φ is *K-consistent* if the set $K \cup \{\varphi\}$ is K-consistent, that a formula φ is *K-consistent with* a belief set T if $T \cup \{\varphi\}$ is consistent, and that two formulæ φ and ψ are *K-equivalent* if $\varphi \leftrightarrow \psi \in K$. For any set Σ, we write $Cn(\Sigma)$ for the set of tautological consequences of Σ. In the following postulates, T is supposed to be a K-theory.

(AGM1) For any formula $\varphi, T * \varphi$ is a K-theory.

(AGM2) $\varphi \in T * \varphi$

(AGM3) $T * \varphi \subseteq Cn(T \cup \{\varphi\})$.

(AGM4) φ is K-consistent with T, then $Cn(T \cup \{\varphi\}) \subseteq T * \varphi$

(AGM5) If φ is K-consistent, then $T * \varphi$ is K-consistent.

(AGM6) If φ and ψ are K-equivalent, then $T * \varphi = T * \psi$.

(AGM7) $T * (\varphi \wedge \psi) \subseteq Cn(T * \varphi \cup \{\psi\})$.

(AGM8) If ψ is K-consistent with $T * \varphi$, then $Cn(T * \varphi \cup \{\psi\}) \subseteq T * (\varphi \wedge \psi)$.

Some of these postulates have received their own names in the literature: (AGM2) is the Success Postulate, (AGM4) the Preservation Postulate and (AGM5) the Consistency Postulate.

This, in a nutshell, is the syntactic side of AGM, the famous paradigm created by Gärdenfors in collaboration with Carlos Alchourrón and David Makinson [109, 113]. Now it turns out, as Gärdenfors himself was the first to observe, that if the condition (RT) is added to the AGM-postulates (after the new operator $\Rrightarrow$ has been added to the object language), then the result is, not inconsistency, but triviality. This is yet another interesting example of how intuitions, which on the face of it seem quite reasonable, turn out jointly to be incompatible. But it is also a wonderful example of the old

saying that they who seek will find, but not always what they are looking for. For even though Gärdenfors did not find his conditional, he did find, together with Alchourrón and Makinson, a seminal theory of belief revision.

2.1.3 Update

A different theory of belief change is given in Katsuno and Mendelzon [122] (see also Grahne [115]). They emphasise a distinction, which they attribute to Keller and Winslett [123], between *knowledge-adding changes* (revisions) and *change-recording updates*. According to Katsuno and Mendelzon, we believe that the real world is one of a certain set of possible worlds, which one we may not know. When we are informed that the real world has changed in a certain respect, we examine each of the old possible worlds and ask how our beliefs would have changed if that particular one had been the real world (notice the counterfactual!). "The fact the real world has changed gives us no grounds to conclude that some of the old worlds were actually not possible." (This is the feature that made us classify Katsuno and Mendelzon's theory as imaging.)

Where AGM have belief sets, KM have *knowledge bases* (abbreviated KBs), each knowledge base consisting of just one formula ("since we need a finite fixed representation of a KB to store it in a computer"). Like AGM, KM also introduce a new operator: if φ is a KB and ψ is a formula (intuitively, the new information) then $\varphi\Diamond\psi$ is the KB that results from updating φ with ψ. Assuming a propositional language with only finitely many letters, they propose the following postulates:

(KM1) $\varphi\Diamond\psi$ implies ψ.

(KM2) If φ implies ψ, then $\varphi\Diamond\psi$ is equivalent to φ.

(KM3) If both φ and ψ are satisfiable, then $\varphi\Diamond\psi$ is also satisfiable.

(KM4) If φ is equivalent to φ' and ψ is equivalent to ψ' then $\varphi\Diamond\psi$ is equivalent to $\varphi'\Diamond\psi'$.

(KM5) $(\varphi\Diamond\psi) \wedge \theta$ implies $\varphi\Diamond(\psi \wedge \theta)$.

(KM6) If $\varphi\Diamond\psi$ implies ψ' and $\varphi\Diamond\psi'$ implies ψ, then $\varphi\Diamond\psi$ is equivalent to $\varphi\Diamond\psi'$.

(KM7) If φ is such that, for all χ, φ implies χ or φ implies $\neg\chi$, then $(\varphi\Diamond\psi) \wedge (\varphi\Diamond\psi')$ implies $\varphi\Diamond(\psi \vee \psi')$.

(KM8) $(\varphi \vee \varphi')\Diamond\psi$ is equivalent to $(\varphi\Diamond\psi) \vee (\varphi'\Diamond\psi)$.

An important difference between the two paradigms is that, while the AGM operator $*$ is not part of the language in which the agent's beliefs are expressed, the KM operator $\Diamond$ is. For this reason, AGM is not a logic, in the usual sense of the word, but KM is.

2.1.4 Translations

To a modal logician, it is obvious that AGM can be re-formulated as a modal logic. A Rosetta stone with inscriptions in ordinary language, AGM language and the language of modal logic might contain the following text:

ordinary language	AGM	modal logic
the agent believes that φ	$\varphi \in T$	$\mathbf{B}\varphi$
after revising his beliefs by φ, the agent believes that χ	$\chi \in T * \varphi$	$[*\varphi]\mathbf{B}\chi$

What is called modal logic here is of course doxastic logic enriched with change operators loaned from dynamic logic. In particular, if φ is a formula, then the expression $*\varphi$ functions like a term that denotes 'the agent's acceptance of φ' — an event, possibly an action. In this way the nonformal theory of AGM can be translated, more or less faithfully, into a formal theory within what we shall call dynamic doxastic logic (DDL); details are provided below. (We prefer "doxastic" to "epistemic" since belief need not be veridical.)

To give a direct translation of KM is more difficult. The KM-operator $\Diamond$ (a binary operator not to be confused with the homonymous unary higher-order operator appearing in DDL-operators of type $[\Diamond\varphi]$) is a propositional connective but not one of classical logic. A KM-formula

$(*)$ $(\varphi \Diamond \psi) \to \chi$

might at first sight seem to represent the claim that if an agent, who believes that φ, updates his beliefs by ψ, then he will believe, after the update, that χ. If so, then the DDL-formula $\mathbf{B}\varphi \to [\Diamond\psi]\mathbf{B}\chi$ would be a natural translation of $(*)$. However, there is a great difference between the total of an agent's beliefs — a knowledge base, to use KM-terminology — and a single belief of the agent. Therefore a faithful translation into DDL requires a strengthening of our current language. One possibility would be to adopt an operator $\mathbf{E}$ of a kind first considered by Hector Levesque, $\mathbf{E}\varphi$ carrying the intuitive meaning "the agent believes exactly that φ (and what follows logically from φ)" or "all that the agent believes is that φ (and what follows logically from φ)". In this more expressive language

$$\mathbf{E}\varphi \to [\Diamond\psi]\mathbf{B}\chi$$

would be an adequate translation of $(*)$. Unfortunately, Levesque's operator is not easy to axiomatise (see [124]).

2.1.5 Some object languages

A number of object languages will figure in the sequel, and it is a good idea to give careful definitions of them at this point. Let LETT be a denumerable set of letters. We assume a truth-functionally complete supply of *boolean* operators, *conditional* operators $\sqsupset$ and $>$, *doxastic* operators $\mathbf{B}$, $\mathbf{b}$, $\mathbf{K}$, and $\mathbf{k}$, as well as a *star operator* $*$, a *rhombus operator* $\Diamond$, and *change operators* $[\ ]$ and $\langle\ \rangle$. The operators $\mathbf{B}$, $\mathbf{K}$ and $[\ ]$ are so-called box operators, while the operators $\mathbf{b}$, $\mathbf{k}$ and $\langle\ \rangle$ are dual so-called diamond operators; for simplicity, in what follows we shall treat the latter as abbreviatory devices: that is, for all appropriate formulæ χ, $\mathbf{b}\chi =_{\mathrm{df}} \neg\mathbf{B}\neg\chi$, $\mathbf{k}\chi =_{\mathrm{df}} \neg\mathbf{K}\neg\chi$, $\mathbf{b}\chi =_{\mathrm{df}} \neg\mathbf{B}\neg\chi$, $\langle *\varphi\rangle\chi =_{\mathrm{df}} \neg[*\varphi]\neg\chi$ and $\langle\Diamond\varphi\rangle\chi =_{\mathrm{df}} \neg[\Diamond\varphi]\neg\chi$. In the same way, we also stipulate that $\varphi > \psi =_{\mathrm{df}} \neg(\varphi \sqsupset \neg\psi)$.

Informally, formulæ of type $\varphi \sqsupset \psi$ and $\varphi > \psi$ may be read as "if φ then ψ" or, if a distinction between them is called for, as "if φ then certainly ψ" and "if φ then conceivably ψ". (But we are not committed to any particular reading, be it "ontic", "epistemic", "dynamic", or whatever.) The operators $\mathbf{B}$ and $\mathbf{K}$ are for belief and for doxastic commitment, respectively. For many purposes a reading of laziness of $\mathbf{K}\varphi$ as

"the agent knows that φ" is all right, but "the agent is doxastically committed to φ" is better, for implicit in the theories we are considering below is the assumption that what is referred to is implied by a certain, usually not specified, sometimes possibly variable, background theory. The change operators are the after-operators of dynamic logic.

Classical language

$\textsc{lett} \subseteq \textsc{boole}$,

$\varphi, \psi \in \textsc{boole} \Rightarrow (\varphi \wedge \psi), (\varphi \vee \psi), (\varphi \to \psi), (\varphi \leftrightarrow \psi), \neg\varphi \in \textsc{boole}$.

Basic doxastic language

$\textsc{boole} \subseteq \textsc{basic}{\cdot}\textsc{dox}$,

$\varphi, \psi \in \textsc{basic}{\cdot}\textsc{dox} \Rightarrow (\varphi \wedge \psi), (\varphi \vee \psi), (\varphi \to \psi), (\varphi \leftrightarrow \psi), \neg\varphi \in \textsc{basic}{\cdot}\textsc{dox}$,

$\varphi \in \textsc{boole} \Rightarrow \mathbf{B}\varphi,\ \mathbf{b}\varphi,\ \mathbf{K}\varphi,\ \mathbf{k}\varphi \in \textsc{basic}{\cdot}\textsc{dox}$.

Full doxastic language

$\textsc{boole} \subseteq \textsc{full}{\cdot}\textsc{dox}$,

$\varphi, \psi \in \textsc{full}{\cdot}\textsc{dox} \Rightarrow$

$(\varphi \wedge \psi), (\varphi \vee \psi), (\varphi \to \psi), (\varphi \leftrightarrow \psi), \neg\varphi, \mathbf{B}\varphi, \mathbf{b}\varphi, \mathbf{K}\varphi, \mathbf{k}\varphi \in \textsc{full}{\cdot}\textsc{dox}$.

Basic revision language

$\textsc{basic}{\cdot}\textsc{dox} \subseteq \textsc{basic}{\cdot}\textsc{rev}$,

$\varphi, \psi \in \textsc{basic}{\cdot}\textsc{rev} \Rightarrow (\varphi \wedge \psi), (\varphi \vee \psi), (\varphi \to \psi), (\varphi \leftrightarrow \psi), \neg\varphi \in \textsc{basic}{\cdot}\textsc{rev}$,

$(\varphi \in \textsc{boole} \ \ \& \ \ \chi \in \textsc{basic}{\cdot}\textsc{rev}) \Rightarrow [*\varphi]\chi,\ \langle *\varphi\rangle\chi \in \textsc{basic}{\cdot}\textsc{rev}$.

Full revision language

$\textsc{full}{\cdot}\textsc{dox} \subseteq \textsc{full}{\cdot}\textsc{rev}$,

$\varphi, \psi \in \textsc{full}{\cdot}\textsc{rev} \Rightarrow (\varphi \wedge \psi), (\varphi \vee \psi), (\varphi \to \psi), (\varphi \leftrightarrow \psi), \neg\varphi \in \textsc{full}{\cdot}\textsc{rev}$,

$(\varphi \in \textsc{full}{\cdot}\textsc{dox} \ \ \& \ \ \chi \in \textsc{full}{\cdot}\textsc{rev}) \Rightarrow [*\varphi]\chi, \langle *\varphi\rangle\chi \in \textsc{full}{\cdot}\textsc{rev}$.

Unlimited revision language

$\textsc{full}{\cdot}\textsc{dox} \subseteq \textsc{unlim}{\cdot}\textsc{rev}$,

$\varphi, \psi \in \textsc{unlim}{\cdot}\textsc{rev} \Rightarrow$

$(\varphi \wedge \psi), (\varphi \vee \psi), (\varphi \to \psi), (\varphi \leftrightarrow \psi), \neg\varphi, \mathbf{B}\varphi, \mathbf{b}\varphi, \mathbf{K}\varphi, \mathbf{k}\varphi \in \textsc{unlim}{\cdot}\textsc{rev}$,

$(\varphi \in \textsc{unlim}{\cdot}\textsc{rev} \ \ \& \ \ \chi \in \textsc{unlim}{\cdot}\textsc{rev}) \Rightarrow [*\varphi]\chi, \langle *\varphi\rangle\chi \in \textsc{unlim}{\cdot}\textsc{rev}$.

Conditional language

$\textsc{boole} \subseteq \textsc{cond}$,

$\varphi, \psi \in \textsc{cond} \Rightarrow$

$(\varphi \wedge \psi), (\varphi \vee \psi), (\varphi \to \psi), (\varphi \leftrightarrow \psi), \neg\varphi, (\varphi \sqsupset \psi), (\varphi > \psi) \in \textsc{cond}$.

Update language

$\textsc{basic}{\cdot}\textsc{dox} \cup \textsc{cond} \subseteq \textsc{update}$,

$\varphi, \psi \in \textsc{update} \Rightarrow (\varphi \wedge \psi), (\varphi \vee \psi), (\varphi \to \psi), (\varphi \leftrightarrow \psi), \neg\varphi \in \textsc{update}$,

$\varphi \in \textsc{cond} \Rightarrow \mathbf{B}\varphi \in \textsc{update}$,

$(\varphi \in \textsc{cond} \ \ \& \ \ \chi \in \textsc{update}) \Rightarrow [\Diamond\varphi]\chi, \langle\Diamond\varphi\rangle\chi \in \textsc{update}$.

We say that a formula is an *agent formula*, relative to BASIC·REV, FULL·REV, UNLIM·REV, or UPDATE, if it can occur both within the scope of a doxastic operator and within the scope of the star operator or rhombus operator, whichever is appropriate.

2.2 Conditional logic

As remarked above, there is a close connection between the theory of belief change and the theory of conditionals. For this reason, we devote an entire section to this topic, which is also, by our lights, a chapter of modal logic.

2.2.1 Topology

Let U be any nonempty set. A *topology* in U is a set T of subsets of U satisfying two conditions: for all $S \subseteq T$, (i) $\bigcup S \in T$, and (ii) if S is finite and nonempty, then $\bigcap S \in T$. A topology always has at least two elements: U is the union of all subsets of U and is therefore a member, and $\varnothing$ is the union of the empty set of subsets of U and is therefore also a member. The structure (U, T) is called a *topological space*, but when it is clear what the intended topology is one usually refers to U itself as the topological space. The elements of T are said to be *open* sets; a *closed* set is one that is the complement of an open set. In general, a set need not be either open or closed, but on the other hand some sets are both; we will use the term *clopen* (adjective or noun) for the latter. Notice that the complement of a clopen set is clopen and that U and $\varnothing$ are clopen in any topology. The (topological) *closure* of a set X, the smallest closed set that includes X, is defined as the intersection of all closed sets that include X.

A *cover* of a set $X \subseteq U$ is a family C of subsets of U such that $X \subseteq \bigcup C$. A cover, every element of which is an open set, is an *open cover*. If C is a cover of X and there is a family $D \subseteq C$ such that $X \subseteq \bigcup D$, then D is a *subcover* of C of X. A topology T is *compact* if every open cover of the whole space has a finite subcover; a logically equivalent condition is that every family of closed subsets of U whose intersection is empty has a finite subfamily whose intersection is empty. A topology T is *totally separated* if, for any pair of distinct elements of U, one is an element of a clopen set of which the other is not. A *Stone topology* is a topology that is compact and totally separated.

A family B of subsets of T is a *base* for the topology if, for every $X \in T$, there is some family $C \subseteq B$ such that $X = \bigcup C$. In other words, B is a base if every open element is the union of some elements of B. It is not difficult to prove that in a Stone topology, the family of clopen sets forms a base.

Let U be a space with a Stone topology. A *sphere system* or, more colloquially, an *onion* (*in* U) is a nonempty family of closed subsets (*spheres*) of U that satisfies two conditions: it is closed under arbitrary nonempty intersection, and it is linearly ordered by set inclusion. An onion is *trivial* if it contains only one sphere and that sphere is the empty set; hence there is a unique trivial onion, namely $\{\varnothing\}$. The *centre* of an onion O is the set $\bigcap O$, and we say that O is centred on $\bigcap O$; thus the trivial onion is centred on the empty set. We say that an onion O *overlaps with* a set X (we assume that X is a subset of U) if $\bigcup O \cap X \neq \varnothing$. The family of spheres of an onion O that intersect with a set X is denoted by $O \bullet X$. If S is a family of sets and X is the smallest element of S, then we may express this by the notation $X \; \mu \; S$ (thus "mu" is a special case of "epsilon"). It is not difficult to prove that if O is an onion that overlaps with a clopen set X, then there is a smallest sphere in O that intersects with X; in symbols, $\bigcup O \cap X \neq \varnothing \Rightarrow \exists Z(Z \; \mu \; (O \bullet X))$; this important condition is called *the limit condition.*

Sphere systems were introduced by David Lewis (who never called them onions) [127]. Ours differ from his in one notable respect: his spheres, but not ours, are closed under unrestricted union. One particular consequence of Lewis's condition is that the empty

set is an element of every sphere system of his, while our onions may, but need not, contain the empty set as an element.

The reader may find it helpful to think of the clopen sets as the agent's propositions of the frame, and closed sets as possible agent's theories (or theory sets, to use a term of Bengt Hansson). The topological setting may surprise some readers, but it provides an elegant way for keeping tabs on the limit condition.

2.2.2 *Semantics*

Let us say a quadruple (U, P, Q, D) is a *Lewis frame* if (i) U is a Stone space, (ii) P is the set of clopen sets, (iii) Q is a quantity (that is, set) of onions in U, (iv) D is a function (the *onion determiner*) assigning to each element u of U an onion Q, and (v) whenever X and Y are clopen subsets of U, then so are

$$\{u \in U : \forall Z(Z \mu (D(u) \bullet X) \Rightarrow Z \cap X \subseteq Y)\}$$

and

$$\{u \in U : \exists Z(Z \mu (D(u) \bullet X) \ \&\ Z \cap X \cap Y \neq \varnothing)\}.$$

We consider a language COND for conditional logic. A *valuation* in a Lewis frame (U, P, Q, D) is a function from the set LETT of propositional letters to P. A *Lewis model* (U, P, Q, D, V) is a Lewis frame (U, P, Q, D) cum valuation V. We define the truth of a formula in a given Lewis model $\mathcal{M} = (U, P, Q, D, V)$ as follows (we suppress reference to $\mathcal{M}$ in the notation). The definition, which proceeds by induction in the usual way, is relative to a point u of U. We use the notation $[\![\varphi]\!]$ for the set called the *truth set* of φ. If $u \in [\![\varphi]\!]$ we say that φ is *true* at u and may write $u \vDash \varphi$.

$$\begin{aligned}
&[\![\varphi]\!] = V(P), \text{ if } P \text{ is a propositional letter},\\
&[\![\varphi \wedge \psi]\!] = [\![\varphi]\!] \cap [\![\psi]\!],\\
&[\![\varphi \vee \psi]\!] = [\![\varphi]\!] \cup [\![\psi]\!],\\
&[\![\neg\varphi]\!] = U - [\![\varphi]\!], \text{ etc.},\\
&[\![\varphi \sqsupset \psi]\!] = \{u \in U : \forall Z(Z \mu D(u) \bullet [\![\varphi]\!] \Rightarrow Z \cap [\![\varphi]\!] \subseteq [\![\psi]\!])\},\\
&[\![\varphi > \psi]\!] = \{u \in U : \exists Z(Z \mu D(u) \bullet [\![\varphi]\!] \ \&\ Z \cap [\![\varphi]\!] \cap [\![\psi]\!] \neq \varnothing)\}.
\end{aligned}$$

(Note that, thanks to the closure rules on P, including (v), $[\![\varphi]\!]$ is a clopen set, for every formula φ.) We say that a formula is *valid* if it is true at all points in all models. A schema is *valid* if all its instances are valid.

2.2.3 *Postulates for David Lewis's VC and VCU*

First, assume as postulates all tautologies and the rule of modus ponens. Then add the rules

(REA) $\varphi \leftrightarrow \varphi' / (\varphi \sqsupset \theta) \leftrightarrow (\varphi' \sqsupset \theta)$,

(REC) $\theta \leftrightarrow \theta' / (\varphi \sqsupset \theta) \leftrightarrow (\varphi \sqsupset \theta')$

and, as axioms, all instances of the following schemata:

(ML1) $(\varphi \sqsupset (\psi \wedge \theta)) \leftrightarrow ((\varphi \sqsupset \psi) \wedge (\varphi \sqsupset \theta))$,

(ML2) $\varphi \sqsupset \top$,

(DF>) $(\varphi > \psi) \leftrightarrow \neg(\varphi \sqsupset \neg\psi)$,

(CL1) $\varphi \sqsupset \varphi$,

(CL2) $(\varphi > \psi) \rightarrow (\psi > \top)$,

(CL3) $\varphi \rightarrow (\psi \rightarrow (\varphi \sqsupset \psi))$,

(CL4) $\varphi \rightarrow ((\varphi \sqsupset \psi) \rightarrow \psi)$,

(CL5) $((\varphi \wedge \psi) \sqsupset \theta) \rightarrow (\varphi \sqsupset (\psi \rightarrow \theta))$,

(CL6) $(\varphi > \psi) \rightarrow ((\varphi \sqsupset (\psi \rightarrow \theta)) \rightarrow ((\varphi \wedge \psi) \sqsupset \theta))$.

Brian Chellas suggested a different notation which highlights the connection with modal logic: writing $[\varphi]\psi$ for $\varphi \sqsupset \psi$ and $\langle\varphi\rangle\psi$ for $\varphi > \psi$. If we rewrite the preceding conditions in Chellas's notation, we get the following result:

(REA′) $\varphi \leftrightarrow \varphi'/[\varphi]\theta \leftrightarrow [\varphi']\theta$,

(REC′) $\theta \leftrightarrow \theta'/[\varphi]\theta \leftrightarrow [\varphi]\theta'$

and, as axioms, all instances of the following schemata:

(ML1′) $[\varphi](\psi \wedge \theta) \leftrightarrow ([\varphi]\psi) \wedge [\varphi]\theta)$,

(ML2′) $[\varphi]\top$,

(DF⟨...⟩) $\langle\varphi\rangle\psi \leftrightarrow \neg[\varphi]\neg\psi)$,

(CL1′) $[\varphi]\varphi$,

(CL2′) $\langle\varphi\rangle\psi \rightarrow \langle\psi\rangle\top$,

(CL3′) $\varphi \rightarrow (\psi \rightarrow [\varphi]\psi)$,

(CL4′) $\varphi \rightarrow ([\varphi]\psi \rightarrow \psi)$,

(CL5′) $[\varphi \wedge \psi]\theta \rightarrow [\varphi](\psi \rightarrow \theta)$,

(CL6′) $\langle\varphi\rangle\psi \rightarrow ([\varphi](\psi \rightarrow \theta) \rightarrow [\varphi \wedge \psi]\theta)$.

The set of theorems of this axiom system coincides with David Lewis's logic VC. To get his VCU, add the schemata:

(4) $\Box\varphi \rightarrow \Box\Box\varphi$

(5) $\neg\Box\varphi \rightarrow \Box\neg\Box\varphi$,

where $\Box\varphi$ is an abbreviation of $\neg\varphi \sqsupset \bot$ (or $[\neg\varphi]\bot$, in Chellas's notation). (Note that the schema $\Box\varphi \rightarrow \varphi$ is derivable in VC).

We say after Lewis that a frame (U, T, Q, D) is *centred* if the onion $D(u)$ is centred on $\{u\}$ for each $u \in U$, and we say that it is *uniform* if $\bigcup D(u) = \bigcup D(v)$, for all $u, v \in U$.

THEOREM 3 ([127]). *A formula of conditional logic is derivable in VC [alternatively: in VCU] if and only if it is valid in all centred [alternatively: uniform centred] Lewis frames.*

There are of course many more completeness results of this kind.

2.3 *Update and the logic of conditionals*

2.3.1 *Semantics*

Consider an update language UPDATE. Let $\mathcal{M} = (U, P, Q, D, V)$ be a given Lewis model. The definition of truth in $\mathcal{M}$ (we will suppress reference to $\mathcal{M}$ in the notation) will be with respect to a *situation*, defined as an ordered pair (B, u) where B is a subset of U and x is a point in U. (Intuitively, B represents the current beliefs of the agent, while x represents the point that is currently actual.) The definition proceeds in two steps. First, we define the *truth set* $[\![\theta]\!]$ of formulæ $\theta \in$ COND in the usual way; thus $[\![\theta]\!]$ is a subset of U. Second, we define *truth in a situation* (B, x) of formulæ φ in UPDATE:

$$\begin{array}{l}
(B,x) \vDash \varphi \text{ iff } x \in [\![\varphi]\!], \text{ if } \varphi \in \text{ COND},\\
(B,x) \vDash \varphi \wedge \psi \text{ iff } (B,x) \vDash \varphi \text{ and } (B,x) \vDash \psi\\
(B,x) \vDash \varphi \vee \psi \text{ iff } (B,x) \vDash \varphi \text{ or } (B,x) \vDash \psi,\\
(B,x) \vDash \neg\varphi \text{ iff } (B,x) \nvDash \varphi,\\
\qquad \text{etc.},\\
(B,x) \vDash \mathbf{B}\varphi \text{ iff } B \subseteq [\![\varphi]\!],\\
(B,x) \vDash \mathbf{K}\varphi \text{ iff } \bigcup\{\bigcup D(u) : u \in B\} \subseteq [\![\varphi]\!],\\
(B,x) \vDash [\Diamond\varphi]\chi \text{ iff } (B',x) \vDash \chi, \text{ where}\\
\qquad B' = \bigcup\{Z \cap [\![\varphi]\!] : \exists u(u \in B \;\&\; Z \;\mu\; (D(u) \bullet [\![\varphi]\!]))\}.
\end{array}$$

We say that a formula is *valid* if it is true in all situations in all models. A schema is *valid* if all its instances are valid.

2.3.2 *Postulates*

We build an axiom system in stages, one block at the time. First block: all postulates (axioms and rules) of Lewis's VC. Second block: normal modal logic for all modal and dynamic operators. Third block:

($\Diamond$0) $\quad \theta \leftrightarrow [\Diamond\varphi]\theta$, if $\theta \in$ COND,

($\Diamond$1) $\quad \langle\Diamond\varphi\rangle\chi \leftrightarrow [\Diamond\varphi]\chi$,

($\Diamond$RT) $\quad \mathbf{B}(\varphi \sqsupset \psi) \leftrightarrow [\Diamond\varphi]\mathbf{B}\psi$

($\Diamond$K) $\quad \mathbf{K}\varphi \leftrightarrow \mathbf{B}\Box\varphi$

($\Diamond$RC) $\quad$ if $\varphi \leftrightarrow \psi$ is derivable, then so is $[\Diamond\varphi]\chi \leftrightarrow [\Diamond\psi]\chi$, for every χ, for all formulæ $\varphi, \psi \in$ COND and $\chi \in$ UPDATE.

(Here, as above, $\Box\varphi$ abbreviates $\neg\varphi \sqsupset \bot$.) The Ramsey condition is essentially a condition of operator shift where both operators and positions change; this fact is especially striking if ($\Diamond$RT) is rewritten in Chellas's notation:

($\Diamond$RT$'$) $\quad \mathbf{B}[\varphi]\psi \leftrightarrow [\Diamond\varphi]\mathbf{B}\psi$.

Call this system U. (Warning: Lewis's U (for "uniform") must not be be confused with our U (for "update").) Let U45 be the system obtained by adding the schemata (4) and (5) mentioned above.

THEOREM 4. *A formula of the update language is derivable in U [alternatively: in U45] if and only if it is valid in all centred [alternatively: uniform centred] Lewis frames.*

Our axiomatisation, in which ($\Diamond$RT) is the only postulate that is really novel, has thus issued in yet another confirmation of the observation of several authors about the close connection between conditional logic and update logic. It is worth remarking that the class of uniform centred frames, which in our object language determines UT45, also, in another object language which does not include the operator **B**, determines the logic Gösta Grahne calls VCU^2, a logic based directly on Lewis's VCU (see [115]).

2.4 Revision and basic DDL

2.4.1 Semantics

In this section we assume a language BASIC-REV for basic revision logic. Two intuitions underlying our presentation are that belief change consists in the transition from belief state to belief state, and that belief states can be modelled by sphere systems (onions). Let us define a *basic revision frame* as a structure (U, P, Q, R) where U is a Stone space, P is the set of clopen sets, Q is a quantity of onions, and R is a function assigning to each clopen set X a binary relation RX over Q. The intuition is this: if the agent is in belief state O, then after accepting (the information carried by) a proposition X, his new belief state is a belief state O' such that $(O, O') \in RX$.

Valuations and models are defined as usual. We define the *truth* of a formula in a given model $\mathcal{M} = (U, P, Q, R, V)$ as follows (as usual, we suppress reference to $\mathcal{M}$ in the notation). The definition, which proceeds by induction, is relative to a *situation*, which is an ordered pair (O, x), where O is an onion and x a point of U. (Intuitively, O is the current belief state of the agent, and x is the current state of the world.) We use the notation $[\![\varphi]\!]$ for the truth set of φ if φ is a Boolean formula.

$$
\begin{aligned}
&(O, x) \models P \text{ iff } x \in V(P), \text{ if } P \text{ is a propositional letter},\\
&(O, x) \models \varphi \wedge \psi \text{ iff } (O, x) \models \varphi \text{ and } (O, x) \models \psi,\\
&(O, x) \models \varphi \vee \psi \text{ iff } (O, x) \models \varphi \text{ or } (O, x) \models \psi,\\
&(O, x) \models \neg\varphi \text{ iff } (O, x) \not\models \varphi, \text{ etc.},\\
&(O, x) \models \mathbf{B}\varphi \text{ iff } \bigcap O \subseteq [\![\varphi]\!],\\
&(O, x) \models \mathbf{K}\varphi \text{ iff } \bigcup O \subseteq [\![\varphi]\!],\\
&(O, x) \models [*\varphi]\chi \text{ iff } \forall O'((O, O') \in R[\![\varphi]\!] \Rightarrow (O', x) \models \chi).
\end{aligned}
$$

Notice that the truth-conditions for the dynamic operators make sense as long as the star operator applies only to Boolean formulæ. *Validity* in a frame [in a class of frames] is then defined as truth relative to all situations in all models on the frame [in all frames].

To try to capture the ideas behind the historical AGM, further conditions are in order. One is that the belief set of a new belief state resulting from some new piece of information equal the overlap between the old onion and the clopen set representing that information:

(i) $(O, O') \in RX$ only if O overlaps with X and $\bigcap O' = Z \cap X$, where $Z \ \mu\ O \bullet X$.

Two other conditions are that every relation RX be serial and functional:

(ii) $\exists O' \in Q(O, O') \in RX$,

(iii) $(O, O') \in RX$ & $(O, O'') \in RX \Rightarrow O' = O''$.

Yet another condition to be considered is that what AGM called the "background" theory (in our jargon, the agent's doxastic commitments) not change when beliefs are revised:

(iv) $O, O' \in Q \Rightarrow \bigcup O = \bigcup O'$.

2.4.2 Translations of the AGM postulates

A direct translation of the AGM postulates formulated in Section 2.1.2 gives the following result:

(∗2) $[*\varphi]\mathbf{B}\varphi$,

(∗3) $[*\varphi]\mathbf{B}\chi \rightarrow \mathbf{B}(\varphi \rightarrow \chi)$,

(∗4) $\mathbf{b}\varphi \rightarrow (\mathbf{B}\chi \rightarrow [*\varphi]\mathbf{B}\chi)$,

(∗5) $\mathbf{k}\varphi \rightarrow \langle *\varphi\rangle\mathbf{b}\top$,

(∗6) $\mathbf{K}(\varphi \leftrightarrow \psi) \rightarrow ([*\varphi]\mathbf{B}\chi \leftrightarrow [*\psi]\mathbf{B}\chi)$,

(∗7) $[*(\varphi \wedge \psi)]\mathbf{B}\chi \rightarrow [*\varphi]\mathbf{B}(\psi \rightarrow \chi)$,

(∗8) $\langle *\varphi\rangle\mathbf{b}\psi \rightarrow ([*\varphi]\mathbf{B}(\psi \rightarrow \chi) \rightarrow [(\varphi \wedge \psi)]\mathbf{B}\chi$.

All instances of these schemata are valid.

2.4.3 Postulates for the basic-DDL version of AGM

We build an axiom system in stages, one block at the time. First block: tautologies and modus ponens. Second block: normal modal logic for **B** and **K** and $[*\varphi]$. Third block: the postulates (∗2)–(∗8) mentioned in the preceding section plus the following additional postulates:

(∗0) $\chi \leftrightarrow [*\varphi]\chi$, if χ is Boolean,

(∗1) $\langle *\varphi\rangle\chi \leftrightarrow [*\varphi]\chi$,

(∗KB) $\mathbf{K}\varphi \rightarrow \mathbf{B}\varphi$,

(∗K) $\mathbf{K}\chi \leftrightarrow [*\varphi]\mathbf{K}\chi$.

(RC) if $\varphi \leftrightarrow \psi$ is derivable, then so is $[*\varphi]\chi \leftrightarrow [*\psi]\chi$, for every χ.

THEOREM 5 ([167]). *A formula of basic revision language is provable in the given axiom system if and only if it is valid in all basic revision frames.*

2.4.4 Comparison with KM

The two paradigms AGM and KM seem rather different. It is interesting, therefore, that the differences between the corresponding logics is not greater than it is. Of the AGM postulates, all are valid according to KM as well, except for the most controversial ones: $(*4)$ and $(*8)$. But even in these cases the two paradigms come close:

DDL version of KM	DDL version of AGM
$\mathbf{B}\varphi \to (\mathbf{B}\chi \to [*\varphi]\mathbf{B}\chi))$	$\mathbf{b}\varphi \to (\mathbf{B}\chi \to [*\varphi]\mathbf{B}\chi)$
$\langle *\varphi\rangle\mathbf{B}\psi \to$ $([*\varphi]\mathbf{B}(\psi \to \chi) \to [*(\varphi \wedge \psi)]\mathbf{B}\chi)$	$\langle *\varphi\rangle\mathbf{b}\psi \to$ $([*\varphi]\mathbf{B}(\psi \to \chi) \to [*(\varphi \wedge \psi)]\mathbf{B}\chi)$

Among schemata valid in KM but not in AGM are $\mathbf{B}\bot \to [*\varphi]\mathbf{B}\bot$ and $\mathbf{B}\bot \to \mathbf{K}\bot$.

One difference between revision and update, remarked upon by Katsuno and Mendelzon, is what they call the "global" behaviour of revision versus the "local" behaviour of update. What they have in mind can be explicated within our framework as follows. In AGM, the belief states of an agent are represented by onions; the belief set of an agent is not enough to determine the entire onion. By contrast, in KM the belief set is enough to determine the belief state of the agent. The reason for this is of course the centred onions assigned to each point ("possible world") in the universe of a frame. In the latter case, the beliefs of the agent come in two steps: beliefs about the world (represented by centred onions), and beliefs about which possible world is the actual one (represented by a belief set). In AGM, belief change is a progression from onion to onion. In KM, belief change is from belief set to belief set, but against the background of an underlying, constant web of beliefs about how the world can change.

2.5 Revision and full or unlimited DDL

2.5.1 Semantics

Basic DDL tries to explicate AGM as originally formulated. This is why in basic DDL the agent's beliefs are all about the world, and the agent's beliefs are not part of the world. As we saw above, the language of AGM and the language of DDL are intertranslatable. Nevertheless, there is one sense in which DDL offers more flexibility: where AGM has $\chi \in T$, DDL offers $\mathbf{B}\chi$, but AGM has no counterpart to $\mathbf{BB}\chi$ — $(\chi \in T) \in T$ is not a well-formed expression. There is no reason why one could not extend the language of AGM to include the **B**-operator, but no-one seems to have done so. And rather than doing so, it seems easier to study the resulting theory in a DDL context.

Therefore, let us move to the language FULL·REV of full revision, in which the agent formulæ are the formulæ of the full doxastic language FULL·DOX. Define a *full revision frame* as a structure (U, P, Q, R, D) *where* (i) U is a Stone space, (ii) P is the set of clopen sets, (iii) Q is a quantity of onions (not necessarily centred), (iv) R is a function assigning to each clopen set X a binary relation RX over Q, (v) D is a function from $U$to Q and finally (vi) whenever X is a clopen subset of U, then both $\{u \in U : \bigcap D(u) \subseteq X\}$ and $\{u \in U : \bigcup D(u) \subseteq X\}$ are clopen. *Truth* at a point u in a model (U, P, Q, R, D, V) is defined along usual lines:

$$
\begin{aligned}
&u \vDash P \text{ iff } u \in V(P), \text{ if } P \text{ is a propositional letter,}\\
&u \vDash \varphi \wedge \psi \text{ iff } u \vDash \varphi \text{ and } u \vDash \psi\\
&u \vDash \varphi \vee \psi \text{ iff } u \vDash \varphi \text{ or } u \vDash \psi,\\
&u \vDash \neg\varphi \text{ iff } u \nvDash \varphi, \text{ etc.,}\\
&u \vDash \mathbf{B}\varphi \text{ iff } \bigcap O \subseteq [\![\varphi]\!], \text{ where } O = D(u),\\
&u \vDash \mathbf{K}\varphi \text{ iff } \bigcup O \subseteq [\![\varphi]\!], \text{ where } O = D(u),\\
&u \vDash [*\varphi]\chi \text{ iff } \forall v((u,v) \in R[\![\varphi]\!] \Rightarrow v \vDash \chi).
\end{aligned}
$$

As usual, a formula is *valid* in a frame if true at all points in all models.

One difference between basic and full DDL is that in the former case the points of a frame represent world states whereas in the latter case they simultaneously represent both world state and belief state. This is why in basic DDL formulæ have to be evaluated at pairs (O,x) where O represents a belief state and x a world state, while in full DDL formulæ are evaluated at points representing total or combined states. In DDL there is thus an ambiguity in the informal term "world state": in a narrow sense, which excludes the agent's beliefs, the points of basic, but not full, DDL represent world states; but in a wide sense, which includes the agent's beliefs, the points of full, but not basic, DDL represent world states. In any case, the intuition in full DDL is this: if the current total state is u, then if the agent accepts (the information carried by) a proposition X, there will be, immediately afterwards, a new current total state v such that $(u, v) \in RX$.

The semantics of unlimited DDL is the same as that of full DDL, with two exceptions: the language whose formulæ are given a meaning is UNLIM·REV, and the definition of an *unlimited revision frame* is obtained from the definition of a full revision frame by adding condition (vii) if X and Y are clopen subsets of U, then both $\{u \in U : \forall v((u,v) \in RX \Rightarrow v \in Y\}$ and $\{u \in U : \exists v((u,v) \in RX \ \&\ v \in Y\}$ are clopen. Intuitively, the points of an unlimited revision frame represents not only the state of the world and the agent's beliefs about the state of the world but also the agent's beliefs about how the world may change.

2.5.2 Redefining revision?

It is interesting that all the old postulates of basic DDL (but now over the formulæ of FULL·REV or UNLIM·REV) are satisfied. However, there are problems. Suppose, for example, that $\mathbf{b}\varphi$ and $\mathbf{B}\neg B\varphi$ are true in a certain situation. Then $[*\varphi]\mathbf{B}\neg\mathbf{B}\varphi$ follows by preservation. By the Success Postulate, we always have $[*\varphi]\mathbf{B}\varphi$. Hence $[*\varphi]\mathbf{B}(\varphi\wedge\neg\mathbf{B}\varphi)$, by modal logic. Or suppose that $\mathbf{b}\varphi$ and $\mathbf{BB}\neg\varphi$ are true in a certain situation. By the same kind of reasoning $[*\varphi]\mathbf{B}(\varphi \wedge \mathbf{B}\neg\varphi)$ follows. Or, even more problematic, note that both $[*(\varphi\wedge\neg\mathbf{B}\varphi)]\mathbf{B}(\varphi\wedge\neg\mathbf{B}\varphi)$ and $[*(\varphi\wedge\mathbf{B}\neg\varphi)]\mathbf{B}(\varphi\wedge\mathbf{B}\neg\varphi)$ are valid. But if it is true, on a certain occasion, that it is raining in Umeå and Sten, who happens to be visiting at Ojmundsbod far from Umeå, does not believe that it is raining in Umeå, or even believes that it is not raining in Umeå, then surely it should be possible for him to accept this information without incurring doxastic inconsistency?

This problem was first noted and left unresolved in van Linder, van der Hoek and Meyer [129]. Two strategies have later been suggested for dealing with it. One is given in Lindström and Rabinowicz [131] in which it is recommended that one perform a certain contraction before revising one's beliefs. Roughly speaking, before accepting new

information, the agent should give up enough currently held beliefs to make sure that new information does not create doxastic inconsistency (assuming the new information is itself consistent). A different though related strategy is proposed in Segerberg [138] where it is recommended that the notion of revision be redefined. Two possibilities are outlined. In both cases, the star operator $*$ is kept but a new revision operator R is introduced. One suggestion is to define

$$[\mathrm{R}\varphi]\chi =_{\mathrm{df}} [*(\varphi \wedge \mathbf{B}\varphi \wedge \ldots \wedge \mathbf{B}^n\varphi)]\chi$$

and require that the logic of $\mathbf{B}$ be of a certain strength, for example, contain at least the schemata $\mathbf{BB}\varphi \to \mathbf{B}\varphi$ and $\mathbf{B}^n\varphi \to \mathbf{B}^{n+1}\varphi$. The other suggestion is to introduce yet a new doxastic operator $\mathbf{C}$ (for "complete" belief) with the semantics

$$u \vDash \mathbf{C}\varphi \text{ iff } \forall n > 0(u \vDash \mathbf{B}^n\varphi),$$

define

$$[\mathrm{R}\varphi]\chi =_{df} [*(\varphi \wedge \mathbf{C}\varphi)]\chi$$

and then require the logic of $\mathbf{B}$ to validate the schema $\mathbf{BB}\varphi \to \mathbf{B}\varphi$. Evidently, the operator $\mathbf{C}$ in effect represents common belief when only one agent is involved. One may note the validity of the following schemata:

$$\begin{aligned}
&\mathbf{C}\varphi \to \mathbf{B}\varphi,\\
&\mathbf{C}\varphi \to \mathbf{CC}\varphi,\\
&\mathbf{BC}\varphi \leftrightarrow \mathbf{CB}\varphi,\\
&(\mathbf{B}\varphi \wedge \mathbf{C}(\varphi \to \mathbf{B}\varphi)) \to \mathbf{C}\varphi.
\end{aligned}$$

In this modelling, which assumes that the doxastic commitments of agents are not open to revision, it is impossible for an agent who values the consistency of his beliefs to accept either the information that it-is-raining-and-he-does-not-believe-that-it-is-raining or the information that it-is-raining-and-he-believes-that-it-is-not-raining. In the terminology of Roy Sorensen [139], $\varphi \wedge \neg\mathbf{B}\varphi$ and $\varphi \wedge \mathbf{B}\neg\varphi$ represent *blindspots*. In general, φ represents a blindspot at u if $\mathbf{k}\varphi \wedge [\mathrm{R}\varphi]\mathbf{B}\bot$ is true at u — if φ is consistent with what the agent knows but revision by φ leads to an absurd belief set.

3 LOGIC OF ACTION AND DEONTIC LOGIC

For natural reasons, deontic logic has been in the hands of deontic logicians from the beginning. As is the case with all modal logicians who do not concentrate on the purely formal aspect of their discipline, they have been acting as philosophers and as logicians at the same time, and so conceptual issues and technical treatment have been intermingled. It is remarkable that, even though deontic logic has been around for a long time, there is as yet not an accepted body of work that extends very far. What is needed to improve the situation in deontic logic, it seems, is to identify and philosophically discuss basic concepts in greater depth than has been done before. Not least must we develop better logics of action. Modal logic should be in a privileged position to inform such work, or so we argue in this essay.

3.1 Logic of action

3.1.1 Logic of action without actions

In the history of the logic of action, there is a line from Anselm in the eleventh century, restarted in modern times by authors like Kanger, Fitch, and A. R. Anderson, and continued by Chellas, which has recently received its most mature expression yet by Belnap, Perloff and Xu. We quickly sketch a version of a theory in this tradition.

We say that a structure (U, A, T, H, E) is a *frame* if the following conditions are met. U is a set of *points* (informally, representing possible (total) states of the world, just as in dynamic logic). A is a finite set of *agents.* T is a linearly ordered set (we refer to the elements of T as *times*), and a *T-history* is a function from T into U. Let H be a certain set of T-histories (from now on, just histories). If $h \in H$ and $t \in T$, then (h, t) is said to be a *moment.* We define two families of equivalence relations over H. First we define two histories h and g as *coinciding up through t*, in symbols, $h \sim_t g$, if $ht' = gt'$, for all t' not later than t (that is, all t' such that $t' \leq t$). For each moment (h, t), define $H_{h,t} = \{g \in H : h \sim_t g\}$. E is a function assigning to each moment (h, t) and agent $a \in A$ a partitioning $E_{h,t,a}$ of $H_{h,t}$. We say that two histories h and g are *action-equivalent for a at t* if h and g are equivalent under $E_{h,t,a}$ (or, equivalently, if h and g are equivalent under $E_{g,t,a}$); we write $h \approx_{t,a} g$ if this is the case. It is clear that both $\sim_t$ and $\approx_{t,a}$ are equivalence relations.

Consider a classical propositional language (for example, BOOLE — see above) to which is added, for each natural number i, a propositional operator D_i with the informal reading "the agent denoted by i brings it about that". A *valuation* in a frame (U, A, T, H, E) is a function assigning to each natural number an element in A and to each propositional letter a set of moments. A *model* on a frame is the frame together with a valuation. The truth-value (*truth* or *falsity)* of a formula at a moment in a model is defined with respect to moments along traditional lines. The formal condition for the action operator D_i is

$$
\begin{aligned}
(h, t) \vDash D_i\varphi \text{ iff } V(i) = a \;\&\; \exists t_0 < t(\forall g(h \approx_{t_0,a} g \Rightarrow (g, t) \vDash \varphi) \;\&\; \\
\exists g(h \sim_{t_0} g \;\&\; (g, t) \nvDash \varphi)).
\end{aligned}
$$

The idea is that, if a is the agent denoted by i, then *a brings it about, with respect to h and t, that φ*, in symbols $D_i\varphi$, iff there exists a time t_0 earlier than t such that two conditions are satisfied, (i) (the positive condition) that φ be true with respect to g and t, where g is *any* history that is action-equivalent with h for a at t_0, and (ii) (the negative condition) that φ be false with respect to g and t, where g is *some* history coinciding with h up through t_0. In other words, speaking somewhat freely, we might say that the positive condition guarantees that φ is true in a certain important respect, while the negative condition shows the necessity of that guarantee.

From a formal point of view (but not philosophically: see [144, p. 197 f.]) the system sketched may be said to present, more or less in the spirit of Chellas [150], the theory of Belnap and Perloff of an operator called by them the "achievement stit" ("stit" for "**s**ees **t**o **i**t **t**hat"). If the negative condition of the truth definition is omitted and we require T to be the set of all (negative and nonnegative) integers, we get a definition which is essentially that of Chellas's do-operator. (In the latter case, the element t_0 mentioned in the truth condition of D_i should be identified as $t - 1$.)

As an operator of agency, the operator D_i differs from many of its competitors in the literature. For example, in the Chellas version, D_i is a normal modal operator; in

particular, $D_i\top$ and $D_i(\varphi \to \psi) \to (D_i\varphi \to D_i\psi)$ and $D_i(\varphi \wedge \psi) \leftrightarrow (D_i\varphi \wedge D_i\psi)$ are all valid (that is, true at all moments in all models); in the Belnap version, none of them is. In particular, even though $(D_i\varphi \wedge D_i\psi) \to D_i(\varphi \wedge \psi)$ is valid in the Belnap version, $D_i(\varphi \wedge \psi) \to (D_i\varphi \wedge D_i\psi)$ is not; only the weaker $D_i(\varphi \wedge \psi) \to (D_i\varphi \vee D_i\psi)$ is valid.

Sometimes, "i is causally responsible for the fact that φ" would seem to be a better translation of $D_i\varphi$ than "i sees to it that φ". For let φ be "the door is closed" and $D_i\varphi$ thus "the agent sees to it that the door is closed" (presumably equivalent to "the agent closes the door"). The validity of $D_i\varphi \to \varphi$ (in both the Chellas version and the Belnap version) implies that (at a certain moment in a certain model) $D_i\varphi$ is true only if φ is; which seems to mean that the door is closed when the agent closes it. But why close a door that is already closed? On a somewhat related point, notice that, with the truth-condition of D_i as defined, there may be a model such that both $(h, t_1) \vDash D_i\varphi$ and $(h, t_2) \vDash D_i\varphi$, where t_1 and t_2 are times such that $t_1 < t_2$ and h is a history such that $(h, t) \vDash \varphi$ for all times t between t_1 and t_2. On the official stit-reading, the agent closes the door at (h, t_1) as well as at (h, t_2), never mind that the door is closed in h throughout the interval $[t_1, t_2]$. The awkwardness disappears on the alternative reading, according to which the agent is causally responsible at (h, t_1) and (h, t_2) for the door being closed. (But other naïve questions remain: Where is the action? When did the door closing take place? Or are such questions not appropriate?)

The theory presented by Belnap and his collaborators is the culmination of a long development in modal logic; it surpasses all earlier efforts by its sophistication, power and comprehensiveness. One reservation one might have is perhaps the one hinted at in the preceding paragraph: it is a logic of action without actions. No author in the Anselm-Kanger-Chellas line up through Belnap — Davidson belongs to a different tradition — has countenanced the existence of actions in his logic: action talk, yes; ontology of actions, no.[24] For those who would like a representation not only of *action language* but of *action* there is therefore a reason to continue the search for a logic of action worth the name (without, of course, any guarantee that such a thing will ever be found).

3.1.2 What dynamic logic can offer

One liberating effect of the introduction of dynamic logic was that it finally permitted modal logicians to talk about actions and events (without necessarily knowing exactly what they were talking about). The novelty was the introduction of a syntactic category of terms and a corresponding semantic category of — well, what? Formally, the meaning of a term is what modal logicians know as an accessibility relation. But since terms were introduced to formalise the action of programs, it was natural for dynamic logicians to think of these accessibility relations — which relate points-before to points-after — as event types or action types. In fact, Vaughan Pratt himself, the originator of the modal logic of programs, as dynamic logic was called in the early days, remarked that he saw his theory as a logic of computer action.

It would seem that if it is reasonable to represent real propositions (propositions about

[24]One author to whom this remark does not apply is J. F. Horty. Horty, who works within the stit-tradition, explicitly refers to choice cells as actions and, in his book [159], actually refers to them as "actions". In correspondence he has made the following comment: "These actions are only action tokens, however — individual concrete actions. There is no such thing as the action type of "opening a window", for example. There are individual, concrete openings of individual windows, but nothing to group them together."

the world) as sets of points, then it cannot be totally unreasonable to represent real events (events in the world) as sets of paths. Such representation has obvious technical advantages. For one thing, the Boolean operations of union and intersection and even complement become well-defined, and so do the operations of relative product and transitive closure. But it also makes it possible more directly to address the question concerning the relationship between events and action, a topic much debated by philosophers. One example from one of the most interesting philosophers of action:

> The notion of a human act is related to the notion of an event, *i.e.*, a change in the world. What is the nature of this relationship? It would not be right, I think, to call acts a kind or species of events. An act *is* not a change in the world. But many acts may quite appropriately be described as the bringing about or *effecting* ('at will') of a change. To act is, in a sense, to *interfere* with 'the course of nature'. ... To every act ... there corresponds a change or an event in the world. [171, 36f., 39]

One wonders why there should be this difference in theoretical status between propositions and events. Given a certain context, propositions may be true of false; but events may occur or not. A proposition perhaps may be made true or made false; but an event may be brought about or avoided. A proposition may be known or be believed or be given a certain normative status by someone competent to do so; but an event can be foreseen or be remembered, be prescribed or proscribed. One may perceive that a proposition is true; but one may also perceive an event. Some authors such as van Benthem have recognised the analogous position of the two categories, propositions and events, and have tried to give them an even-handed treatment. Unfortunately, philosophers have remained unimpressed so far.

3.1.3 Thinking about change

There already exist modal logical modellings containing interpretations of events, not so much in the philosophical as in computer science literature, [149, 163]. In general, we believe that philosophers have much to learn from the theoretical computer scientists, whose assault on conceptual problems is often fresh and undaunted ("never mind what Aristotle said"). But how are we to make philosophical sense of their constructions and avoid *ad hoc*-ishness?

There is an environment, also referred to as *the world*. The world is always in some (total) *state* or other. The states themselves never change, but the state in which the world is (the currently *actual* state) may change from time to time. The way the world changes is influenced, but perhaps not completely determined, by *agents* outside the world. Furthermore, all change is regular: it takes place according to some *change rule*.

Trying to incorporate these ideas into the semantics of traditional modal logic, think of a *system* as a triple (U, A, C), where U represents the world, A is the set of all agents (assumed to be finitely many), and C is a function representing the change rule. Of these three primitives, two are old: the universe U of *points* (representing total world states) and the set A of agents are as above (for simplicity, we shall think of the agents as a set of integers $\{0, 1, \ldots, n-1\}$, where n is nonnegative (if $n = 0$, then A is empty and the system is agentless)). To describe the change function, the one new primitive, is more complicated. The world is always in some total world state or other. Change in the

world (which for simplicity's sake is assumed to be discrete) is completely described by the change function. Any finite change is from a point-before to a point-after, perhaps via a number of intermediate points; an infinite change can be described in the same way except that there is no point-after. Suppose the world is in a state $u \in U$. Suppose the agents, at this point, make individual "contributions" or "inputs" $i_0, \ldots, i_{n-1}$, respectively, and that there are no further contributions from the agents, nor any other kind of interference. The result will be a change in the world (one possible change is of course the null change), which we may represent as a sequence $p = C(u, i_0, \ldots, i_{n-1})$ of points of which u is the first element; we say that p is the *theoretical result* of the input $(i_0, \ldots, i_{n-1})$. Points to be noted. (1) C depends on the currently actual state of the world but not on any other possible state. (2) The nature of the agents' inputs is not specified (in this modelling). But (3) they are assumed to be outside (not a part of) the world. (4) Since the change rule is represented by a given function, the system as described is deterministic. (It would be nondeterministic if the change rule were represented by a function assigning to each $n+1$-tuple $(u, i_0, \ldots, i_{n-1})$, not a path, but a set of paths. Such indeterminacy would be called *ontic*: not due to limited knowledge on our part, but a property of the system itself.) (5) It is possible for an agent to make no proper contribution. When this happens we say, for book-keeping purposes, that his input is the *null input,* and we use the symbol 0 to denote it.

3.1.4 What a modal logic of actions and agency might look like

Suppose we (as outside observers) witness a certain development taking place in a system. What would it be to have a record of it? Any development in the world consists in the succession of one state after the other, therefore to know the sequence of states, in the order they were realised, would be to have a representation of what took place. But knowing the inputs of the agents would yield a fuller understanding. So perhaps we should think of a record as a certain sequence of elements of type $(u, i_0, \ldots, i_{n-1})$. (There are a number of technical details that would need to be addressed in a rigorous exposition. Let us mention one: if $(u, i_0, \ldots, i_{n-1})$ and $(u', i'_0, \ldots, i'_{n-1})$ are consecutive elements of a history, then u' must be the second element of the path $C(u, i_0, \ldots, i_{n-1})$.)

Technically we may think of a record, from now on more often called a *history*, as a function that assigns to each proper subpath q of a certain path p an n-tuple $(i_0, \ldots, i_{n-1})$; we refer to $(i_0, \ldots, i_{n-1})$ as *the agents' input after q*. The path p is called the *trace* of h; in symbols, $tr(h) = p$. Compared to the "thin" histories of classical modal logic, ours are a lot "fatter", but there is an obvious connexion: the trace of a fat history is a thin history.

As for *events*, we think of them as sets of finite paths (a *path* in U is a sequence of points in U). If p is a path in e (that is, if $p \in e$), then we may say that *p realises e*. So if we witness p played out before our eyes, we also witness a realisation of e. Given this terminology, what would it mean to say that the agents bring about or realise a certain event e? This is a question to which at the present time no-one seems to have an answer. One source of difficulty is the complexity of the many-agent case. The effects of the input of one agent can be modified or completely altered if there are inputs of other agents, either at the same time or later. Agents also sometimes change their mind, thus modifying or altering the effects of their own earlier inputs. For these and other reasons it is often difficult, not only in abstract theory but also in real life, to determine agency

and to allocate (causal) responsibility.

Let us examine one particularly simple case. We say that a history h with trace p is *simple* if $p = C(u, i_0, \ldots, i_{n-1})$, where $i_a \neq 0$ for at least some $a < n$, and, furthermore, $h(q) = (0, \ldots, 0)$, for all $q < p$ such that $q \neq \varnothing$. Thus a simple history is one where the trace is the theoretical result of the initial input. In this very special case, it makes sense to make comments such as the following: the action of the agents was allowed to run its course; the agents brought about the path p; the agents' action realised all events e for which there are paths p', p'' and q such that $q \in e$ and $p = p'qp''$; the agents are (causally) responsible for every event realised by their action.

The one-agent case is of special interest. In this case, we treat the other agents, if any, as part of the background. Technically, if a is an agent, then define the *a-reduct of C* as the function C^a, which assigns to each pair (u,i) the set

$$C^a(u, i) = \{p : \exists i_0, \ldots, i_{n-1}(c_a = i \;\&\; p = C(u, i_0, \ldots, i_{n-1}))\}.$$

In general, $C^a(u, i)$ is not a singleton set, so in this case we face a certain indeterminacy. Note, however, that the latter may be said to be *epistemic* in kind, in contrast to the possible ontic indeterminacy discussed above.

So far we have left open the question about the nature of the agents' input. In this particular case, however, it would be tempting to think that the input i of the agent a consists in calling up a program or plan or, as it was termed in Segerberg [164], routine $\mathbf{r}$ such that, if $\mathbf{r}$ is started with the world in the state u, then the paths in $C^a(u, i)$ correspond to possible developments according to $\mathbf{r}$ (computations according to $\mathbf{r}$, if $\mathbf{r}$ is a program). A mathematician might even go as far as identifying the input, the routine and the corresponding reduct: $\mathbf{r} = C^a(u, \mathbf{r})$.

Summarising this discussion: there are three entities that should not be confused: the routine $\mathbf{r}$; the event of running $\mathbf{r}$; the result of running $\mathbf{r}$ (on a particular occasion or in general).

Carrying out the routine $\mathbf{r}$ is, in a sense, what the agent "really does". In the case of individual physical human action — the case that dominates analytical philosophical discussion of action — an agent's routines may be identified with his ways of moving parts of his body:

> If we interpret the idea of a bodily movement generously, a case can be made for saying that all primitive actions are bodily movements. [...] We never do more than move our bodies: the rest is up to nature. [154, 49 and 50]

But of course by our bodily movements we accomplish many other actions. If we introduce a distinction (not honoured by ordinary language) between *doing* and *realising* an action, we might reserve the former locution for what the agent "really does" or "does directly", and the latter for what the agent may accomplish by his action or "does indirectly". In a modal language we might accordingly introduce event operators does_i, done_i and $\mathsf{realises}_i$, $\mathsf{realised}_i$ and contemplate appropriate meaning-conditions for them. There are no direct counterparts in natural language to these operators, but we have something like the following in mind. Let e be the event that is the interpretation of α

and a the agent assigned to i:

> $\mathsf{does}_i\alpha$: a is just about to do e,
> $\mathsf{done}_i\alpha$: a has just finished doing e,
> $\mathsf{realises}_i\alpha$: because of a's action, e is just about to be realised,
> $\mathsf{realised}_i\alpha$: because of a's action, e has just been realised.

It is a challenge as yet unmet to give fruitful conditions for the latter two operators, which seems like the more important pair. The challenge will not be met in this paper either, but it may be instructive to see what the difficulty is.

Let us say that a history is *well-behaved* if it is the sequence of simple histories. Furthermore, let us say that (h, g) is an *articulated history* if the last element of the trace of h is also the first element of the trace of g; call the latter element the *virtual present* of (h, g). Note that it is natural to think of h as the past history up to the virtual present moment of (h, g) and g as a possible future history from there on. The following semi-formal meaning-conditions summarise the remarks above concerning the one-agent case. Assume that (h, g) is an articulated history and that both h and g are well-behaved. We assume that a is the agent assigned to i, that α is an event term and that the interpretation of an event term α is an event $[\![\alpha]\!]$:

$(h, g) \vDash \mathsf{does}_i\alpha$ iff g begins with an initial simple subhistory g' such that $C^a(u, i) = [\![\alpha]\!]$ and $tr(g') \in [\![\alpha]\!]$, where $i \neq \varnothing$ is a's contribution after h,

$(h, g) \vDash \mathsf{done}_i\alpha$ iff h ends with an terminal simple subhistory h' such that $C^a(v, i) = [\![\alpha]\!]$ and $tr(h') \in [\![\alpha]\!]$, where $h = h''h'$, for some history h'', and v is the first element of $tr(h')$, and $i \neq \varnothing$ is a's contribution after h''.

For the other pair one might try conditions such as these:

$(h, g) \vDash \mathsf{realises}_i\alpha$ iff $\exists g', g'', g_0, g_1, g_2, p(g = g'g''$ & g' is simple & $g' = g_0g_1g_2$ & $p = tr(g_1)$ & $p \in [\![\alpha]\!])$,

$(h, g) \vDash \mathsf{realised}_i\alpha$ iff $\exists h_0, h_1, h_2, g', g'', p(h = h_0h_1h_2$ & $g = g'g''$ & h_1h_2g' is simple & $p = tr(h_2)$ & $p \in [\![\alpha]\!])$

or

$(h, g) \vDash \mathsf{realises}_i\alpha$ iff $\exists h', h'', g_0, g_1, g_2, u, p, i(h = h'h''$ & $g = g_0g_1g_2$ & $h''g_0g_1$ is simple & $p = tr(g_0)$ & $p \in [\![\alpha]\!]$ & u is first in $tr(h'')$ & $tr(h''g') = C^a(u, i)$ & $\forall q(q \in C^a(u, i) \Rightarrow \exists q_0, q_1, q_2(q = q_0q_1q_2$ & $q_1 \in [\![\alpha]\!])))$,

$(h, g) \vDash \mathsf{realised}_i\alpha$ iff $\exists h_0, h_1, h_2, g', g'', u, p, i(h = h_0, h_1, h_2$ & $g = g'g''$ & h_1h_2g' is simple & $p = tr(h_2)$ & $p \in [\![\alpha]\!]$ & u is first in $tr(h_1)$ & $tr(h_1h_2g) = C^a(u, i)$ & $\forall q(q \in C^a(u, i) \Rightarrow \exists q_0, q_1, q_2(q = q_0q_1q_2$ & $q_1 \in [\![\alpha]\!])))$.

Call the former pair of conditions the weak definition and the latter pair the strong definition of action realisation. The weak definition is probably too wide, and the strong definition probably too narrow, for either properly to reflect an intuitive understanding of an action or event being realised. Another complication is that in daily life there is a tendency to consider that an agent has realised an action (whether he intended it or not) if and only if we hold him causally responsible for it; that is, if we can attribute agency to him. Insofar as the attribution of agency is normative in this sense, it is beyond our simple modelling.

3.2 Deontic logic

3.2.1 Background

Deontic logic is the formal study of normative concepts. Here we shall concentrate on the concepts 'obligatory' and 'ought'. There are many 'oughts', and it is well to keep them apart. In particular, we wish to call attention to three distinctions. One that is particularly relevant to this paper is that between 'ought-to-be' (*Seinsollen*) and 'ought-to-do' (*Tunsollen*): 'oughts' that apply to the state of the world, and 'oughts' that apply to actions. That they really are different notions that require different logics was argued particularly forcefully by Castañeda. The distinction itself is older and often associated with Meinong, who seems to have held that, even though they are different concepts, *Tunsollen* is in the final analysis logically reducible to *Seinsollen*. This view was endorsed by Chisholm who gave it a more precise formulation: in his view — dubbed the Meinong/Chisholm thesis by Horty —

(1) it ought to be that i brings it about that φ,

(2) i ought to bring it about that φ,

are logically equivalent [152, 159]. Actually, this thesis involves also another important distinction: that between the *personal* and the *impersonal*. This is seen more clearly if (2) is rephrased as "it is obligatory for i to bring it about that φ" or even "i has an obligation to bring it about that φ". So in a discussion of the Meinong/Chisholm thesis there are actually two distinctions to bear in mind.

Yet another important distinction is that between *standing* versus *one-time* notions of deontic concepts. A standing obligation (permission, prohibition) has a certain scope and covers everything in that scope, while a one-time obligation (permission, prohibition) concerns one particular item (event, occasion, alternative, possibility, or what not). The two kinds of concepts differ in respect to performance of the actions involved. For example, while a one-time obligation is discharged when one performs the particular action it concerns, a standing obligation can be violated but never, within it scope, completely discharged.

To bring analytical order to this field, von Wright 1963 introduced deontic logic. Relatively quickly Standard Deontic Logic emerged, simply classical logic with an extra propositional operator $\mathbf{O}$ with the informal reading of $\mathbf{O}\varphi$ as "it is obligatory that φ" or "it ought to be the case that φ" and satisfying certain extra postulates: all instances of the schemata $\mathbf{O}(\varphi \wedge \psi) \leftrightarrow (\mathbf{O}\varphi \wedge \mathbf{O}\psi)$ and $\mathbf{O}\varphi \rightarrow \neg\mathbf{O}\neg\varphi$ are axioms, and the rule of replacement of provable equivalents holds. Some authors would also include further axiom schemata, for example, $\mathbf{O}\top$ (making the system normal), $\mathbf{O}\varphi \rightarrow \mathbf{O}\mathbf{O}\varphi, \mathbf{O}\mathbf{O}\varphi \rightarrow \mathbf{O}\varphi$ and $\mathbf{O}(\mathbf{O}\varphi \rightarrow \varphi)$. (For definitions and criticisms of SDL, see [156, 153].)

Needless to say, this simple theory — which was a great step forward at the time — was unable to deal with the barrage of counterexamples and conundrums posed by moral philosophers. Some have concluded that the dream of an adequate formal deontic logic is a chimæra, other have looked for ways in which to increase the expressiveness of that very primitive object language. In particular, some authors, including von Wright himself, decided that deontic logic needs a logic of action as a base.

3.2.2 Deontic logic within dynamic logic?

Someone who accepts dynamic logic as a logic of action could reasonably try the simple device of directly adding deontic operators. The latter would of course apply to terms, not formulæ. For example, let us write $\mathsf{ob}_a\alpha, \mathsf{pm}_a\alpha$, and $\mathsf{fb}_a\alpha$ for "α is obligatory for a", "α is permitted for a" and "α is forbidden for a", respectively. In order to define these notions, one might resort to a well-known device going back to Stig Kanger and Alan Ross Anderson, independently of one another, of introducing a constant OK (for approval or absence of a sanction) or a constant S (for disapproval or presence of a sanction); the two approaches are equivalent on the assumption that the formula $\mathsf{S} \leftrightarrow \neg\mathsf{OK}$ is valid. [161, 141, 142] or permission and prohibition this would seem to provide a start, at least initially. In fact, two possibilities come to mind:

(1) $\mathsf{pm}_a\alpha \leftrightarrow [\alpha]\mathsf{OK}$ and $\mathsf{fb}_a\alpha \leftrightarrow \neg[\alpha]\mathsf{OK}$,

(2) $\mathsf{pm}_a\alpha \leftrightarrow \langle\alpha\rangle\mathsf{OK}$ and $\mathsf{fb}_a\alpha \leftrightarrow \neg\langle\alpha\rangle\mathsf{OK}$.

Both have a certain plausibility. Alternative (1) is in the spirit of so-called free-choice permission: permission implies that any outcome of doing the permitted will meet with approval. Alternative (2) is more insidious: if the agent has permission to do something there may nevertheless be outcomes of exercising the permission that will incur the sanction. It seems we do have concepts of permission with these features, say, strong permission and weak permission. There are analogous remarks about prohibition; in either case, the formula $\mathsf{fb}_a\alpha \leftrightarrow \neg\mathsf{pm}_a\alpha$, is valid. So far, so good. But for obligation there is a problem: how to express it? In Standard Deontic Logic, φ is obligatory if and only if the negation of φ is not forbidden. So perhaps one might try $\mathsf{ob}_a\alpha \leftrightarrow \neg\mathsf{pm}_a(-\alpha)$, where pm is one of the alternative operators above and $-\alpha$ is "the complement of α". (See [162] for an effort of this kind; cf. [146].) However, there are difficulties with this approach, which seem hard to overcome. The main difficulty is perhaps that, although the notion of the complement of α can be given a precise meaning in the formal semantics, it does not agree well with intuitive notions. If events are binary relations in a set U, then the complement $U \times U - e$ of an event e is of course again a binary relation. But in general the complement may not be recognised as an intuitively well-defined event corresponding to that set-theoretical entity. It is also worth noticing that sanctions and absence of sanctions may apply not to points but to paths: not so much to *what* is done as *how* it is done. It may be all right to drive from one place to another, but if you do so by going in the wrong direction on a one-way street you may find yourself in trouble. Again, one would wish for a more general analysis.

3.2.3 Norms, norm systems and norm functions

There are norms of different kinds. Every time a mode of behaviour is prescribed or proscribed, approved or disapproved, a norm or a norm system is created. Not only do we have moral and legal codes of varying complexity, but in general all standards of behaviour set norms. 'Etiquette', 'decorum', '*savoir-faire*', '*comme-il-faut*' and 'tasteful' exemplify concepts that are meaningful only in relation to some norm system. The norm systems we meet in daily life are usually neither exact nor complete. For any complex norm system, we need experts, pundits, arbiters, judges, connoisseurs or some such authority to implement it. The ten commandments and the Golden Rule form the

basis of a (religiously founded) morality, but we need theologians to explain what they mean, and ministers to tell us how to apply them. The law attempts to give rules for assessing any possible situation that may come up, but lawyers often disagree about what the law says in a particular case; in many countries, even the Supreme Court decides its issues by vote.

What would it be to have a complete norm system? Consider a given, maximal history. If the norm system, call it the Norm, is complete and we (the analysts) have a full understanding of it, then it should be possible for us, at least in principle, to examine the history, from beginning to end, and see whether at any stage there has been a violation of the Norm. If there has, then paint the history red. Otherwise, ask if there is some over all respect in which the history fails to comply with the Norm. If there is, then paint the history yellow. Finally, if after all this the history is not painted either red or yellow, then paint it green. The set of green histories could be called "legal" if the Norm is legal, "moral" if the Norm is moral, "politically correct" if the Norm is political correctness, and so on. Here, to use a neutral, expression, we shall call the green histories *normal*. At this point, we shall not make a distinction between yellow and red but simply call all histories of that colour *non-normal*.

Strictly speaking, it is not enough that a norm system can partition the set of maximal histories into normal and non-normal; for any past history, the set of future histories must be similarly partitioned. For in general — unless the Norm is totally unforgiving or recognises the possibility of so-called tragic dilemmas or, at the other extreme, is totally tolerant or permissive — any past will admit of possible futures that are red or yellow or green in the sense just described.

In order formally to represent a norm system in this sense — there could of course be several, but we shall be dealing with only one — we now introduce the concept of a norm function. Consider the model theory outlined in the section on the logic of action. Let U and T be as in subsection 3.1.1. A (*total*) *T-history* is a function from T to U; a partial function from T to U is *a partial T-history*. A *past* is a partial history h such that $hg \in H$, for some history g. By the same token, a *future* is a history g such that $hg \in H$ for from some history h. If h is a past, we write $cont(h)$ and $cont^\circ(h)$ for the set of all *complete continuations* of h in H and the set of all *incomplete continuations* of h in H, respectively; in symbols, $cont(h) = \{g : hg \in H\}$ and $cont^\circ(h) = \{g_0 : \exists g_1(hg_0g_1 \in H)\}$. Now, a *norm function* is a function N from the set of all possible pasts to the set of subsets of all possible futures such that, for every possible past $h, N(h) \subseteq cont(h)$. If $g \in N(h)$ and $g = g'g''$, then we say that g' is a *normal continuation of* h *and that* g is a *complete normal continuation of* h.

We end this subsection by noting a number of modal operators that can be introduced with truth conditions in the modelling of the previous section. First, there are three box operators $[\mathsf{x}]$ and corresponding dual diamond operators $\langle\mathsf{x}\rangle$, where x is $\textsc{h}$ ("historically"), $\textsc{d}$ ("deontically") or $\textsc{f}$ ("future"):

$$(h, g) \vDash [\textsc{h}]\varphi \text{ iff } \forall g'(g' \in cont(h) \Rightarrow (h, g') \vDash \varphi).$$
$$(h, g) \vDash [\textsc{d}]\varphi \text{ iff } \forall g'(g' \in norm(h) \Rightarrow (h, g') \vDash \varphi).$$
$$(h, g) \vDash [\textsc{f}]\varphi \text{ iff } \forall h', g'((hg = h'g' \;\&\; \exists f(f \neq \varnothing \;\&\; h' = hf)) \Rightarrow (h', g') \vDash \varphi).$$

$[\textsc{h}]$ is the operator called "historical necessity" by Chellas and "unavoidability" by Thomason. $[\textsc{d}]$ is a deontic operator that should not be automatically translated as "it is obligatory that"; if a reading other than the literal "for every normal continuation" is insisted

on, we recommend "ideally", but care has to be taken not to read too much into that word. $[\text{F}]$ and $\langle\text{F}\rangle$ are Prior's operators G and F, respectively. We are of course able to help us to all the usual temporal operators, including Kamp's UNTIL:

$$\begin{aligned}(h,g) \vDash (\text{UNTIL}\varphi)\chi \text{ iff either } & \forall g', g''(g = g'g'' \Rightarrow (hg', g'') \nvDash \varphi) \\ \text{or else } & \exists g_1, g_2(g = g_1g_2 \ \&\ (hg_1, g_2)\varphi \ \&\ (1) \ \&\ (2))\end{aligned}$$

where (1) and (2) are the following conditions:

(1) $\forall g', g''((g = g'g'' \ \&\ (hg', g'') \vDash \varphi) \Rightarrow \exists g^*(g' = g_1g^*))$,

(2) $\forall k, k'((g = kk' \ \&\ \exists k^*(g_1 = kk^*)) \Rightarrow (hk, k') \vDash \chi))$.

3.2.4 A fragment of dynamic deontic logic

Deontic logic and doxastic logic are often thought to be formally quite similar. Nevertheless, to develop a dynamic deontic logic (DΔL) as a counterpart to the dynamic doxastic logic (DDL) outlined in the previous section would require much effort. Here we shall be content to offer one example of what $D\Delta L$ might look like by considering how an operator of the personal, one-time, ought-to-do type might be definable in our framework.

In other words, what would a meaning-condition for $\mathsf{ob}_i\alpha$ look like if it is to carry something like the intuitive meaning of "e is obligatory for a" or "it is obligatory for a to see to it that e is done" (where e is an event or action and a is an agent)? A careful explication in natural language might run as follows (*first formulation*): "As long as you haven't done whatever it is that you are obligated to do, you are still supposed to do it (if the obligation has not, for some reason, lapsed), never mind violations of the norm that may have taken place in the past; but when you then do it in a normal way, you thereby discharge that particular obligation." Dressing this vernacular suggestion in semi-technical language may give this result (*second formulation*): an event e is *one-time-obligatory for* agent i, given the past history h, if and only if, *if* at the end of any continuation f_0 of h the event e has not yet been realised by i, *then* (i) e is realised in every normal continuation of hf_0, and (ii) if k_0 is an incomplete normal continuation of hf_0 in which e has been realised, then there is a normal continuation of hf_0k_0 in which e is never again realised.

To make this semi-technical version a notch more formal, counterfactually assume that we possess a definition of action realisation (remember that we were not quite able to work one out in the section on action logic). The semi-formal formulation above may the be replaced by the following formal definition (*third formulation*):

$$\begin{aligned}(h,g) \vDash \quad & \mathsf{ob}_i\alpha \text{ iff } \forall f \in \mathit{cont}(h)\forall f_0, f_1((f = f_0f_1 \ \&\ (hf_0, f_1) \nvDash \mathsf{realised}_i\alpha) \Rightarrow \\ & (\forall k \in \mathit{norm}(hf_0)\exists k_0, k_1(k = k_0k_1 \ \&\ (hf_0k_0, k_1) \vDash \mathsf{realised}_i\alpha \ \&\ \\ & \exists l \in \mathit{norm}(hf_0k_0)\forall l_0, l_1(l = l_0l_1 \Rightarrow (hf_0k_0l_0, l_1) \nvDash \mathsf{realised}_i\alpha))).\end{aligned}$$

The final, fully syntactic version of our definition of personal one-time ought-to-do obligation is the following valid schema (*fourth formulation*):

$$\mathsf{ob}_i\alpha \leftrightarrow [\text{H}](\text{UNTIL}\mathsf{realised}_i\alpha)[\text{D}]\langle\text{F}\rangle(\mathsf{realised}_i\alpha \wedge \langle\text{D}\rangle[\text{F}]\neg\mathsf{realised}_i\alpha).$$

The ob-operator is of course only one of a number of operators explicating a notion of obligatoriness (cf. [169]). Complicated as it is, it nevertheless neglects at least one

important aspect, namely, what may be called the Problem of the Implicit Dead-line: the time within which a one-time obligation should be discharged is often not explicit, but there may still be some time limit that is tacitly understood. (See, for example, [155]).

3.2.5 Normative positions

The modelling presented in the last two sections is limited in numerous ways. Some of them would take much effort to overcome. However, there is one particular shortcoming that is philosophically important and deserves a comment here. Norm systems are usually systematic. If one past history is a (not necessarily normal) continuation of another, then one would expect the normative situation after the former to be in some intimate sense related to the normative situation after the latter: a norm that does not possess a certain minimum of coherence will not be viable. In order to give an example of a possible coherence criterion, let us first augment the modelling of the previous section.

Describing the AGM paradigm above, we introduced sphere systems to model belief states (see subsection 2.2.1). Now we shall use sphere systems to model what we will call the "normative position". Thus we redefine the concept of a *norm function* to be a function N from the set of all possible pasts such that, for every possible past $h, N(h)$ is a sphere system in $cont(h)$ (meaning that $X \subseteq cont(h)$, for every element $X \in N(h)$). It is the sphere system $N(h)$ that we term the *normative position after h*.

We adopt the following technical definitions. If h is a past history, g an incomplete continuation of h, and X is a set of complete continuations of h, then we write X^g for the set of continuations of hg that are final segments of elements of X. Schematically, if h is a past history and $g \in cont^\circ(h)$, then for all $X \subseteq cont(h)$,

$$X^g =_{df} \{f : f \in cont(hg) \; \& \; gf \in X\}.$$

Similarly, if S is a set of subsets of $cont(h)$, then we write S^g for the set of nonempty subsets Y of $cont(hg)$ such that $Y = X^g$, for some $X \in H$. Schematically,

$$S^g = \{X^g : X \in H \; \& \; X^g \neq \varnothing\}.$$

Note that S^g is a sphere system in $cont(hg)$ if S is a sphere system in $cont(h)$.

We are now ready for the definition that is the point of this exercise: we define a norm function as *coherent* if, for all finite continuations g of any past history h,

$$N(hg) = (N(h))^g.$$

Technically, the change from $N(h)$ to $N(hg)$ is related to the notion of irrevocable change discussed in a context of belief revision in [166]. (It is worth recalling that the original concern of Carlos Alchourrón — professor of jurisprudence and one of the fathers of AGM — was, not belief change, but legal change.)

3.2.6 Moral

We have included the non-standard material found in the last few sections — no doubt trying the reader's patience to the limit — in the hope of driving home four theses:

- as first argued by von Wright, deontic logic depends on the logic of action,

- as argued by Castañeda, for logical analysis propositions (formulæ) may not be enough — we also need something like actions (terms),
- the logic of even common normative concepts is more complex than is usually thought,
- modal logic is well equipped to deal with that particular kind of complexity.

ACKNOWLEDGEMENTS

In writing this paper we have benefited from the advice of a select group of colleagues: Joseph Almog, Robert Demolombe, Vincent Hendricks, Jeff Horty. Most of their advice was gratefully followed. The reason for not following all of it — in particular not the most radical suggestion, to go back to square one and write a completely new article — is a familiar one: not enough time and not enough space. We are indebted to them for all their careful, extensive and, on the whole, encouraging comments. Lindström's work was supported by The Bank of Sweden Tercentenary Foundation via the research project "Medvetande, Materialism och Möjlighet" ("Mind, Materialism, and Modality").

BIBLIOGRAPHY

The following bibliography contains not only references in the narrow sense of being explicitly referred to in the main text but also a number of works that it has seemed important to include as a help to those readers who might wish to pursue interests that the authors hope the reading of this essay has stimulated.
